$$V_{\mathcal{A}} := [R\pi_{g*} \overline{B}_X^{(g)}(\mathcal{A})] \in K^0(\overline{\mathcal{M}}_g).$$

PROPOSITION 14.5.46 (*Characteristic hierarchy*;). The virtual bar K -class $V_{\mathcal{A}}$ determines a three-level hierarchy of invariants:

(L1) *Scalar level*. The first Chern class of the determinant line bundle recovers the scalar modular characteristic:

$$c_1(\det V_{\mathcal{A}}) = \kappa(\mathcal{A}) \cdot \lambda \in \text{Pic}(\overline{\mathcal{M}}_g),$$

where $\lambda = c_1(\det \mathbb{E}^{\vee})$ is the Hodge class. This is Theorem 13.21.44: $\kappa(\mathcal{A})$ is the scalar modular characteristic.

(L2) *Spectral level*. The Chern character of $V_{\mathcal{A}}$ determines the spectral discriminant:

$$\Delta_{\mathcal{A}}(x) = \det(1 - x \cdot T_{\text{rec}}) = \prod_i (1 - \lambda_i x),$$

where the λ_i are the Chern roots of $V_{\mathcal{A}}$ and T_{rec} is the recursion operator (Theorem K.7.1). This encodes the full bar cohomology dimensions at all weights.

(L₃) *Holonomy level.* The flat connection on $V_{\mathcal{A}}$ (from the Gauss–Manin connection on $R\pi_{g*}$) determines the periodicity profile

$$\Pi_{\mathcal{A}} = (M_{\mathcal{A}}, Q_{\mathcal{A}}, G_{\mathcal{A}}) : \text{monodromy, quasiperiod, Galois data}$$

(Remark 12.5.10). For rational central charge, the monodromy group $M_{\mathcal{A}} \leq \mathrm{GL}(V_{\mathcal{A}})$ has finite image (the T -matrix has finite order on the character space).

The three levels correspond to $\det$, ch , and Hol respectively: the standard filtration of information in a K -class with connection.

Proof. (L₁) By Grothendieck–Riemann–Roch on the universal curve $\pi_g : \overline{C}_g \rightarrow \overline{\mathcal{M}}_g$ (§13.1.3):

$$c_1(\det R\pi_{g*} \overline{B}^{(g)}) = \pi_{g*}(\mathrm{ch}_1(\overline{B}|_{\mathrm{fiber}}) \cdot \mathrm{Td}(T_{\pi})).$$

The fiber Chern character $\mathrm{ch}_1(\overline{B}|_{\Sigma_g}) = \kappa(\mathcal{A})$ (Theorem 13.21.44), and $\pi_{g*}(\mathrm{Td}_1(T_{\pi})) = \lambda$ (Mumford’s formula [329]). Hence $c_1(\det V_{\mathcal{A}}) = \kappa(\mathcal{A}) \cdot \lambda$.

(L₂) The full Chern character $\mathrm{ch}(V_{\mathcal{A}})$ encodes the dimensions $\dim H^n(\overline{B}_{[h]}^{(g)})$ at each weight h and bar degree n , which are the coefficients of the spectral discriminant generating function (Theorem K.7.1).

(L₃) The Gauss–Manin connection on $\overline{B}_X^{(g)}(\mathcal{A}) \rightarrow \overline{\mathcal{M}}_g$ is flat (its curvature is the Kodaira–Spencer class, which acts nilpotently on cohomology by Theorem 13.15.31). The monodromy representation records the action of $\pi_1(\overline{\mathcal{M}}_g) = \mathrm{MCG}(\Sigma_g)$ on the bar cohomology fibers. $\square$

Remark 14.5.47 (Three readings of the virtual bar class). The hierarchy (L₁)–(L₃) reflects the three standard ways of extracting invariants from a K -class: Euler characteristic, Chern character, holonomy. In the categorical logarithm paradigm:

- (L₁) $\det V_{\mathcal{A}} = \kappa \cdot \lambda$ is the *leading coefficient* of the logarithm (Theorem D_{scal}).
- (L₂) $\mathrm{ch}(V_{\mathcal{A}}) \leftrightarrow \Delta_{\mathcal{A}}(x)$ is the *Taylor expansion* of the logarithm (Theorem D_Δ).
- (L₃) $\mathrm{Hol}(V_{\mathcal{A}}) = \Pi_{\mathcal{A}}$ is the *monodromy* of the logarithm, the ambiguity in choosing a branch (the periodicity profile).

This realizes the passage $\kappa \rightarrow \Delta \rightarrow \Pi$ (*scalar* $\rightarrow$ *spectral* $\rightarrow$ *holonomy*) as the natural filtration of information in the K -class $V_{\mathcal{A}}$, just as the passage $c_1 \rightarrow \mathrm{ch} \rightarrow \nabla$ is the natural filtration of information in a vector bundle with connection. The Heisenberg specialization (Chapter 2, Definition 2.13.1) illustrates all three levels: $\kappa = k$ (the level), $\Delta = 1/(1-x)$ (free boson), $\Pi = (\mathbb{Z}, k\mathbb{Z}, \{1\})$ (abelian periodicity). The precise minimal periodicity of the bar cohomology dimensions is still open; the proved hierarchy records only the finite-image monodromy consequence at rational central charge.

14.5.8.5 Chiral homology from the modular bar complex

THEOREM 14.5.48 (*Chiral homology recovery*;). Let $\mathcal{A}$ be a modular Koszul chiral algebra on a smooth projective curve X of genus g . Then:

- (i) *Fiberwise identification.* The chiral homology of $\mathcal{A}$ on the fixed curve Σ_g is computed by the bar complex:

$$H_n^{\mathrm{ch}}(\Sigma_g, \mathcal{A}) \cong H^n(\overline{B}_X^{(g)}(\mathcal{A})|_{[\Sigma_g]}, D_g|_{[\Sigma_g]})$$

for all $n \geq 0$, where $D_g|_{[\Sigma_g]}$ is the square-zero flat comparison differential at $[\Sigma_g] \in \overline{\mathcal{M}}_g$. When $\kappa(\mathcal{A}) \neq 0$, the curved fiber operator $d_{\text{fib}}^{(\Sigma_g)}$ is interpreted only coderivively.

(ii) *Center sheaf.* The local system on $\overline{\mathcal{M}}_g$ whose fiber over $[\Sigma_g]$ is $H_*^{\text{ch}}(\Sigma_g, \mathcal{A})$ is the center sheaf:

$$\mathcal{Z}_{\mathcal{A}} = R^*\pi_{g*}(\overline{B}_X^{(g)}(\mathcal{A}), D_g) \in \text{Loc}(\overline{\mathcal{M}}_g).$$

(iii) *Global sections.* The ambient complementarity complex (Theorem 13.15.14) is recovered as

$$C_g(\mathcal{A}) = R\Gamma(\overline{\mathcal{M}}_g, \mathcal{Z}_{\mathcal{A}}) \cong H^*(\overline{B}_X^{(g)}(\mathcal{A}), D_{\text{tot}}),$$

and the Verdier involution σ on $C_g(\mathcal{A})$ arises from Verdier duality $\mathbb{D}_{\text{Ran}}$ on the bar coalgebra (Theorem 13.18.4).

(iv) *Genus tower.* The full genus tower of chiral homology is assembled by the completed bar complex:

$$\bigoplus_{g \geq 0} \hbar^g H_*^{\text{ch}}(\Sigma_g, \mathcal{A}) \cong H^*(\overline{B}_X^{\text{tot}}(\mathcal{A}), D_{\text{tot}}),$$

with the genus filtration corresponding to the $\hbar$ -adic filtration on the completed bar.

Proof. Part (i). On a fixed curve Σ_g , the chiral homology $H_*^{\text{ch}}(\Sigma_g, \mathcal{A})$ is by definition [40, 3.4.4] the derived pushforward of $\mathcal{A}^{\boxtimes n}$ along the Ran space $\text{Ran}(\Sigma_g)$. The bar construction computes this pushforward (Theorem 6.1.66 for genus 0; Theorem 15.12.26 for the extension to all genera via the Feynman transform): the bar complex on $\overline{C}_n(\Sigma_g)$ with the flat comparison differential $D_g|_{[\Sigma_g]}$ computes the same ordinary cohomology as the Ran-space pushforward. If $\kappa(\mathcal{A}) \neq 0$, the raw fiberwise operator $d_{\text{fib}}^{(\Sigma_g)}$ is curved and therefore belongs on the coderived side rather than in ordinary cohomology.

Part (ii). The assignment $[\Sigma_g] \mapsto H_*^{\text{ch}}(\Sigma_g, \mathcal{A})$ varies in a local system because the flat comparison bar complex is a square-zero family over $\overline{\mathcal{M}}_g$ (the bar family of (13.6)), and the formation of cohomology of a flat family produces a local system. The resulting local system is precisely the center sheaf $\mathcal{Z}_{\mathcal{A}}$ of Beilinson–Drinfeld [40, 3.4.10].

Part (iii). Global sections of $\mathcal{Z}_{\mathcal{A}}$ over $\overline{\mathcal{M}}_g$ compute $R\Gamma(\overline{\mathcal{M}}_g, \mathcal{Z}_{\mathcal{A}})$ by definition. By the Leray spectral sequence for $\pi_g: \overline{C}_g \rightarrow \overline{\mathcal{M}}_g$, this agrees with $H^*(\overline{B}_X^{(g)}(\mathcal{A}), D_{\text{tot}})$ when the total differential is used (incorporating both the fiberwise part and the moduli variation). The Verdier involution on $C_g(\mathcal{A})$ arises from the Verdier duality $\mathbb{D}_{\text{Ran}} \overline{B}_X(\mathcal{A}) \simeq \overline{B}_X(\mathcal{A}^!)$ (Theorem 13.18.4), which exchanges $\mathcal{A}$ and $\mathcal{A}^!$ on the bar level and induces σ on global sections.

Part (iv). The genus-completed product (14.17) is an inverse limit $\overline{B}^{\text{tot}} = \varprojlim_g \bigoplus_{h \leq g} \hbar^h \overline{B}^{(h)}$. Each finite truncation has well-defined cohomology by parts (i)–(iii). The transition maps are surjective on cohomology (the genus filtration is separated and complete by Proposition 13.21.91(a)), so the Mittag-Leffler condition is satisfied and $H^*(\overline{B}^{\text{tot}}, D_{\text{tot}}) \cong \varprojlim_g H^*(\bigoplus_{h \leq g} \overline{B}^{(h)}, D_{\text{tot}})$ by [395, Proposition 3.5.7]. Theorem 14.5.42(i) gives $D_{\text{tot}}^2 = 0$. $\square$

Remark 14.5.49 (The full recovery diagram). The constructions of this subsection fit into a single commutative diagram:

$$\begin{array}{ccccc}
 \text{Quantum } L_\infty & \xrightarrow{\text{MC}} & \Theta_{\mathcal{A}} \in \text{MC}(\text{Def}^{\text{mod}}) & \xrightarrow{\text{twist}} & (\bar{B}^{\text{tot}}, D_{\text{tot}}) \\
 \downarrow g=0 & & \downarrow \text{clutch} & & \downarrow R\pi_{g*} \\
 \text{Cyclic } L_\infty & \xrightarrow{\text{Kill.}} & \xi^*(\Theta^{(g)}) & & \mathcal{Z}_{\mathcal{A}} \xrightarrow{R\Gamma} C_g = Q_g \oplus Q_g^!
 \end{array}$$

Three paths through this diagram recover three aspects of the modular homotopy type:

Top row (“algebraic path”): the quantum L_∞ operations, packaged as the MC element $\Theta_{\mathcal{A}}$, twist the genus-0 bar differential to produce D_{tot} . This is the bar-coalgebra route: the modular homotopy type is the *totalization* of the genus tower.

Right column (“geometric path”): the total bar complex pushes forward along the universal curve to produce the center sheaf $\mathcal{Z}_{\mathcal{A}}$; its global sections are the complementarity complex $C_g(\mathcal{A}) = Q_g \oplus Q_g^!$. This is the sheaf-on-moduli route: the modular homotopy type is the *variation* of the bar complex over $\overline{\mathcal{M}}_g$.

Bottom row (“clutching path”): the genus-0 cyclic L_∞ produces the tree-level structure; the clutching maps $\xi_{\text{sep}}^*, \xi_{\text{ns}}^*$ reconstruct the full center sheaf from its boundary behavior: the Getzler–Kapranov route, where the modular homotopy type is the *modular operad structure* on the collection $\{H_*^{\text{ch}}(\Sigma_g, \mathcal{A})\}$.

All three paths commute. The single geometric fact underlying all of them is $\partial^2 = 0$ on $\overline{\mathcal{M}}_{g,n}$, read through the Feynman transform.

14.5.9 NON-SCALAR UNIVERSAL CLASSES

Corollary 13.21.120 gives only one-channel line concentration in general:

$$\Theta_{\mathcal{A}}^{\min} = \eta \otimes \Gamma_{\mathcal{A}} \quad \text{whenever } \dim H_{\text{cyc}}^2(\mathcal{A}, \mathcal{A}) = 1.$$

On the proved scalar lane this further specializes to

$$\Theta_{\mathcal{A}}^{\min} = \kappa(\mathcal{A}) \cdot \eta \otimes \Lambda \quad \text{with } \Gamma_{\mathcal{A}} = \kappa(\mathcal{A})\Lambda.$$

We construct the universal non-scalar class for algebras with $\dim H_{\text{cyc}}^2(\mathcal{A}, \mathcal{A}) \geq 2$.

Construction 14.5.50 (HPT non-scalar MC recursion). Let $L = \text{Def}_{\text{cyc}}(\mathcal{A})$ be the cyclic deformation complex with homotopy transfer data (i, p, h, ℓ_n) from a minimal model. Choose a basis $\eta_1, \dots, \eta_r \in H_{\text{cyc}}^2(\mathcal{A}, \mathcal{A})$ and modular coefficients $U_1, \dots, U_r \in \mathfrak{m}_R$ (the maximal ideal of the modular deformation ring). The universal non-scalar MC element is built recursively:

$$\Theta^{(1)} = i\left(\sum_{i=1}^r \eta_i \otimes U_i\right), \quad \Theta^{(N)} = -h\left(\sum_{n \geq 2} \frac{1}{n!} \sum_{\substack{N_1 + \dots + N_n = N \\ N_j \geq 1}} \ell_n(\Theta^{(N_1)}, \dots, \Theta^{(N_n)})\right). \quad (14.21)$$

The obstruction equations cut out the modular deformation locus:

$$p\left(\sum_{n \geq 2} \frac{1}{n!} \ell_n(\Theta, \dots, \Theta)\right) = 0.$$

Example 14.5.51 (Two-channel explicit formula). For $r = 2$, with basis η_1, η_2 , the first terms of the non-scalar universal class are:

$$\begin{aligned} \Theta_{\mathcal{A}}^{\text{ns}} &= \eta_1 \otimes U_1 + \eta_2 \otimes U_2 - \frac{1}{2} h\ell_2(\eta_1, \eta_2) \otimes U_1 U_2 \\ &\quad - \frac{1}{6} h\ell_3(\eta_1, \eta_1, \eta_2) \otimes U_1^2 U_2 - \frac{1}{6} h\ell_3(\eta_1, \eta_2, \eta_2) \otimes U_1 U_2^2 + O(4). \end{aligned}$$

The class is genuinely non-scalar if and only if some mixed coefficient $U_i U_j$ survives in gauge-normal form.

PROPOSITION 14.5.52 (Non-scalar criterion;). The universal class $\Theta_{\mathcal{A}}$ is genuinely non-scalar if and only if, in minimal cyclic model form, some mixed transferred bracket $\ell_n(\eta_{i_1}, \dots, \eta_{i_n})$ with at least two distinct basis indices produces a homotopy correction not removable by gauge transformation. Equivalently: after reduction to gauge-normal form, some mixed monomial $U_{i_1} \cdots U_{i_k}$ with $|\{i_1, \dots, i_k\}| \geq 2$ has nonzero coefficient.

Proof. The gauge group acts by $\Theta \mapsto e^g \cdot \Theta := \sum_{n=0}^{\infty} \frac{1}{n!} \ell_n(g, \dots, g, \Theta)$ for $g \in L^1$. In gauge-normal form $\text{Im}(h) \cap \text{Im}(\Theta) = 0$, the recursion (14.21) has no further gauge freedom. A non-scalar monomial $U_i U_j$ in $\Theta^{(2)}$ arises from $h\ell_2(\eta_i, \eta_j) \neq 0$ in the homotopy-transfer data. Since h is a homotopy (not a chain map), this correction is algebraically independent of the scalar terms. $\square$

Remark 14.5.53 (Non-scalar landscape). All accessible families considered here (Kac–Moody at generic level, Virasoro, principal $\mathcal{W}_N$) have $\dim H_{\text{cyc}}^2(\mathcal{A}, \mathcal{A}) = 1$, so their minimal Maurer–Cartan class lies on a single cyclic line. On the proved uniform-weight scalar lane this line is $\kappa(\mathcal{A})\Lambda$; for principal $\mathcal{W}_N$ with $N \geq 3$ that stronger identification remains open. Non-scalar $\Theta_{\mathcal{A}}$ requires $\dim H_{\text{cyc}}^2 \geq 2$; candidates include admissible-level Kac–Moody, products, and extended algebras.

14.6 STRATIFIED PERIODICITY FRAMEWORK

14.6.1 OVERVIEW: THREE SOURCES OF PERIODICITY

The Hochschild cohomology of chiral algebras can exhibit three types of periodicity: *Type I (Modular)*, from rational central charge and modular transformations; *Type II (Quantum)*, from quantum groups at roots of unity; and *Type III (Geometric)*, from the topology of the underlying curve.

Remark 14.6.1. The unconditional core is the quantum periodicity input and the structural theorem that independent periodicity sources combine by lcm. Explicit modular periods, sharp geometric periods, and higher-rank closed formulas are conjectural outside the rank-1/minimal-model test cases.

14.6.2 TYPE I: MODULAR PERIODICITY FROM RATIONAL CENTRAL CHARGE

14.6.2.1 The mechanism

Remark 14.6.2 (Periodicity as exponential of the scalar characteristic). The scalar characteristic $\kappa(\mathcal{A})$ is the infinitesimal datum; the modular period N is the exponential datum (Remark 6.1.9). For $c = p'/q'$, the T -matrix eigenvalues $\lambda_{r,s} = \exp(2\pi i(h_{r,s} - c/24))$ have period $N = 24q'/\gcd(p', 24)$, the smallest N with $Nc/24 \in \mathbb{Z}$. The periodicity profile $\Pi(\mathcal{A}) = (M_{\mathcal{A}}, Q_{\mathcal{A}}, G_{\mathcal{A}})$ (Remark 12.5.10) is the exponential package of the logarithmic package $(\kappa(\mathcal{A}), \Delta_{\mathcal{A}}, \Theta_{\mathcal{A}})$.

Conjecture 14.6.3 (Modular periodicity for minimal models;). Let $M(p, q)$ be a Virasoro minimal model with $2 \leq p < q$, $\gcd(p, q) = 1$, and central charge $c = 1 - 6(p - q)^2/(pq)$. Write $c = p'/q'$ in lowest

terms and set

$$N = \frac{24q'}{\gcd(p', 24)}.$$

Then for all bar degrees n and all sufficiently large conformal weight h :

$$\dim H^n(\bar{B}_{[h+N]}^{\text{ch}}(M(p, q))) = \dim H^n(\bar{B}_{[h]}^{\text{ch}}(M(p, q))).$$

(Part of the MC2 theorem package; Theorem 13.21.117.)

Evidence. The following three-step argument establishes the structural framework; however, Step 2 contains a gap in the passage from theta-function periodicity to weight-space dimension periodicity (the convolution with $1/\eta$ does not preserve eventual periodicity of Fourier coefficients, confirmed computationally in Computation 14.6.5). Step 1 (T -matrix periodicity) is unconditional.

The argument proceeds in three steps: we establish T -matrix periodicity, deduce periodicity of the module decomposition data, and lift to the bar complex.

Step 1: T -matrix periodicity. The minimal model $M(p, q)$ has exactly $(p-1)(q-1)/2$ irreducible modules $V_{r,s}$ with $1 \leq r \leq p-1$, $1 \leq s \leq q-1$, subject to the identification $V_{r,s} = V_{p-r, q-s}$. Their conformal weights are

$$h_{r,s} = \frac{(qr - ps)^2 - (q - p)^2}{4pq}.$$

The T -matrix is diagonal: $T_{(r,s), (r',s')} = \delta_{(r,s), (r',s')} e^{2\pi i(h_{r,s} - c/24)}$. Write

$$\lambda_{r,s} := e^{2\pi i(h_{r,s} - c/24)}.$$

Then $\lambda_{r,s}^N = 1$ is equivalent to $N(h_{r,s} - c/24) \in \mathbb{Z}$. Since $h_{r,s} - c/24$ is rational with denominator dividing $24pq$ and $N = 24q'/\gcd(p', 24)$, one gets $T^N = \text{Id}$ on the finite-dimensional character space:

$\tau \mapsto \tau + 1$ multiplies the character by the phase $e^{-2\pi ic/24}$, while

$$\frac{cN}{24} = \frac{p'N}{24q'} = \frac{p'}{\gcd(p', 24)} \in \mathbb{Z},$$

because $\gcd(p', 24)$ divides p' .

Step 2: Periodicity of weight-space dimensions. The character of each irreducible module $V_{r,s}$ is given by the Rocha-Caridi formula:

$$\text{ch}_{V_{r,s}}(\tau) = \frac{\Theta_{r,s}(\tau)}{\eta(\tau)}$$

where $\Theta_{r,s} = \theta_{qr-ps, 2pq} - \theta_{qr+ps, 2pq}$ is a difference of level- $2pq$ theta functions and η is the Dedekind eta function. The Fourier coefficients of the level- ℓ theta function $\theta_{m,\ell}(\tau) = \sum_{n \in \mathbb{Z}} q^{(m+2\ell n)^2/(4\ell)}$ are supported on the arithmetic progression $\{(m+2\ell n)^2/(4\ell) : n \in \mathbb{Z}\}$ and are periodic in the exponent variable with period ℓ .

Now $\dim V_{r,s, [k]}$ is the coefficient of $q^{h_{r,s} + k - c/24}$ in $\text{ch}_{V_{r,s}}$. This coefficient equals the convolution of the theta-function coefficients with the partition function $p(\cdot)$ (from $1/\eta$). The theta-function numerator $\Theta_{r,s}$ has exact period dividing $2pq$ in the exponent. Since N is a multiple of $2pq$ (by construction from $c = p'/q'$ and the formula $N = 24q'/\gcd(p', 24)$), the numerator coefficients satisfy $a_{\Theta}(k + N) = a_{\Theta}(k)$ for all k .

For the convolution: writing $\dim V_{r,s,[k]} = \sum_{j \geq 0} a_{\Theta}(k-j) p(j)$ where a_{Θ} denotes the theta-function coefficients and $p(j)$ the partition function, the N -periodicity of a_{Θ} gives

$$\dim V_{r,s,[k+N]} - \dim V_{r,s,[k]} = \sum_{j > k} (a_{\Theta}(k+N-j) - a_{\Theta}(k-j)) p(j)$$

which vanishes for k sufficiently large (specifically, for k exceeding the maximal pole order of $\Theta_{r,s}/\eta$, the sum on the right is empty). Hence $\dim V_{r,s,[k+N]} = \dim V_{r,s,[k]}$ for all $k \gg 0$.

Remark 14.6.4 (Step 2 gap: stabilization threshold). The convolution $\dim V_{r,s,[k]} = \sum_j a_{\Theta}(k-j) p(j)$ does not preserve eventual periodicity because $p(j)$ grows sub-exponentially.

COMPUTATION 14.6.5 ($M(5,8)$ weight-space dimensions;). For $M(5,8)$ ($c = -7/20$, 14 modules, $N = 480$), the Rocha-Caridi formula $\dim V_{r,s,[k]} = \sum_{n \in \mathbb{Z}} [p(k - \delta_n^+) - p(k - \delta_n^-)]$ (where $\delta_n^{\pm}$ are the standard null-vector exponents) gives monotonically increasing sequences for all 14 modules through $k = 80$. No eventual periodicity is detected at any period dividing $N = 480$ or $pq = 40$.

Bar cohomology periodicity may still hold via the bar differential, but this requires computing OPE structure constants of $M(5,8)$.

Step 3: Lift to bar complex. The bar complex $\bar{B}_{[h]}^{(n)}(M(p,q))$ in degree n at conformal weight h has dimension given by a finite sum over module labels weighted by fusion multiplicities:

$$\dim \bar{B}_{[h]}^{(n)} = \sum_{\substack{(r_1,s_1), \dots, (r_n,s_n) \\ k_1 + \dots + k_n = h - \sum_j h_{r_j,s_j}}} \prod_{j=1}^n \dim V_{r_j,s_j,[k_j]} \cdot F(r_1 s_1, \dots, r_n s_n)$$

where F encodes the fusion multiplicities from the Verlinde formula (depending only on module labels, not on h), and the sum is over non-negative integers k_j . Since there are finitely many modules $((p-1)(q-1)/2$ of them), for $h > h_{\max} := \max_{r,s} h_{r,s}$ all modules contribute. By Step 2, each factor $\dim V_{r_j,s_j,[k_j]}$ is N -periodic in k_j for large k_j . Under $h \mapsto h + N$ the constraint shifts to $\sum k_j = h + N - \sum h_{r_j,s_j}$, and the N -periodicity of each weight-space dimension gives $\dim \bar{B}_{[h+N]}^{(n)} = \dim \bar{B}_{[h]}^{(n)}$ for $h \gg 0$.

It remains to show that the bar cohomology dimensions, not just the chain-space dimensions, are periodic. The bar differential $d: \bar{B}_{[h]}^{(n)} \rightarrow \bar{B}_{[h]}^{(n+1)}$ is determined by the OPE structure constants of $M(p,q)$. For minimal models, three-point functions on the sphere factor as a fusion multiplicity times a universal Virasoro conformal block contribution. The conformal block at relative weights (k_1, k_2, k_3) is a rational function of the conformal weights $h_{r,s}$ and the relative weights k_j , determined by the Shapovalov form. By the same theta-function periodicity as in Step 2, the matrix entries of d at weight $h + N$ are identified with those at weight h via the canonical isomorphism $V_{r,s,[k+N]} \cong V_{r,s,[k]}$ (which respects the Virasoro module structure at the level of the weight-space basis). Therefore $\ker d$ and $\text{im } d$ at weight $h + N$ are isomorphic to those at weight h , giving $\dim H^n(\bar{B}_{[h+N]}^{\text{ch}}) = \dim H^n(\bar{B}_{[h]}^{\text{ch}})$ for all h sufficiently large.

Conjecture 14.6.6 (Modular periodicity for general rational chiral algebras;). Let $\mathcal{A}$ be a rational chiral algebra with central charge $c = p/q$, $\gcd(p,q) = 1$. Set

$$N = \frac{24q}{\gcd(p, 24)}.$$

Then for all bar degrees n and all sufficiently large conformal weight h :

$$\dim H^n(\bar{B}_{[h+N]}^{\text{ch}}(\mathcal{A})) = \dim H^n(\bar{B}_{[h]}^{\text{ch}}(\mathcal{A})).$$

Remark 14.6.7 (Scope and examples). Steps 1 and 3 are proved for minimal models and WZW; the gap is Step 2 (convolution with $1/\eta$). Examples: Ising $N \mid 48$, $\widehat{\mathfrak{sl}}_2$ at $k = 1$ gives $N = 24$.

Conjecture 14.6.8 (Modular periodicity for WZW models;). Let $\widehat{\mathfrak{g}}_k$ be an affine Kac–Moody algebra at positive integer level $k \geq 1$, with $\mathfrak{g}$ a finite-dimensional simple Lie algebra of rank r . Write the central charge $c = k \dim(\mathfrak{g})/(k + h^\vee) = p/q$ in lowest terms and set

$$N = \frac{24q}{\gcd(p, 24)}.$$

Then for all bar degrees n and all sufficiently large conformal weight h :

$$\dim H^n(\bar{B}_{[h+N]}^{\text{ch}}(\widehat{\mathfrak{g}}_k)) = \dim H^n(\bar{B}_{[h]}^{\text{ch}}(\widehat{\mathfrak{g}}_k)).$$

Evidence. The same three-step strategy as Conjecture 14.6.3 applies, using the Weyl–Kac character formula (Kac [238, §12.7]) in place of Rocha-Caridi. Step 1 ($T^N = \text{Id}$) holds since $h_\lambda = \langle \lambda, \lambda + 2\rho \rangle / 2(k + h^\vee)$ is rational with denominator dividing $24(k + h^\vee)$. Step 2: the level- $(k + h^\vee)$ theta functions in the Weyl–Kac numerator have N -periodic Fourier coefficients. Step 3: the bar differential is controlled by quantum Clebsch–Gordan coefficients via the KL equivalence (Kazhdan–Lusztig [257]), and $q^{2(k+h^\vee)} = 1$ ensures the same periodicity.

Remark 14.6.9 (Scope). T -matrix periodicity (Step 1) is unconditional for both minimal models and WZW. The gap is Step 2: convolution with $1/\eta$ does not preserve eventual periodicity. General rational chiral algebras remain open. (Part of the MC2 theorem package; Theorem 13.21.117.)

14.6.2.2 Koszul dual behavior

Conjecture 14.6.10 (Reflected modular periodicity;). If $\mathcal{A}$ has rational central charge $c = p/q$ and modular period $N = 24q/\gcd(p, 24)$, and its Koszul dual $\mathcal{A}^!$ has central charge $c' = p'/q'$ (determined by the level duality $k \mapsto k' = -k - 2h^\vee$ via the Sugawara formula) and modular period $N' = 24q'/\gcd(p', 24)$, then:

$$\frac{1}{N} + \frac{1}{N'} = \frac{\gcd(p, 24) + \gcd(p', 24)}{24q} \quad (14.22)$$

where $q' = q$ whenever $\gcd(26q - p, q) = 1$ (which holds when $\gcd(p, q) = 1$). In particular, $\frac{1}{N} + \frac{1}{N'} = \frac{1}{12}$ if and only if $\gcd(p, 24) + \gcd(p', 24) = 2q$, which for $q = 1$ requires both p and $p' = 26 - p$ to be coprime to 24.

Remark 14.6.11 (Precise hypotheses). The conjecture requires the following hypotheses to be well-posed:

1. $\mathcal{A}$ is a rational chiral algebra (finitely many irreducible modules) with $c = p/q \in \mathbb{Q}$, $\gcd(p, q) = 1$.
2. $\mathcal{A}$ admits a Koszul dual $\mathcal{A}^!$ in the sense of Definition 11.1.15, with $\mathcal{A}^!$ also rational.
3. The modular periods N, N' are defined as the minimal positive integers such that T^N acts trivially on the space of characters of $\mathcal{A}, \mathcal{A}^!$ respectively, where $T : \tau \mapsto \tau + 1$.
4. When $\mathcal{A}$ arises from an affine Lie algebra at level k , the dual central charge $c' = c(\mathcal{A}^!)$ is determined from the dual level $k' = -k - 2h^\vee$ via the Sugawara formula $c' = k' \dim(\mathfrak{g})/(k' + h^\vee)$.

The relation (14.22) is verified for the Heisenberg algebra ($c = c' = 1, N = N' = 24, \text{sum} = 1/12$) and for the $\widehat{\mathfrak{sl}}_2$ WZW model at level $k = 1$ ($c = 1, c' = 1, N = N' = 24$). For $c = 5, c' = 21$ (both coprime to 24 but $\gcd(21, 24) = 3$), one gets $N = 24, N' = 8$, and $1/N + 1/N' = 1/6 \neq 1/12$, showing the special case $1/N + 1/N' = 1/12$ requires both p and p' coprime to 24.

Remark 14.6.12 (Scope). The formula (14.22) depends on Conjecture 14.6.6; the principal obstruction is that Koszul duality need not preserve rationality. Part of MC2 (Theorem 13.21.117).

14.6.3 TYPE II: QUANTUM GROUP PERIODICITY

14.6.3.1 The quantum group structure

PROPOSITION 14.6.13 (*Quantum periodicity profile under admissible-level KL/DS transport;*). Let $\mathcal{W}^k(\mathfrak{g})$ be the $\mathcal{W}$ -algebra at admissible level $k = -h^\vee + p/q$ where $h^\vee$ is the dual Coxeter number, $p \geq h^\vee$, $q \geq h^\vee$, $\gcd(p, q) = 1$. Then the quantum integers, quantum dimensions, and fusion coefficients (transported through the KL/DS interface) recur with period dividing

$$M = 2h^\vee pq / \gcd(p, q, h^\vee).$$

This records only the Type II quantum input to the periodicity profile ($N_{\text{mod}}, N_{\text{quant}}$); upgrading to full bar complex periodicity requires a separate OPE transport theorem.

Proof. At admissible level $k = -h^\vee + p/q$, we write $q_{\text{KL}} = \exp(\pi i / (k + h^\vee)) = \exp(\pi i \cdot q/p)$ for the Kazhdan–Lusztig quantum parameter. Since $\gcd(p, q) = 1$, this q_{KL} is a root of unity of order dividing $2p$.

Step 1: Semisimplicity. By Arakawa’s theorem [12], the category $\mathcal{O}_k(\mathcal{W}^k(\mathfrak{g}))$ at admissible level is semisimple with finitely many simple objects, indexed by the admissible weights.

Step 2: Kazhdan–Lusztig equivalence and DS reduction. The Kazhdan–Lusztig equivalence [257] provides a braided tensor equivalence $\mathcal{O}_k(\widehat{\mathfrak{g}}) \simeq \mathcal{C}(U_q(\mathfrak{g}))$, where $\mathcal{C}(U_q(\mathfrak{g}))$ is the semisimplified tilting quotient (Remark K.7.1) with quantum parameter $q = \exp(\pi i / (k + h^\vee))$. The Drinfeld–Sokolov reduction functor $H_{\text{QDS}}^0 : \mathcal{O}_k(\widehat{\mathfrak{g}}) \rightarrow \mathcal{O}_k(\mathcal{W}^k(\mathfrak{g}))$ is exact at admissible levels (Arakawa [12]), and the composition transports the bar complex structure from $\widehat{\mathfrak{g}}$ -modules to $\mathcal{W}^k(\mathfrak{g})$ -modules.

Step 3: Quantum integer periodicity. The quantum integers $[n]_{q_{\text{KL}}} = (q_{\text{KL}}^n - q_{\text{KL}}^{-n}) / (q_{\text{KL}} - q_{\text{KL}}^{-1})$ satisfy $[n + 2\ell]_{q_{\text{KL}}} = [n]_{q_{\text{KL}}}$ where ℓ is the order of $q_{\text{KL}}^2 = \exp(2\pi i q/p)$ as a root of unity; since $\gcd(p, q) = 1$, this order is $\ell = p$.

The quantum dimension of the simple module $L(\lambda)$ is the Weyl character formula:

$$\dim_q L(\lambda) = \prod_{\alpha \in \Delta^+} \frac{[\langle \lambda + \rho, \alpha^\vee \rangle]_{q_{\text{KL}}}}{[\langle \rho, \alpha^\vee \rangle]_{q_{\text{KL}}}}.$$

This is a product of $|\Delta^+|$ quantum integers with arguments determined by the weight λ . The periodicity of each factor gives $\dim_q L(\lambda + 2\ell\rho) = \dim_q L(\lambda)$, so the quantum dimensions (hence fusion coefficients via the Verlinde formula) are periodic in λ with period $2\ell\rho = 2pp$.

The admissible weights are indexed by pairs (r, s) with $0 \leq r \leq p - h^\vee$ and $0 \leq s \leq q - h^\vee$ (for generic simple $\mathfrak{g}$; the precise range depends on Δ^+). Combining the three sources

- (a) quantum integer period: $2\ell = 2p$,
- (b) Weyl group orbit: $|W|$ copies with inner period $h^\vee$ (from $\langle \rho, \alpha_{\text{max}}^\vee \rangle = h^\vee - 1$),

(c) q -restricted weight lattice: period q ,

we obtain a common period dividing $M = 2h^\vee pq / \gcd(p, q, h^\vee)$ for the quantum integers, quantum dimensions, and fusion data transported through the admissible-level KL/DS interface. $\square$

Example 14.6.14 (Quantum periodicity for $\widehat{\mathfrak{sl}}_2$ at $k = -1/2$). At the admissible level $k = -1/2$ ($p = 3$, $q = 2$, $h^\vee = 2$), the quantum parameter is $q_{\text{KL}} = \exp(\pi i \cdot 2/3) = e^{2\pi i/3}$ (a primitive third root of unity). The Kazhdan–Lusztig category $\mathcal{O}_k$ is semisimple with 2 simple modules (Example G.11.22), and the quantum dimensions are:

$$\dim_q(\mathcal{L}_0) = 1, \quad \dim_q(\mathcal{L}_1) = [2]_q = q + q^{-1} = -1$$

(using $q = e^{2\pi i/3}$, so $[2]_q = 2 \cos(2\pi/3) = -1$).

The quantum integer periodicity has $\ell = 3$ ($[n+6]_q = [n]_q$, since $q^2 = e^{4\pi i/3}$ has order 3). The period is $M = 2 \cdot 2 \cdot 3 \cdot 2 / \gcd(3, 2, 2) = 24$.

The chiral Hochschild cohomology of $L_{-1/2}(\widehat{\mathfrak{sl}}_2)$ has:

$$\begin{aligned} CH^0 &= \mathbb{C} && \text{(center),} \\ CH^1 &= 0 && \text{(no outer derivations),} \\ CH^2 &= \mathbb{C} && \text{(one marginal deformation: the level),} \end{aligned}$$

The deformation in CH^2 corresponds to the level family $k \mapsto k+t$; the vanishing $CH^1 = 0$ reflects rigidity (no outer derivations). The quantum period $M = 24$ manifests not in CH^n (which vanishes for $n > 2$ by Theorem 14.4.12) but in the *weight-graded bar complex cohomology*: $\dim H^n(\bar{B}_{[h+24]}^{\text{ch}}) = \dim H^n(\bar{B}_{[h]}^{\text{ch}})$ for $h \gg 0$ (Conjecture 14.6.6).

14.6.4 TYPE III: GEOMETRIC TAUTOLOGICAL DEPTH

14.6.4.1 Genus dependence and nilpotent depth

The geometric contribution to bar cohomology from higher genus provides *bounded tautological depth* rather than periodicity: the Kodaira–Spencer operator is nilpotent and the bar spectral sequence terminates after finitely many steps.

THEOREM 14.6.15 (*Geometric tautological depth bound*;). For a chiral algebra $\mathcal{A}$ on a genus $g \geq 2$ curve X , the Kodaira–Spencer image of the Hodge class is nilpotent:

$$\kappa(c_1(\mathbb{E}))^{3g-2} = 0 \quad \text{in } CH^*(\mathcal{A}).$$

In particular, the geometric direction of the bar spectral sequence has bounded tautological depth: at most $3g - 3$ nontrivial geometric filtration layers can contribute.

At $g = 0$, no Hodge bundle contributes; at $g = 1$, the relation $c_1(\mathbb{E}) = \frac{1}{12}\delta$ absorbs the Hodge contribution into the modular data.

Proof. The Kodaira–Spencer map (Theorem 13.15.31) provides a ring homomorphism

$$\kappa: H^*(\overline{\mathcal{M}}_g, \mathbb{Q}) \longrightarrow CH^*(\mathcal{A})$$

whose image controls the geometric contributions to bar cohomology. The geometric operator σ_{geom} acts via multiplication by $\kappa(\lambda)$, where $\lambda = c_1(\mathbb{E})$ is the first Chern class of the Hodge bundle $\mathbb{E} \rightarrow \overline{\mathcal{M}}_g$.

Since $\dim_{\mathbb{C}} \overline{\mathcal{M}}_g = 3g - 3$, every cohomology class of degree exceeding $2(3g - 3) = 6g - 6$ vanishes. In particular,

$$\lambda^{3g-2} = c_1(\mathbb{E})^{3g-2} = 0 \quad \text{in } H^{2(3g-2)}(\overline{\mathcal{M}}_g, \mathbb{Q}),$$

since $2(3g - 2) = 6g - 4 > 6g - 6$ for all $g \geq 2$. Applying κ :

$$\kappa(\lambda)^{3g-2} = \kappa(\lambda^{3g-2}) = \kappa(0) = 0 \quad \text{in } CH^*(\mathcal{A}).$$

Therefore σ_{geom} is nilpotent of index at most $3g - 2$, giving at most $3g - 3$ nontrivial filtration steps. At $g = 0$ there is no Hodge bundle; at $g = 1$, $c_1(\mathbb{E}) = \frac{1}{12}\delta$ absorbs into N_{mod} . $\square$

Remark 14.6.16 (Nilpotent depth vs. periodicity). σ_{geom} is nilpotent ($\sigma^N = 0$), not periodic ($\sigma^N = \text{id}$): the geometric contribution provides a stabilization threshold (cf. Remark 14.6.27).

THEOREM 14.6.17 (Sharp geometric depth on smooth moduli;). For a chiral algebra $\mathcal{A}$ on a smooth genus $g \geq 2$ curve, suppose the Kodaira–Spencer map factors through the cohomology of the smooth moduli space:

$$\kappa: H^*(\mathcal{M}_g, \mathbb{Q}) \longrightarrow CH^*(\mathcal{A}).$$

Then the nilpotency index of $\kappa(\lambda)$ is at most $g - 1$:

$$\kappa(c_1(\mathbb{E}))^{g-1} = 0 \quad \text{in } CH^*(\mathcal{A}).$$

In particular:

- (a) At genus 2, the Hodge class contribution vanishes entirely: $\kappa(\lambda) = 0$.
- (b) At genus 3, the geometric depth is at most 2 (compared to 7 from the compactified bound).
- (c) In general, the sharp bound $g - 1$ improves the compactified bound $3g - 2$ by a factor of approximately 3.

Proof. The tautological ring $R^*(\mathcal{M}_g)$ of the smooth moduli space satisfies the Graber–Vakil vanishing theorem [21] (extending Looijenga [301]):

$$R^d(\mathcal{M}_g) = 0 \quad \text{for } d > g - 2.$$

The Hodge class $\lambda = c_1(\mathbb{E})$ is a tautological class of degree 1. On the smooth moduli space, the Mumford relation reduces to $\lambda|_{\mathcal{M}_g} = \kappa_1/12$ (since the boundary class δ vanishes on $\mathcal{M}_g$). Therefore

$$\lambda^{g-1} \in R^{g-1}(\mathcal{M}_g) = 0$$

since $g - 1 > g - 2$. Applying κ :

$$\kappa(\lambda)^{g-1} = \kappa(\lambda^{g-1}) = 0.$$

For genus 2: $g - 1 = 1$, so $\lambda^1 = \lambda \in R^1(\mathcal{M}_2)$. Since $R^d(\mathcal{M}_2) = 0$ for $d > 0$, we get $\lambda|_{\mathcal{M}_2} = 0$, hence $\kappa(\lambda) = 0$. This means the Hodge class produces no geometric correction to bar cohomology at genus 2: the genus-2 bar complex, at the level of the Hodge class contribution, is determined entirely by the genus-0 data. $\square$

Remark 14.6.18 (Factorization hypothesis). The factorization through $H^*(\mathcal{M}_g)$ holds on smooth curves. On $\overline{\mathcal{M}}_g$, boundary divisor classes δ_i can increase nilpotent depth beyond $g - 1$ (but never beyond $3g - 2$, Theorem 14.6.15).

Conjecture 14.6.19 (Geometric amplitude on compactified moduli;). For a Koszul chiral algebra $\mathcal{A}$ on $\overline{\mathcal{M}}_g$ with factorization extensions to the boundary, the nilpotency index of the geometric operator $\kappa(\lambda)$ on $\overline{\mathcal{M}}_g$ is controlled by the Mumford relation $12\lambda = \kappa_1 + \delta$: the boundary contribution $\kappa(\delta)$ increases the nilpotency index beyond the interior bound $g - 1$ by at most the depth of the boundary tautological ring. Precisely, there exists a function $\text{nil}_\partial(g)$, depending only on the genus, such that:

$$\text{nil}(\kappa(\lambda)) \leq (g - 1) + \text{nil}_\partial(g), \quad \text{nil}_\partial(g) \leq 2g - 1.$$

The additive structure reflects the Mumford decomposition $12\lambda = \kappa_1 + \delta$, with the interior contributing at most $g - 1$ (proved) and the boundary contributing $\text{nil}_\partial(g)$ additional layers.

Remark 14.6.20 (Scope and provenance). The interior bound $g - 1$ is proved (Theorem 14.6.17, Graber–Vakil); the compactified bound $3g - 2$ is proved (Theorem 14.6.15). The conjecture interpolates via the Mumford relation. The geometric contribution is nilpotent ($\sigma^N = 0$), not periodic ($\sigma^N = \text{id}$); true periodicity arises from Types I and II only. (Part of the MC2 theorem package; Theorem 13.21.117.)

14.6.4.2 Examples at different genera

Example 14.6.21 (Genus 0: the sphere). No geometric tautological depth (simply connected, no moduli).

Example 14.6.22 (Genus 1: the torus). For elliptic curve E_τ :

- Period lattice $\Lambda = \mathbb{Z} + \tau\mathbb{Z}$
- Four spin structures (fermions have period 8)
- Modular parameter τ gives $SL_2(\mathbb{Z})$ action

Free fermion on E_τ : the weight-graded bar complex cohomology satisfies

$$\dim H^n(\bar{B}_{[h+8]}^{\text{ch}}(\mathcal{F}, E_\tau)) = \dim H^n(\bar{B}_{[h]}^{\text{ch}}(\mathcal{F}, E_\tau)) \quad \text{for } h \gg 0.$$

The period 8 comes from: 4 spin structures $\times$ 2 (fermion parity). (The total $CH^n(\mathcal{F})$ vanishes for $n > 2$ by Theorem 14.4.12; the periodicity is in conformal weight, not in Hochschild degree.) The Hodge class is absorbed into the modular data via $c_1(\mathbb{E}) = \frac{1}{12}\delta$.

Example 14.6.23 (Genus 2: Hodge class vanishing). By Theorem 14.6.17, the Hodge class contribution vanishes entirely at genus 2: $\kappa(\lambda) = 0$ in $CH^*(\mathcal{A})$. This follows from the Graber–Vakil vanishing $R^d(\mathcal{M}_2) = 0$ for $d > 0$. The genus-2 bar complex receives no geometric corrections from $c_1(\mathbb{E})$; any higher-genus modifications at $g = 2$ must arise from other tautological classes or from boundary contributions on $\overline{\mathcal{M}}_2$ (which reduce to $\mathcal{M}_{1,1} \times \mathcal{M}_{1,1}$ and $\mathcal{M}_{1,2}$ data).

14.6.5 STRATIFIED PERIODICITY

This subsection separates the unconditional structural part of the periodicity story from the conditional numerical values.

Conjecture 14.6.24 (Stratified periodicity package (partial);). For a rational chiral algebra $\mathcal{A}$ on a genus g curve with central charge $c = p/q$ ($\gcd(p, q) = 1$) and quantum group level inducing period M , the bar cohomology dimensions are eventually periodic in conformal weight:

$$\text{Period}(\mathcal{A}) \mid \text{lcm}(N_{\text{modular}}, N_{\text{quantum}})$$

where:

$$N_{\text{modular}} = \frac{24q}{\gcd(p, 24)} \quad (\text{Conjectures 14.6.3, 14.6.8 for minimal/WZW; Conjecture 14.6.6 in general})$$

$$N_{\text{quantum}} = M \text{ (from quantum group; proved)}$$

and the conformal weight threshold beyond which this periodicity holds is controlled by the geometric tautological depth $\text{nil}(\kappa(\lambda)) \leq g - 1$ (Theorem 14.6.17).

Evidence. The unconditional content is structural rather than numerical. What is proved is the Type II quantum input and the tautological depth bound. What remains conjectural is the sharp Type I modular input.

The bar spectral sequence

$$E_2^{p,q} = H^q(\overline{C}_{p+2}(X)) \otimes H^0(\mathcal{A}^{\otimes(p+2)})$$

admits a tridegree decomposition $(d_{\text{mod}}, d_{\text{quant}}, d_{\text{geom}})$, where the three indices record respectively the representation-theoretic weight, the fusion-theoretic degree, and the configuration-space cohomological degree.

Step 1: Inputs.

1. *Modular (Type I).* For the rational families treated above, Step 1 of Conjectures 14.6.3 and 14.6.8 proves only the T -matrix phase bound on the finite-dimensional character space. Upgrading that phase bound to eventual periodicity of the bar cohomology with order N_{mod} is precisely the conjectural input of the Type I modular-periodicity package.
2. *Quantum (Type II).* The quantum-integer periodicity $[n + 2\ell]_q = [n]_q$ is theorematic in the admissible-level KL/DS regime of Proposition 14.6.13, so the Type II profile contributes a proved N_{quant} factor.
3. *Geometric (Type III).* Theorem 14.6.17 proves $\kappa(\lambda)^{g-1} = 0$ on smooth moduli, giving a sharp tautological depth bound. This is a *nilpotent stabilization*, not a periodicity source: it bounds the transient before modular/quantum periodicity takes hold, rather than contributing a periodic factor to the lcm (Remark 14.6.16).

Step 2: Structural mechanism. The genuine periodicity operators σ_{mod} and σ_{quant} act on the first two tridegree directions. Their combined order divides $\text{lcm}(N_{\text{mod}}, N_{\text{quant}})$. The geometric direction is *bounded*, not periodic: the nilpotent operator $\sigma_{\text{geom}} = \kappa(\lambda)$ satisfies $\sigma_{\text{geom}}^{g-1} = 0$ (Theorem 14.6.17), so the geometric spectral sequence has at most $g - 2$ nontrivial filtration steps.

The bookkeeping separation is:

- the modular input acts on the representation-theoretic component via T -eigenvalues / conformal weights (periodic, conjectural);
- the quantum input acts on the fusion-theoretic component via quantum dimensions and Clebsch–Gordan data (periodic, proved);
- the geometric input acts on the configuration-space component via tautological classes on $\mathcal{M}_g$ (*nilpotent*, proved).

Step 3: Combined structure. The genuine period of $\mathcal{A}$ is governed by the periodic operators only: $\text{Period}(\mathcal{A}) \mid \text{lcm}(N_{\text{mod}}, N_{\text{quant}})$. The geometric contribution controls the *stabilization threshold*: bar cohomology dimensions become $\text{Period}(\mathcal{A})$ -periodic in conformal weight once the weight exceeds a threshold determined by the tautological depth. On $\overline{\mathcal{M}}_g$ the depth is at most $3g - 2$ (Theorem 14.6.15); on $\mathcal{M}_g$ the sharp bound is $g - 1$ (Theorem 14.6.17).

Remark 14.6.25 (Scope). Conjectured because the modular bound (Conjecture 14.6.6) is open. Quantum periodicity is proved; the geometric contribution is nilpotent depth (proved), not a periodic source. The lcm formula $\text{Period}(\mathcal{A}) \mid \text{lcm}(N_{\text{mod}}, N_{\text{quant}})$ is the correct statement. (Part of the MC2 theorem package; Theorem 13.21.117.)

Remark 14.6.26 (Periodicity profile refinement). The scalar period is the shadow of the richer profile $\Pi(\mathcal{A}) = (M_{\mathcal{A}}, Q_{\mathcal{A}}, G_{\mathcal{A}})$ (Remark 12.5.10): $M_{\mathcal{A}}$ carries the modular T -eigenvalue action (conjectural), $Q_{\mathcal{A}}$ encodes quantum CG periodicity (proved), and $G_{\mathcal{A}}$ encodes the nilpotent tautological depth (Theorem 14.6.17).

Remark 14.6.27 (Stratified periodicity). The mature formulation separates periodic from nilpotent contributions: (a) the lcm mechanism for the two genuine periodic sources is proved (Proposition 14.6.28); quantum periodicity is explicit; geometric depth $\leq g - 1$ (Theorem 14.6.17) is proved. (b) Minimal models and WZW have explicit T -matrix periodicity, but bar-periodicity remains conjectural (Conjectures 14.6.3, 14.6.8; Step 2 gap). (c) For general Koszul chiral algebras, the period divides $\text{lcm}(N_{\text{mod}}, N_{\text{quant}})$; the spectral radius of T_{rec} bounds N_{mod} (Theorem K.7.1). See the editorial companion for the full research programme.

14.6.6 KOSZUL DUALITY AND PERIODICITY INTERACTION

PROPOSITION 14.6.28 (*Periodicity-profile transport under Koszul duality*;). Let $(\mathcal{A}, \mathcal{A}^!)$ be a Koszul dual pair of rational chiral algebras on a genus g curve X . Then:

1. The geometric tautological depth is unchanged: $\text{nil}(\kappa(\lambda))_{\mathcal{A}} = \text{nil}(\kappa(\lambda))_{\mathcal{A}^!}$.
2. The dual modular phase bound is determined by the dual central charge: $N'_{\text{mod}} = 24q'/\gcd(p', 24)$ where $c' = c(\mathcal{A}^!) = p'/q'$ in lowest terms.
3. If both algebras lie in the admissible-level KL/DS regime of Type II above, then the quantum periodicity input is preserved: $N_{\text{quant}}(\mathcal{A}) = N_{\text{quant}}(\mathcal{A}^!)$.

In particular, Koszul duality transports the periodicity *profile* $(N_{\text{mod}}, N_{\text{quant}})$ and the geometric depth component-wise; it does not assert equality of scalar periods, since the modular component changes with the dual central charge. Whenever both periodic profile components are defined, the total period of $\mathcal{A}^!$ divides $\text{lcm}(N'_{\text{mod}}, N_{\text{quant}})$.

Proof. (1) *Geometric tautological depth is unchanged.* Both $\mathcal{A}$ and $\mathcal{A}^!$ live on the same curve X . The Hodge bundle contribution from $\overline{\mathcal{M}}_g$ (via the Kodaira–Spencer map, Theorem 13.15.31) depends only on the geometry of X , not on the chiral algebra. Since $\kappa(\lambda)$ is the image of $\lambda = c_1(\mathbb{E})$ under the same ring homomorphism for both $\mathcal{A}$ and $\mathcal{A}^!$, the nilpotency index is preserved.

(2) *Modular period of the dual.* The dual central charge c' is determined by the level duality $k \mapsto k' = -k - 2h^\vee$ via the Sugawara formula, giving $c' = p'/q'$ in lowest terms. The T -matrix of $\mathcal{A}^!$ has eigenvalues $e^{2\pi i(h'_\lambda - c'/24)}$, and the same elementary argument as in Step 1 of the periodicity proofs (requiring only

$c'N'/24 \in \mathbb{Z}$ and rationality of conformal weights) gives $T^{N'} = \text{Id}$ for $N'_{\text{mod}} = 24q'/\gcd(p', 24)$. This T -matrix periodicity is unconditional: it depends only on rationality of c' , not on any conjecture about bar cohomology.

(3) *Quantum input in the admissible-level regime.* In the Type II admissible-level KL/DS regime, the quantum component is encoded by quantum integers, quantum dimensions, and fusion data. Koszul duality sends level k to $k' = -k - 2h^\vee$, hence $q \mapsto q^{-1}$. Since $[n]_{q^{-1}} = [n]_q$ for all n , the Type II quantum input is preserved under duality whenever that regime applies. $\square$

Remark 14.6.29 (Modular period exchange). Proposition 14.6.28 establishes unconditionally that the geometric tautological depth is preserved and that the dual modular phase bound is determined by the dual central charge. In the admissible-level KL/DS regime it also preserves the Type II quantum input. The sum of reciprocal modular periods is given by Conjecture 14.6.10: writing $c = p/q$ and $c' = p'/q'$,

$$\frac{1}{N_{\text{mod}}} + \frac{1}{N'_{\text{mod}}} = \frac{\gcd(p, 24) + \gcd(p', 24)}{24q}.$$

This equals $\frac{1}{12}$ precisely when $\gcd(p, 24) + \gcd(p', 24) = 2q$; for $q = 1$ and $c + c' = 26$, this requires both p and $26 - p$ coprime to 24 (e.g. $c = 1, c' = 25$ or $c = 7, c' = 19$, but *not* $c = 5, c' = 21$ since $\gcd(21, 24) = 3$).

14.7 PHYSICAL APPLICATIONS

14.7.1 MARGINAL DEFORMATIONS IN CFT

In 2D conformal field theory, $CH^2(\mathcal{A})$ classifies marginal deformations $S \rightarrow S + \lambda \int_{\Sigma} \phi(z, \bar{z}) d^2z$. Conformal invariance is preserved when ϕ has weight $(1, 1)$ (marginality), $[\phi] \in CH^2$ is a cocycle (preserving the OPE algebra), and the obstruction in CH^3 vanishes (extending to all orders).

Example 14.7.1 (Exactly marginal deformations). For the free boson, $CH^2 = \mathbb{C}$ gives the radius deformation; for $N = 4$ SYM, $CH^2 = \mathbb{C}^{3(g-1)}$ gives gauge coupling and theta angles; for minimal models, $CH^2 = 0$ (isolated in moduli space).

14.7.2 STRING FIELD THEORY

The A_∞ structure encoded in Hochschild cohomology gives string field theory vertices:

THEOREM 14.7.2 (*String field theory from Hochschild [409];*). The operations $m_n : \mathcal{A}^{\otimes n} \rightarrow \mathcal{A}[2 - n]$ extracted from $CH^\bullet$ satisfy:

$$\sum_{\substack{r+s+t=n \\ r,t \geq 0, s \geq 1}} (-1)^{r+s+t} m_{r+1+t}(\text{id}^{\otimes r} \otimes m_s \otimes \text{id}^{\otimes t}) = 0$$

These give:

- m_1 : BRST operator Q
- m_2 : String multiplication
- m_3 : Four-string vertex

- Higher m_n : Contact terms

The action:

$$S[\Psi] = \frac{1}{2} \langle \Psi, Q\Psi \rangle + \sum_{n \geq 3} \frac{1}{n!} \langle \Psi, m_n(\Psi, \dots, \Psi) \rangle$$

14.7.3 HOLOGRAPHIC DUALITY

Conjecture 14.7.3 (Holographic Koszul duality;). A holographic Koszul template for $\text{AdS}_3/\text{CFT}_2$ should exchange:

- a suitable bulk gravity package $\leftrightarrow$ a boundary CFT package
- Boson-like fields $\leftrightarrow$ Fermion-like fields
- the boundary algebra should arise as a Koszul-dual shadow of a suitable bulk package, heuristically $\mathcal{A}_{\text{bulk}}^! \simeq \mathcal{A}_{\text{boundary}}$

Remark 14.7.4 (Scope). This conjecture lies outside the present monograph: it is a physical interpretation, not a theorem. A precise formulation would require specifying the bulk as a factorization algebra on a 3-manifold with boundary (Costello–Li). The relation $c_{\text{bulk}} + c_{\text{boundary}} = 26$ has no known proof from Koszul duality alone. (Contributing to Conjecture K.7.1.)

Three pieces of evidence: the central charges satisfy $c_{\text{bulk}} + c_{\text{boundary}} = 26$, the Hochschild cohomologies are Koszul dual, and the twisting morphism exhibits the formal pattern of the conjectural holographic dictionary.

14.8 COMPUTING CHIRAL HOCHSCHILD COHOMOLOGY VIA BAR-COBAR RESOLUTION

14.8.1 THE BAR-COBAR RESOLUTION STRATEGY

The bar-cobar approach computes Hochschild cohomology via the quasi-isomorphism $CH^n(\mathcal{A}) = H^n(\text{Hom}_{\text{Alg}}(\Omega(\bar{B}(\mathcal{A})), \mathcal{A}))$, using the cofree coalgebra resolution $\bar{B}(\mathcal{A})$ and the free algebra resolution $\Omega(\bar{B}(\mathcal{A}))$.

14.8.2 THE FUNDAMENTAL QUASI-ISOMORPHISM

THEOREM 14.8.1 (*Bar-cobar resolution;).* [Regime: quadratic at genus 0; curved-central at genus $g \geq 1$ on the Koszul locus (Convention 1.10.2).]

For any chiral Koszul algebra $\mathcal{A}$ on a curve X (Definition 11.1.15), the counit is a quasi-isomorphism:

$$\Omega^{\text{geom}}(\bar{B}^{\text{geom}}(\mathcal{A})) \xrightarrow{\sim} \mathcal{A}$$

Proof. This is a consequence of Theorem 11.1.84 (III), which establishes $\Omega^{\text{ch}}(\bar{B}^{\text{ch}}(\mathcal{A})) \simeq \mathcal{A}$ for Koszul chiral algebras. We summarize the argument structure; full details are in Chapter 13.

The bar complex $\bar{B}^{\text{geom}}(\mathcal{A})$ is a conilpotent chiral coalgebra with $d_0^2 = 0$ (Theorem 6.1.21). The cobar construction $\Omega^{\text{ch}}(\bar{B}^{\text{ch}}(\mathcal{A}))$ is a free chiral algebra (Theorem 7.0.50), hence the composite is a free resolution.

The augmentation $\epsilon: \Omega^{\text{ch}}(\bar{B}^{\text{ch}}(\mathcal{A})) \rightarrow \mathcal{A}$ is a quasi-isomorphism by the following spectral sequence argument: the bar filtration induces a spectral sequence with $E_2^{p,q} = H^p(\mathcal{A}^1) \otimes H^q(\mathcal{A})$ (Theorem 8.6.15), which collapses at E_2 for Koszul algebras (Theorem 8.6.16). The abutment gives $H^*(\Omega(\bar{B}(\mathcal{A}))) \cong \mathcal{A}$.

For general (not necessarily Koszul) chiral algebras, the classical bar-cobar adjunction is acyclic in the *connected* graded setting ([299], Theorem 2.2.5), but the chiral analog requires the Koszul or pro-nilpotent hypothesis: at admissible affine levels and minimal-model loci, the counit $\Omega(\bar{B}(\mathcal{A})) \rightarrow \mathcal{A}$ is not a quasi-isomorphism (Remark G.12.4). $\square$

Remark 14.8.2. The bar-cobar construction “undoes itself”:

$$\begin{aligned} \mathcal{A} &\xrightarrow{\bar{B}} \text{Coalgebra (with boundaries)} \\ &\xrightarrow{\Omega} \text{Algebra (with singularities)} \\ &\xrightarrow{\epsilon} \mathcal{A} \quad (\text{back to original}) \end{aligned}$$

The composition $\epsilon \circ \Omega \circ \bar{B}$ is homotopic to the identity, giving the resolution.

14.8.3 CHIRAL HOCHSCHILD COHOMOLOGY FORMULA

THEOREM 14.8.3 (*HH* via configuration spaces*;). The chiral Hochschild cohomology of a chiral algebra $\mathcal{A}$ is computed by:

$$CH^n(\mathcal{A}) = H^n\left(\Gamma\left(\bar{C}_{n+2}(X), \text{Hom}_{\mathcal{D}_X}(\mathcal{A}^{\boxtimes n+2}, \mathcal{A}) \otimes \Omega^n(\log D)\right), d_{\text{Hoch}}\right)$$

where the chiral Hochschild differential d_{Hoch} has three components:

$$d_{\text{Hoch}} = d_{\text{internal}} + d_{\text{factor}} + d_{\text{form}} \tag{14.23}$$

Component descriptions.

1. d_{internal} : Internal differential on $\mathcal{A}$ -factors
2. d_{factor} : Factorization using chiral product (OPE collisions)
3. d_{form} : de Rham differential on configuration space forms

Proof. Step 1: Definition of chiral Hochschild cochains.

By definition:

$$C_{\text{Hoch}}^n(\mathcal{A}) = \text{Hom}_{\mathcal{A}^e}(\mathcal{A}^{\otimes n+2}, \mathcal{A})$$

An $\mathcal{A}^e$ -linear map must commute with the bimodule structure, which for chiral algebras means:

- Commutes with $\mathcal{D}_X$ -module structure
- Respects locality (support properties)
- Compatible with chiral products

Step 2: Geometric realization.

These maps are parametrized by configuration spaces: a chiral Hochschild n -cochain assigns to each configuration of $n + 2$ points a multilinear map.

Explicitly, $f \in C_{\text{Hoch}}^n$ corresponds to a section:

$$f \in \Gamma(\overline{C}_{n+2}(X), \text{Hom}(\mathcal{A}^{\boxtimes n+2}, \mathcal{A}) \otimes \Omega^n(\log D))$$

The logarithmic forms account for the singular behavior as points collide.

Step 3: Differential.

The chiral Hochschild differential is:

$$\begin{aligned} (df)(a_0, \dots, a_{n+1}) &= \mu(a_0, f(a_1, \dots, a_{n+1})) + \sum_{i=1}^n (-1)^i f(a_0, \dots, \mu(a_i, a_{i+1}), \dots, a_{n+1}) \\ &\quad + (-1)^{n+1} \mu(f(a_0, \dots, a_n), a_{n+1}). \end{aligned}$$

Geometrically, each term corresponds to:

- First term: factorization at boundary (first two points collide)
- Middle terms: factorization at interior points
- Last term: factorization at opposite boundary

Combined with the de Rham differential on forms, we get d_{Hoch} as described. $\square$

Remark 14.8.4 (Decomposition of the differential). The decomposition (14.23) mirrors the bar differential:

Bar	chiral Hochschild	Meaning
d_{internal}	d_{internal}	Differential on $\mathcal{A}$
d_{residue}	d_{factor}	Extract boundary data
d_{form}	d_{form}	Configuration space geometry

14.8.4 EXPLICIT COMPUTATION: FREE BOSON (HEISENBERG ALGEBRA)

Example 14.8.5 (chiral Hochschild of Heisenberg). For the free boson $\mathcal{B}$ (Heisenberg chiral algebra) with field $\alpha(z)$ and OPE:

$$\alpha(z_1)\alpha(z_2) \sim \frac{k}{(z_1 - z_2)^2}$$

We compute all chiral Hochschild cohomology groups.

14.8.4.1 Degree 0: $CH^0(\mathcal{B})$

$$CH^0(\mathcal{B}) = Z(\mathcal{B}) = \{a \in \mathcal{B} : a(z)b(w) \text{ is regular for all } b \in \mathcal{B}\}$$

Since $\alpha(z)\alpha(w) \sim k/(z-w)^2$, the only fields with trivially regular OPE against all of $\mathcal{B}$ are the scalars $\mathbb{C} \cdot 1$. Hence:

$$CH^0(\mathcal{B}) = \mathbb{C}.$$

14.8.4.2 Degree 1: $CH^1(\mathcal{B})$

$$CH^1 = \text{Der}(\mathcal{B})/\text{Inn}(\mathcal{B})$$

where $\text{Der}(\mathcal{B})$ is the space of chiral derivations and $\text{Inn}(\mathcal{B})$ the inner derivations.

A chiral derivation D is determined by $D(\alpha) = f$, a field in $\mathcal{B}$. The derivation property applied to $\{\alpha_\lambda \alpha\} = k\lambda$ forces $\{D(\alpha)_\lambda \alpha\} + \{\alpha_\lambda D(\alpha)\} = 0$ (since $D(k\lambda) = 0$). For the rank-1 Heisenberg, the only fields with trivially regular OPE with α are multiples of the identity $\mathbf{1}$, so $D(\alpha) = c \cdot \mathbf{1}$ for some $c \in \mathbb{C}$. This gives $\text{Der}(\mathcal{B}) = \mathbb{C}$.

An inner derivation by a field a acts as $a_{(0)}(\alpha)$. But the zero mode $\alpha_{(0)} = \alpha_0$ is *central* in the Heisenberg mode algebra: $[\alpha_0, \alpha_n] = k \cdot 0 \cdot \delta_{0+n,0} = 0$ for all n . Hence $\alpha_{(0)}\alpha = 0$. Similarly $\mathbf{1}_{(0)}\alpha = 0$. No element $a \in \mathcal{B}$ satisfies $a_{(0)}\alpha = \mathbf{1}$, so $\text{Inn}(\mathcal{B}) = 0$.

Therefore:

$$CH^1(\mathcal{B}) = \text{Der}/\text{Inn} = \mathbb{C}/0 = \mathbb{C},$$

generated by the outer chiral derivation $D(\alpha) = \mathbf{1}$.

Remark 14.8.6 (Classical vs. chiral Hochschild). The classical Hochschild HH^1 of the Weyl algebra (the mode algebra of $\mathcal{B}$) is 0 by Whitehead's theorem: every derivation of the Weyl algebra is inner. The discrepancy with $CH^1(\mathcal{B}) = \mathbb{C}$ arises because the chiral inner derivations use the *vertex algebra* zero mode $a_{(0)}$, not the *associative algebra* commutator $[a, -]$. The zero mode $\alpha_{(0)}$ is central in the Heisenberg vertex algebra (it acts by the residue of the OPE, which has no first-order pole), while the mode α_{-1} is non-central in the Weyl algebra but does *not* define a chiral inner derivation.

14.8.4.3 Degree 2: $CH^2(\mathcal{B})$

CH^2 classifies deformations of the chiral algebra structure.

A deformation is given by modifying the OPE:

$$\alpha(z_1) \times_t \alpha(z_2) = \alpha(z_1)\alpha(z_2) + t \cdot \phi(z_1, z_2) + O(t^2)$$

where ϕ is a 2-cocycle.

Cocycle condition. Associativity to first order in t :

$$(\alpha \times_t \alpha) \times_t \alpha = \alpha \times_t (\alpha \times_t \alpha)$$

This imposes:

$$d\phi = 0$$

(cohomological condition)

Trivial cocycles. If $\phi = d\psi$ for some ψ , the deformation is trivial (comes from a redefinition of α).

Nontrivial deformations. The only independent deformation is changing the level k :

$$\alpha(z_1)\alpha(z_2) \sim \frac{k+t}{(z_1-z_2)^2}$$

This gives a 1-dimensional space:

$$CH^2(\mathcal{B}) = \mathbb{C} \cdot [k].$$

Here $[k]$ is the cohomology class of the level.

14.8.4.4 Higher degrees: $CH^n(\mathcal{B})$ for $n \geq 3$

For the Heisenberg algebra (free boson), all higher Hochschild cohomology vanishes:

$$CH^n(\mathcal{B}) = 0 \quad \text{for } n \geq 3$$

Proof. The Heisenberg algebra $\mathcal{B}$ is chiral Koszul (Theorem 11.1.20): its bar construction $\bar{\mathcal{B}}(\mathcal{B})$ is quasi-isomorphic to $\text{CE}(\mathfrak{h}_{-k})$, which is concentrated in bar degrees ≤ 2 (the only generating relation is the quadratic OPE $\alpha(z)\alpha(w) \sim k/(z-w)^2$, involving exactly two fields). The Koszul resolution therefore has the form:

$$\mathcal{B} \otimes \mathcal{B}^! \otimes \mathcal{B} \xrightarrow{d_2} \mathcal{B} \otimes (s\alpha) \otimes \mathcal{B} \xrightarrow{d_1} \mathcal{B} \otimes \mathcal{B}$$

with $\mathcal{B}^! = \text{CE}(\mathfrak{h}_{-k})$ generated by a single element $s\alpha$ in bar degree 1 and its square in bar degree 2. Applying $\text{Hom}_{\mathcal{B}, \mathcal{B}}(-, \mathcal{B})$ to this length-2 resolution yields a cochain complex concentrated in degrees 0, 1, 2. Hence $CH^n(\mathcal{B}) = 0$ for $n \geq 3$.

14.8.4.5 Summary for Heisenberg

$$CH^*(\mathcal{B}) = \begin{cases} \mathbb{C} & n = 0 \text{ (center = scalars)} \\ \mathbb{C} & n = 1 \text{ (outer derivation } D(\alpha) = 1) \\ \mathbb{C} & n = 2 \text{ (level deformation)} \\ 0 & n \geq 3 \text{ (Koszul resolution length 2)} \end{cases}$$

The Poincaré polynomial is $P_{\mathcal{B}}(t) = 1 + t + t^2$. For algebras whose OPE among generators has *no simple pole* (i.e., the zero mode $a_{(0)}$ is central), all outer derivations survive and $CH^1 = \mathbb{C}^d$ where d is the number of strong generators. The Heisenberg ($d = 1$, double pole only) is the prototypical case. For algebras with simple poles, the structure of CH^1 depends on the family: for affine Kac–Moody $V_k(\mathfrak{g})$ at generic level, $CH^1(V_k(\mathfrak{g})) \cong \mathfrak{g}$ (Proposition A.11.25), reflecting the $\dim(\mathfrak{g})$ -dimensional space of current-algebra deformations; for the bc and $\beta\gamma$ systems, the simple-pole sector is one-dimensional and $CH^1 = \mathbb{C}$ (Remark 14.5.5).

14.8.5 EXPLICIT COMPUTATION: FREE FERMION

Example 14.8.7 (chiral Hochschild of free fermion). For the free fermion $\mathcal{F}$ with fields $\psi(z), \psi^*(z)$ and OPE:

$$\psi(z_1)\psi^*(z_2) \sim \frac{1}{z_1 - z_2}$$

14.8.5.1 Degree 0: $CH^0(\mathcal{F})$

Endomorphisms must preserve the fermionic OPE. By similar reasoning to the bosonic case:

$$CH^0(\mathcal{F}) = \mathbb{C}$$

14.8.5.2 Degree 1: $CH^1(\mathcal{F})$

Derivations of the fermionic algebra. The Leibniz rule for fermions includes sign factors:

$$D(\psi\psi^*) = D(\psi)\psi^* + (-1)^{|\psi|}\psi D(\psi^*)$$

Since the OPE has no deformation parameters, we find:

$$CH^1(\mathcal{F}) = 0$$

14.8.5.3 Degree 2: $CH^2(\mathcal{F})$

Deformations of the fermionic structure. The free fermion bc ghost system admits a one-parameter family of deformations parametrized by the spin λ : the conformal weights $(h_b, h_c) = (\lambda, 1 - \lambda)$ vary while the OPE $b(z)c(w) \sim 1/(z - w)$ is preserved. This gives:

$$CH^2(\mathcal{F}) = \mathbb{C}$$

14.8.5.4 Summary for free fermion

$$CH^*(\mathcal{F}) = \begin{cases} \mathbb{C} & n = 0 \\ 0 & n = 1 \\ \mathbb{C} & n = 2 \\ 0 & n \geq 3 \end{cases}$$

As a graded algebra:

$$CH^*(\mathcal{F}) \cong \Lambda(c)$$

(exterior algebra on one generator of degree 2)

14.8.6 KOSZUL DUALITY AND HH^* PAIRING

The Koszul duality for Hochschild cohomology (Theorem 14.4.10) is now verified on examples.

VERIFICATION 14.8.8 (*bc*/βγ Koszul duality;). The Koszul pair (bc ghost system $\mathcal{F}_{bc}$, βγ system $\mathcal{BG}$) satisfies:

$$CH^0(\mathcal{F}_{bc}) = \mathbb{C} \xleftrightarrow{\text{dual}} CH^2(\mathcal{BG})^* = \mathbb{C}$$

$$CH^1(\mathcal{F}_{bc}) = 0 \xleftrightarrow{\text{dual}} CH^1(\mathcal{BG})^* = 0$$

$$CH^2(\mathcal{F}_{bc}) = \mathbb{C} \xleftrightarrow{\text{dual}} CH^0(\mathcal{BG})^* = \mathbb{C}$$

Note that $CH^1(\mathcal{F}_{bc}) = 0$ (Remark 14.5.5: the simple pole in the bc OPE makes all derivations inner), which differs from $CH^1(\mathcal{B}) = \mathbb{C}$ for the Heisenberg boson. The duality pairing is between $\mathcal{F}_{bc}$ and $\mathcal{BG}$, *not* between $\mathcal{B}$ and $\mathcal{BG}$.

14.8.7 COMPARISON WITH CLASSICAL HOCHSCHILD COHOMOLOGY

Remark 14.8.9 (*Chiral vs. classical*). Chiral CH^* differs from classical $HH_{\text{classical}}^n(A) = \text{Ext}_{A^e}^n(A, A)$ by locality, configuration-space integrals, differential-form coefficients, and the spatial direction from X . For constant fields: $CH^n(\mathcal{A})|_{\text{constant}} \cong HH_{\text{classical}}^n(H^0(\mathcal{A}))$.

14.8.8 THE CHIRAL GERSTENHABER BRACKET FROM CONFIGURATION SPACES

THEOREM 14.8.10 (*Chiral Gerstenhaber structure on CH^* ;*). The single-insertion residue sum of Construction 14.8.11 induces a degree- (-1) pre-Lie product

$$\circ: CH^p(\mathcal{A}) \otimes CH^q(\mathcal{A}) \longrightarrow CH^{p+q-1}(\mathcal{A}),$$

and its antisymmetrization

$$[f, g]_G := f \circ g - (-1)^{(|f|-1)(|g|-1)} g \circ f$$

defines a degree- (-1) bracket

$$[-, -]_G: CH^p(\mathcal{A}) \otimes CH^q(\mathcal{A}) \longrightarrow CH^{p+q-1}(\mathcal{A}).$$

For homogeneous classes f, g, h , this bracket is graded skew-symmetric, satisfies the graded Jacobi identity, and is a derivation of the cup product:

$$[f, g \smile h]_G = [f, g]_G \smile h + (-1)^{(|f|-1)|g|} g \smile [f, h]_G.$$

Hence $CH^*(\mathcal{A})$ is a Gerstenhaber algebra. This is the chiral analogue of Gerstenhaber's classical bracket [197] on associative Hochschild cochains, realized here by OPE residues on configuration spaces.

Proof. By Remark A.11.4, the geometric chiral Hochschild complex of this chapter is identified with the algebraic cochain complex $C_{\text{ch}}^\bullet(A, A)$ of Definition A.11.3. In that algebraic model, the single brace $f\{g\}$ is the pre-Lie insertion of Example A.11.6, and the Gerstenhaber bracket is its antisymmetrization (Definition A.11.7):

$$[f, g]_G = f\{g\} - (-1)^{(|f|-1)(|g|-1)} g\{f\}.$$

Construction 14.8.11 is the geometric realization of the same operation: each residue $f \circ_i g$ inserts the g -configuration into the i -th marked point of the f -configuration, so the sum over insertion places is the geometric avatar of the single brace $f\{g\}$. We therefore write

$$f \circ g = f\{g\}$$

under the comparison of Remark A.11.4, and the displayed formula above is exactly the bracket coming from Construction 14.8.11.

The graded Jacobi identity follows from the pre-Lie identity for the single insertion. Algebraically this is Proposition A.11.9; geometrically it is the statement that the two ways of performing successive insertions are the two boundary decompositions of the same codimension-1 face in the Fulton–MacPherson space $\text{FM}_3(\mathbb{C})$. Associativity of the chiral operadic composition on these boundary strata gives

$$(f \circ g) \circ h - f \circ (g \circ h) = (-1)^{(|g|-1)(|h|-1)} ((f \circ h) \circ g - f \circ (h \circ g)),$$

which is the Stasheff-type boundary relation for triple insertion. Antisymmetrizing a pre-Lie product gives a graded Lie bracket, so $[-, -]_G$ satisfies graded skew-symmetry and Jacobi on cochains.

Next, the chiral Hochschild differential is $\delta = [m, -]$ on $C_{\text{ch}}^\bullet(A, A)$. Theorem A.11.11 shows that δ is a derivation of the brace operations; hence

$$\delta[f, g]_G = [\delta f, g]_G + (-1)^{|f|-1} [f, \delta g]_G.$$

Therefore the bracket descends to cohomology.

For compatibility with the cup product, use the universal local chiral Swiss-cheese pair of Theorem A.11.16. In that operadic model, the cup product is the binary closed operation and the single brace is the boundary insertion operation obtained from the same $\text{SC}^{\text{ch}, \text{top}}$ -structure. The mixed codimension-1 boundary relation in the Swiss-cheese operad is exactly the brace-cup compatibility, so on cochains one has

$$[f, g \smile h]_{\text{G}} = [f, g]_{\text{G}} \smile h + (-1)^{(|f|-1)|g|} g \smile [f, h]_{\text{G}}.$$

Since both the bracket and the cup product descend through the differential, the same identity holds on cohomology. This is the Gerstenhaber compatibility recorded abstractly in Corollary A.11.21. Hence $CH^{\bullet}(\mathcal{A})$ is a Gerstenhaber algebra with the stated residue bracket. $\square$

Construction 14.8.11 (Geometric realization of bracket). The Gerstenhaber bracket has a natural geometric interpretation via configuration spaces.

For $f \in CH^p$ and $g \in CH^q$, represented as:

$$f \in \Gamma(\overline{C}_{p+2}(X), \dots)$$

$$g \in \Gamma(\overline{C}_{q+2}(X), \dots)$$

For each insertion place $1 \leq i \leq p+1$, let $f \circ_i g$ be the residue obtained by colliding the output point of the g -configuration with the i -th marked point of the f -configuration. The total single-insertion sum

$$f \circ g := \sum_{i=1}^{p+1} (-1)^{(q-1)(i-1)} f \circ_i g.$$

is the geometric pre-Lie product on chiral Hochschild cochains. The chiral Gerstenhaber bracket is its antisymmetrization:

$$[f, g]_{\text{G}} := f \circ g - (-1)^{(p-1)(q-1)} g \circ f.$$

Equivalently, the construction proceeds in three stages:

1. *Diagonal insertion:* insert one configuration into a marked point of the other
2. *Summation:* Sum over all possible insertion points
3. *Residue:* Extract the coefficient of singular terms

Explicitly, the first insertion sum has the form

$$f \circ g = \sum_{i=1}^{p+1} (-1)^{\epsilon_i} \text{Res}_{z_0 \rightarrow z_i} [f(\dots, z_i, \dots) \cdot g(z_0, \dots, z_q)],$$

and $g \circ f$ is defined by the same formula with f and g interchanged. The residue extracts the collision behavior along the relevant boundary divisor in the Fulton–MacPherson compactification, so $f \circ g$ is the geometric realization of the single brace operation and $[f, g]_{\text{G}}$ is the corresponding Gerstenhaber bracket.

Example 14.8.12 (Gerstenhaber bracket for Heisenberg). For $\mathcal{B}$ (Heisenberg), $CH^2 = \mathbb{C} \cdot [k]$ (level class).

The bracket:

$$[[k], [k]] = [k, k]$$

must have degree $2 + 2 - 1 = 3$. But $CH^3(\mathcal{B}) = 0$, so:

$$[[k], [k]] = 0$$

This reflects that the level is a *central element* in the Lie algebra structure (it commutes with everything).

14.8.9 HIGHER STRUCTURE: L_∞ OPERATIONS

Remark 14.8.13 (Beyond Gerstenhaber: full L_∞). Configuration space geometry encodes a full L_∞ structure $\ell_n: CH^*(\mathcal{A})^{\otimes n} \rightarrow CH^{*+2-n}(\mathcal{A})$ via

$$\ell_n(f_1, \dots, f_n) = \int_{C_{n,1}(X)} f_1 \wedge \dots \wedge f_n \wedge K_n,$$

where $K_n \in \Omega^{n-2}(\bar{C}_{n+1}(X), \text{End}(\mathcal{A}))$ is the propagator kernel ($K_2 = dz/(z_1 - z_2)$ recovers the Gerstenhaber bracket). Formal deformations are MC elements $\gamma \in CH^2(\mathcal{A})[[\hbar]]$ satisfying $\sum_{n \geq 1} \frac{1}{n!} \ell_n(\gamma, \dots, \gamma) = 0$.

14.8.10 COMPUTATIONAL STRATEGY

Remark 14.8.14 (Computing CH^ in practice).* To compute $CH^n(\mathcal{A})$ for a chiral algebra given by generators and OPE data, one proceeds as follows: (1) construct the bar complex $\bar{B}^n(\mathcal{A})$ using configuration space integrals; (2) build the cobar complex $\Omega(\bar{B}(\mathcal{A}))$ by inserting distributional duals; (3) form the Hom complex $\text{Hom}(\Omega(\bar{B}(\mathcal{A})), \mathcal{A})$; (4) compute cohomology $\ker(d)/\text{im}(d)$ at each degree. For Koszul algebras, the concentration of the bar coalgebra $\bar{B}(\mathcal{A})$ (whose dual is $\mathcal{A}^!$) reduces the computation to lower-dimensional complexes.

Remark 14.8.15 (Noncommutative Hodge degeneration). The pole-order filtration on the chiral Hochschild complex degenerates at E_1 for Koszul algebras (Theorem 8.6.16), giving a mixed structure analogous to Kaledin's noncommutative Hodge theory [243]. Theorem C (complementarity) is Verdier duality in this setting, exchanging the Hodge filtrations of $\mathcal{A}$ and $\mathcal{A}^!$.

14.8.11 SUMMARY AND OUTLOOK

The bar-cobar approach to Hochschild cohomology provides explicit formulas (all CH^* groups computable via configuration space integrals), a geometric interpretation (CH^* from topology of configuration spaces), the Gerstenhaber bracket and L_∞ operations, Koszul duality ($CH^n(\mathcal{A}) \leftrightarrow CH^{2-n}(\mathcal{A}^!)$), and deformation theory (CH^2 controls deformations, obstructions in CH^3). We apply this framework throughout to quantum corrections, W-algebras, level-rank duality, and higher genus contributions.

The deformation-obstruction theory developed above is universal: it applies to any Koszul chiral algebra. In Part 2, we make this concrete. For every major family of vertex algebras (Heisenberg, free fermion, $\beta\gamma$ -bc, affine Kac–Moody, Virasoro, W-algebras, Yangians) we compute the bar complex, identify the Koszul dual, determine the obstruction coefficient $\kappa(\mathcal{A})$, and verify the complementarity and genus universality theorems explicitly. The shared discriminant phenomenon (Theorem K.7.1) and the $\hat{A}$ -genus appearance in genus expansions emerge as consequences of the modular characteristic package, not as isolated coincidences.

14.9 COSIMPLICIAL DESCENT AND THE CHIRAL HOCHSCHILD–ČECH COMPARISON

The chiral Hochschild complex $C_{\text{chiral}}^\bullet(\mathcal{A})$ is built from configuration spaces of points on X : the complex in cochain degree n involves $(n+2)$ marked points (§14.8). When the points are restricted to lie in a fixed affine open, the complex degenerates to local data. Globalizing via an open cover introduces a second

direction of complexity, the Čech direction, and the interplay between the chiral Hochschild and Čech differentials is controlled by the homotopy chiral algebra structure of Malikov–Schechtman [309].

Remark 14.9.1 (Eilenberg–Zilber operad as genus-0 convolution control). The Eilenberg–Zilber operad $\mathcal{Y}(n) = \mathcal{Z}(n) \otimes_k \text{Lie}(n)$ of [309] is the genus-0 projection of the modular convolution algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ (Definition 13.22.1). The key identifications are:

- (i) The Eilenberg–Zilber chain complex $\mathcal{Z}(n) = \text{Tot Hom}_{\Delta}(Z, Z^{\otimes n})$ encodes the simplicial combinatorics of n -fold intersections in a cover. It is acyclic: $H^i(\mathcal{Z}(n)) = 0$ for $i \neq 0$, $H^0(\mathcal{Z}(n)) = k$ ([309, §2.5], originating in Dold [434]).
- (ii) At genus 0, the role of $\mathcal{Z}(n)$ is equivalent to that of the cellular chains on the associahedron $C_*(K_n)$, which in turn model $C_*(\overline{\mathcal{M}}_{0,n+1})$. The augmentation $\varepsilon: \mathcal{Z}(n) \rightarrow k$ and the cellular augmentation $C_*(K_n) \rightarrow k$ are quasi-isomorphisms controlling the same homotopy-coherent data.
- (iii) At genus $g \geq 1$, the role of $\mathcal{Z}(n)$ is replaced by $C_*(\overline{\mathcal{M}}_{g,n+1})$, and the HCA structure extends to the modular Feynman transform. The genus-0 Eilenberg–Zilber operations F_n are the tree-level truncation of the modular L_{∞} brackets $\ell_n^{(0)}$ (Construction 13.22.7).
- (iv) The Malikov–Schechtman operadic model ($\tau_{\leq 0}\mathcal{Y}$ -algebras, [309, §2.6]) and the Loday–Vallette coalgebraic model (codifferentials on cofree coalgebras, [299, §10.3]) are equivalent over characteristic-0 fields: both encode L_{∞} structures with the same MC moduli (Remark 3.1.15).

14.9.1 THE BICOMPLEX

Fix an affine cover $\mathcal{U} = \{U_i\}$ of X . Define the bicomplex

$$E_0^{p,q} = \bigoplus_{i_0 < \dots < i_p} C_{\text{chiral}}^q(\mathcal{A}|_{U_{i_0 \dots i_p}})$$

with horizontal differential $d_{\check{C}}$ (Čech) and vertical differential d_{Hoch} (chiral Hochschild, Theorem 14.2.2). Both differentials square to zero individually, but they do not strictly anticommute: the failure is measured by the Čech Jacobiator (Definition 16.9.1).

PROPOSITION 14.9.2 (*chiral Hochschild–Čech spectral sequence*;). The bicomplex $E_0^{p,q}$ gives rise to two spectral sequences:

- (i) *Čech-first*: $E_2^{p,q} = \check{H}^p(X, \mathcal{H}_{\text{ch}}^q(\mathcal{A})) \Rightarrow CH^{p+q}(\mathcal{A})$, where $\mathcal{H}_{\text{ch}}^q(\mathcal{A})$ is the sheaf of local chiral Hochschild cohomology.
- (ii) *chiral-Hochschild-first*: $E_2^{p,q} = H_{\text{ch}}^q(\check{C}^p(\mathcal{U}; \mathcal{A})) \Rightarrow CH^{p+q}(\mathcal{A})$.

Both converge for quasi-coherent $\mathcal{A}$ on a separated scheme X (by the standard bounded-below complete convergence theorem).

Proof. The convergence follows from the vanishing of Čech cohomology of quasi-coherent sheaves on affines: for any affine $U_{i_0 \dots i_p}$, the local chiral Hochschild complex computes $H_{\text{ch}}^q(\mathcal{A}|_U)$ and the Čech differentials are well-defined on cohomology sheaves. Both spectral sequences are bounded in the horizontal direction (the cover is finite) and bounded below in the vertical direction. $\square$

14.9.2 HCA ENHANCEMENT OF THE BICOMPLEX

The Čech-first spectral sequence sees only the Čech cohomology of the cohomology sheaves; it does not see the *algebraic structure* on the resolution. Malikov–Schechtman’s theorem (Theorem 8.10.5) enriches the Čech direction with HCA operations $\{F_n\}$, which produce a stronger convergence statement.

Conjecture 14.9.3 (HCA structure on local chiral Hochschild cochains;). The Čech complex of the presheaf $U \mapsto C_{\text{chiral}}^\bullet(\mathcal{A}|_U)$ carries an HCA MC element $\Phi_{CH} \in \text{MC}(\mathfrak{g}_{CH}^{\check{C}})$ in the Čech convolution algebra (Definition 8.10.3), with components:

- (i) F_2 is the brace operation (Theorem 12.3.4), encoding the Gerstenhaber bracket;
- (ii) F_3 is the Jacobiator homotopy for the brace bracket (nonzero only when $\check{C}^2 \neq 0$, i.e., for covers with three or more overlapping opens);
- (iii) the full MC element Φ_{CH} satisfies $D\Phi + \frac{1}{2}[\Phi, \Phi] = 0$, whose projections to each degree give the L_∞ relations on $CH^\bullet(\mathcal{A})$.

In particular, the Gerstenhaber algebra structure on $CH^\bullet(\mathcal{A})$ is the cohomological shadow of the MC element Φ_{CH} : the bracket is the degree-2 projection, and Jacobi holds on cohomology because F_3 is exact.

Remark 14.9.4 (Comparison with the modular deformation complex). The HCA structure on the chiral Hochschild–Čech bicomplex is the genus-0 shadow of the modular cyclic deformation complex $\text{Def}_{\text{cyc}}^{\text{mod}}(\mathcal{A})$ (Definition 14.5.12). At genus 0, the operadic control is via the Eilenberg–Zilber operad $\mathcal{Y}(n)$ acting on the Čech direction. At genus $g \geq 1$, the modular operad replaces $\mathcal{Y}(n)$ with the Feynman transform FCom , and the cosimplicial identities that make $d_{\check{C}}^2 = 0$ are replaced by the boundary relations on $\overline{\mathcal{M}}_{g,n}$ that make $d_{\text{fib}}^2 = \kappa \cdot \omega_g$. At each finite order, the shadow obstruction tower (Definition 13.22.46) unifies both the genus-0 HCA relations and the higher-genus Maurer–Cartan structure; the all-degree limit $D\Theta + \frac{1}{2}[\Theta, \Theta] = 0$ on $\text{Def}_{\text{cyc}}^{\text{mod}}(\mathcal{A})$ is the full master equation, proved by the bar-intrinsic construction (Theorem 13.21.69).

14.10 AMBIENT COMPLEMENTARITY: THE SHIFTED-SYMPLECTIC THEOREM

Theorem C establishes that $Q_g(\mathcal{A}) \oplus Q_g(\mathcal{A}^!) \subset R\Gamma(\overline{\mathcal{M}}_g, Z(\mathcal{A}))$ as complementary summands. That is the linear shadow. The proper theorem is not a splitting but a Lagrangian polarization: there is a single (-1) -shifted symplectic formal moduli problem, and the two dual packages are complementary Lagrangian maps into it.

Definition 14.10.1 (Kernel deformation complex). Let $(\mathcal{A}, \mathcal{A}^!)$ be a cyclic modular Koszul chiral pair on X , and let $\tau_{\mathcal{A}} \in \text{MC}(\mathcal{A}^! \widehat{\otimes} \mathcal{A})$ be the universal twisting kernel (Convention 6.0.2). Define

$$K_{\mathcal{A}} := (\mathcal{A}^! \widehat{\otimes} \mathcal{A})[1],$$

with differential twisted by $\tau_{\mathcal{A}}$. The linearizations of $\tau_{\mathcal{A}}$ in the $\mathcal{A}$ - and $\mathcal{A}^!$ -directions give maps

$$\nabla_{\mathcal{A}} : \text{Def}_{\text{cyc}}(\mathcal{A}) \rightarrow K_{\mathcal{A}}, \quad \nabla_{\mathcal{A}^!} : \text{Def}_{\text{cyc}}(\mathcal{A}^!) \rightarrow K_{\mathcal{A}}.$$

Definition 14.10.2 (Ambient complementarity tangent complex). Define

$$T_{\text{comp}}(\mathcal{A}) := \text{fib}(\nabla_{\mathcal{A}} - \nabla_{\mathcal{A}^!} : \text{Def}_{\text{cyc}}(\mathcal{A}) \oplus \text{Def}_{\text{cyc}}(\mathcal{A}^!) \longrightarrow K_{\mathcal{A}}).$$

A tangent vector is a simultaneous first-order deformation of $\mathcal{A}$, of $\mathcal{A}^!$, and of $\tau_{\mathcal{A}}$, constrained by the linearized Maurer–Cartan equation. The formal moduli problem of triples $(\mathcal{A}', \alpha, B')$ with $\mathcal{A}'$ a deformation of $\mathcal{A}$, B' a deformation of $\mathcal{A}^!$, and $\alpha \in \text{MC}(B' \widehat{\otimes} \mathcal{A}')$ a deformation of $\tau_{\mathcal{A}}$, has tangent complex $T_{\text{comp}}(\mathcal{A})$.

Conjecture 14.10.3 (Self-duality;). Assume $\text{Def}_{\text{cyc}}(\mathcal{A})$ and $\text{Def}_{\text{cyc}}(\mathcal{A}^!)$ carry the cyclic pairings of Definition 14.5.6. Then $T_{\text{comp}}(\mathcal{A})$ carries a canonical nondegenerate pairing of degree -1 .

Evidence. Pair the two outer summands by the cyclic/Koszul pairing, and pair $K_{\mathcal{A}}$ with itself by the evaluation-residue pairing. Compatibility with $\tau_{\mathcal{A}}$ makes the fiber differential skew-adjoint. Nondegeneracy follows from perfectness of the cyclic/Koszul pairings on the Koszul locus.

Conjecture 14.10.4 (One-sided isotropy;). The one-sided deformation maps

$$i_{\mathcal{A}} : \mathcal{M}_{\mathcal{A}} \rightarrow \mathcal{M}_{\text{comp}}(\mathcal{A}), \quad i_{\mathcal{A}^!} : \mathcal{M}_{\mathcal{A}^!} \rightarrow \mathcal{M}_{\text{comp}}(\mathcal{A}),$$

obtained by varying only $\mathcal{A}$ or only $\mathcal{A}^!$ (together with the induced first-order variation of $\tau_{\mathcal{A}}$), are isotropic.

Evidence. Differentiate the Maurer–Cartan equation for $\tau_{\mathcal{A}}$. The pullback of the ambient pairing to the graph of one-sided variations equals the quadratic term in the differentiated MC equation, hence vanishes.

Conjecture 14.10.5 (Ambient complementarity;). Assume the cyclic deformation complexes $\text{Def}_{\text{cyc}}(\mathcal{A})$ and $\text{Def}_{\text{cyc}}(\mathcal{A}^!)$ exist as filtered cyclic L_{∞} -algebras. Then:

- (i) $T_{\text{comp}}(\mathcal{A})$ is canonically self-dual of degree -1 (Conjecture 14.10.3).
- (ii) The one-sided deformation maps define complementary Lagrangian subcomplexes inside $T_{\text{comp}}(\mathcal{A})$ (Conjecture 14.10.4 for isotropy; maximality from bar-cobar inversion and perfectness of the cyclic/Koszul pairing).
- (iii) Any filtered cyclic L_{∞} -enhancement of $T_{\text{comp}}(\mathcal{A})$ defines a pointed (-1) -shifted symplectic formal moduli problem $\mathcal{M}_{\text{comp}}(\mathcal{A})$, and the induced maps $\mathcal{M}_{\mathcal{A}} \rightarrow \mathcal{M}_{\text{comp}}(\mathcal{A}) \leftarrow \mathcal{M}_{\mathcal{A}^!}$ are Lagrangian.
- (iv) The normal complex to $\mathcal{M}_{\mathcal{A}}$ in $\mathcal{M}_{\text{comp}}(\mathcal{A})$ is quasi-isomorphic to $T_{\mathcal{M}_{\mathcal{A}^!}}^{\vee}[-1]$, and symmetrically with $\mathcal{A}$ and $\mathcal{A}^!$ exchanged.
- (v) After applying the genus- g realization functor, one recovers the proved Lagrangian polarization $Q_g(\mathcal{A}), Q_g(\mathcal{A}^!) \subset R\Gamma(\overline{\mathcal{M}}_g, Z(\mathcal{A}))$ of Theorem 13.15.14.

Evidence. The ambient deformation functor is the homotopy pullback of the deformation functors of $\mathcal{A}$, $\mathcal{A}^!$, and the Maurer–Cartan functor of $\tau_{\mathcal{A}}$. Linearizing yields $T_{\text{comp}}(\mathcal{A})$. The conjectures above give self-duality and isotropy. Maximality comes from bar-cobar inversion (Theorem 13.18.4) and perfectness of the cyclic/Koszul pairing on the Koszul locus, which identify the normal complex of one side with the shifted dual tangent complex of the other. A cyclic minimal-model transfer upgrades the tangent complex to a (-1) -shifted symplectic formal moduli problem. Part (v) is the compatibility already proved between the BV and Verdier pictures.

Definition 14.10.6 (Complementarity potential: cotangent normal form). The shifted cotangent normal form (formal Darboux lemma for (-1) -shifted symplectic stacks) identifies $\mathcal{M}_{\text{comp}}(\mathcal{A})$ with $T^*[-1]\mathcal{M}_{\mathcal{A}}$ near the base point. Under this identification, $\mathcal{M}_{\mathcal{A}^\dagger}$ is the graph of a closed 1-form $\alpha_{\mathcal{A}} = dS_{\mathcal{A}}$ for a formal function

$$S_{\mathcal{A}} \in \widehat{\mathcal{O}}(\mathcal{M}_{\mathcal{A}})^0,$$

the *complementarity potential* of the Koszul pair $(\mathcal{A}, \mathcal{A}^\dagger)$.

Conjecture 14.10.7 (Derived critical locus;). There is a canonical equivalence

$$\mathcal{M}_{\mathcal{A}} \times_{\mathcal{M}_{\text{comp}}(\mathcal{A})}^h \mathcal{M}_{\mathcal{A}^\dagger} \simeq \text{Crit}(S_{\mathcal{A}}).$$

The simultaneous deformations of $\mathcal{A}$ and $\mathcal{A}^\dagger$ that preserve complementarity are governed by the derived critical locus of the complementarity potential.

Remark 14.10.8 (Evidence). The hypotheses of Definition 13.19.6 provide (conditional on the perfectness and nondegeneracy of the cyclic/Koszul pairing) a (-1) -shifted symplectic structure on $\mathcal{M}_{\text{comp}}(\mathcal{A})$ and a formal Darboux identification $\mathcal{M}_{\text{comp}}(\mathcal{A}) \simeq T^*[-1]\mathcal{M}_{\mathcal{A}}$ near the base point. Under this identification, $\mathcal{M}_{\mathcal{A}}$ is the zero section and $\mathcal{M}_{\mathcal{A}^\dagger}$ is the graph of the closed 1-form $dS_{\mathcal{A}}$. The derived fiber product of the zero section Z and the graph Γ_{dS} of a closed 1-form on a smooth formal scheme Y over $T^*[-1]Y$ is

$$Z \times_{T^*[-1]Y}^h \Gamma_{dS} \simeq \text{Spec}(\text{Sym}(\Omega_Y[1]), dS) = \text{Crit}(S),$$

the derived critical locus of S (the Koszul complex of dS , cf. [340, Proposition 2.1]). Applying this to $Y = \mathcal{M}_{\mathcal{A}}$ and $S = S_{\mathcal{A}}$ yields the stated equivalence.

Conjecture 14.10.9 (Formal Legendre duality;). By symmetry there is also a complementarity potential $S_{\mathcal{A}^\dagger}$ on $\mathcal{M}_{\mathcal{A}^\dagger}$. The two potentials $S_{\mathcal{A}}$ and $S_{\mathcal{A}^\dagger}$ are formal Legendre transforms of one another: both generate the same Lagrangian subspace inside the same shifted symplectic ambient moduli problem, viewed from the two opposite cotangent charts.

Evidence. The shifted cotangent normal form may be applied with either $\mathcal{M}_{\mathcal{A}}$ or $\mathcal{M}_{\mathcal{A}^\dagger}$ as the zero section. The change from one cotangent chart to the other is the formal Legendre transform.

Remark 14.10.10 (Fake complementarity criterion). The complementarity potential $S_{\mathcal{A}}$ detects genuine complementarity: $S_{\mathcal{A}}$ is quadratic if and only if the dual Lagrangian $\mathcal{M}_{\mathcal{A}^\dagger}$ is linear in formal Darboux coordinates, which holds if and only if the derived critical locus $\text{Crit}(S_{\mathcal{A}})$ is governed entirely by its Hessian complex. The cubic and higher Taylor coefficients of $S_{\mathcal{A}}$ are the first obstructions to fake complementarity, the regime where an eigenspace splitting mimics Lagrangian geometry without being one. The Hessian $\text{Hess}_0(S_{\mathcal{A}})$ is exactly the linear complementarity isomorphism $T_0\mathcal{M}_{\mathcal{A}} \xrightarrow{\sim} T_0\mathcal{M}_{\mathcal{A}^\dagger}^\vee[-1]$.

Remark 14.10.11 (Modular extension and the true invariant). Once the universal Maurer–Cartan class $\Theta_{\mathcal{A}}$ is constructed and shown to satisfy clutching and Verdier compatibilities, the closed 1-forms $dS_{\mathcal{A}}$ inherit the same compatibilities. After choosing pointed primitives, the complementarity potentials globalize over the modular operad; their scalar trace recovers the established tower $\kappa(\mathcal{A}) \cdot \lambda_g$ (uniform-weight). The true invariant is not the additive decomposition $\mathcal{Q}_g(\mathcal{A}) \oplus \mathcal{Q}_g(\mathcal{A}^\dagger)$ but the formal generating function $S_{\mathcal{A}}$. Its Hessian is the linear complementarity (already proved). Its cubic term is the first place where genuine complementarity departs from a fake linear splitting. A natural target: compute the cubic term of $S_{\mathcal{A}}$ for Heisenberg, $\widehat{\mathfrak{sl}}_2$, and $\beta\gamma$.

Remark 14.10.12 (Nonlinear shadow calculus). The first nonlinear jets of $S_{\mathcal{A}}$ are developed systematically in Chapter 18, where the quartic shadow cocycle $\Theta_{\mathcal{A}}^{\leq 4} = H_{\mathcal{A}} + \mathfrak{C}_{\mathcal{A}} + \mathfrak{Q}_{\mathcal{A}}$ is constructed, its master and clutching equations are proved, and the three frame families are shown to realize the Gaussian, Lie/tree, and contact/quartic archetypes respectively. The modular quartic resonance class $\mathfrak{R}_{4,g,n}^{\text{mod}}(\mathcal{A})$ constructed there is the first Picard-valued nonlinear characteristic of the theory.

Remark 14.10.13 (Branch-line reductions). Appendix 19 extracts exact finite-dimensional quotients of the full modular deformation problem: the scalar Maurer–Cartan skeleton, the spectral cumulant hierarchy, and rank-two branch-line reductions. On every one-line branch quotient with scalar square, genus-2 is transparent and the first primitive traceless coefficient begins in genus 3 with the universal constant 7 on the shared $\widehat{\mathfrak{sl}}_2/\text{Virasoro}/\beta\gamma$ spectral sheet.

Remark 14.10.14 (The categorical logarithm and its Taylor jets). The ambient complementarity section, together with the two preceding pointer remarks, articulates a single hierarchy rooted in the categorical logarithm paradigm (Remark 1.9.1). The complementarity potential $S_{\mathcal{A}}$ is the connected generating function of the categorical logarithm applied to the Koszul pair $(\mathcal{A}, \mathcal{A}^!)$. Its Taylor jets have precise identities:

- the Hessian $H_{\mathcal{A}}$ is the quadratic term, the proved linear complementarity of Theorem C;
- the cubic coefficient $\mathfrak{C}_{\mathcal{A}}$ is the first connected cumulant, the first obstruction to fake complementarity, whose cohomology class $[\mathfrak{C}_{\mathcal{A}}]$ is a canonical modular invariant;
- the quartic resonance class $\mathfrak{R}_{4,g,n}^{\text{mod}}(\mathcal{A})$ is the first Picard-valued nonlinear characteristic, with clutching correction governed by the cubic tree divisor.

The branch-line reductions (Appendix 19) are the spectral cumulants of the logarithm restricted to one-dimensional sub-problems: the universal genus-3 constant 7 is the first primitive traceless cumulant on the shared $\widehat{\mathfrak{sl}}_2/\text{Virasoro}/\beta\gamma$ spectral sheet. The canonical homotopy degree of the subregular hook family is the canonical Taylor degree of the logarithm in the non-principal $\mathcal{W}$ -algebra sector: it measures how many Taylor jets are needed before the duality structure stabilizes.

14.II THE FACTORIZATION ENVELOPE SHADOW FUNCTOR

A Lie conformal algebra R over a smooth curve X determines, via the factorization envelope construction (Nishinaka [448, 448]), a vertex algebra $V(R)$, the enveloping vertex algebra of R . The Maurer–Cartan shadow obstruction tower of $V(R)$ (Definition 13.22.49) is an invariant of the vertex algebra; the content of the following proposition is that this invariant is *already determined at the level of the Lie conformal input* R , without passing through the full vertex algebra.

PROPOSITION 14.II.1 (*Factorization envelope shadow functor*;). Let R be a cyclically admissible Lie conformal algebra (Definition 13.22.341), and let $V(R)$ denote its factorization envelope.

- (i) (Modular characteristic from λ -bracket.) The modular characteristic $\kappa(V(R))$ is determined by the degree-2 part of the bar complex of $V(R)$, which depends only on the self-pairing data of R :

$$\kappa(V(R)) = \kappa_R,$$

where κ_R is determined by the λ -bracket $[-_{\lambda} -]$ and the invariant bilinear form of R . Explicitly:

Lie conformal R	Envelope $V(R)$	κ_R
Free Lie $\{x_h\}$ at level k , $h = 1$	Heisenberg $\mathfrak{H}_k$	k
Cur($\mathfrak{g}$) at level k	$V_k(\mathfrak{g})$	$\dim(\mathfrak{g}) (k + h^\vee)/(2h^\vee)$
Virasoro LCA at c	Vir $_c$	$c/2$

(ii) (Shadow depth from Lie conformal structure.) The shadow depth class (Definition 13.22.121) of $V(R)$ is determined by the structural complexity of the λ -bracket of R :

- Class G ($r_{\max} = 2$): R abelian ($[a_\lambda b] = k(a, b)\lambda$ for some pairing). Envelope = free field.
- Class L ($r_{\max} = 3$): $R = \text{Cur}(\mathfrak{g})$ for a simple Lie algebra $\mathfrak{g}$ (the Lie bracket of $\mathfrak{g}$ generates cubic shadows via tree-level graphs).
- Class C ($r_{\max} = 4$): R has a generator of weight ≥ 2 with nonzero quartic contact invariant but no higher forced shadows ($\beta\gamma$ system).
- Class M ($r_{\max} = \infty$): $V(R)$ has a higher-pole OPE (pole order ≥ 4 in the self-OPE of a generator), forcing an infinite shadow obstruction tower. Virasoro and $\mathcal{W}_N$ for $N \geq 2$.

(iii) (Functoriality.) The assignment $R \mapsto (\kappa_R, \text{shadow class})$ is *functorial*: a morphism $f: R_1 \rightarrow R_2$ of Lie conformal algebras induces a compatible map on shadow data. In particular:

- For a subalgebra inclusion $\text{Cur}(\mathfrak{h}) \hookrightarrow \text{Cur}(\mathfrak{g})$ at the same level k , the shadow map sends $\kappa_{\mathfrak{h}}$ to $\kappa_{\mathfrak{g}}$.
- For the Drinfeld–Sokolov reduction $\text{Cur}(\mathfrak{g}) \twoheadrightarrow R_f$ (with R_f the $\mathcal{W}$ -algebra Lie conformal data), the shadow map sends $\kappa(\widehat{\mathfrak{g}}_k)$ to $\kappa(\mathcal{W}_k(\mathfrak{g}, f)) = \rho(\mathfrak{g}) c_{\mathcal{W}}$, where $\rho(\mathfrak{g}) = H_N - 1$ is the anomaly ratio for type A_N .

Proof. **Part (i).** The modular characteristic $\kappa(V(R))$ is defined as the degree-2 scalar projection of the Maurer–Cartan element $\Theta_{V(R)}$ in the modular convolution algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ (Definition 13.22.1). At degree 2, the bar complex $B(V(R))_2$ involves exactly the binary OPE of $V(R)$, which is determined by the λ -bracket of R together with the symmetric invariant form. The factorization envelope construction (Nishinaka [448]) builds $V(R)$ as the universal vertex algebra generated by R with OPE given by the λ -bracket. No higher-degree vertex algebra data enters the degree-2 bar component.

The explicit values follow from the modular characteristic computations proved in the body of the monograph. For the current algebra $\text{Cur}(\mathfrak{g})$ at level k , the weight-1 space is $\mathfrak{g}$ with the Sugawara correction, giving $\kappa = \dim(\mathfrak{g})(k + h^\vee)/(2h^\vee)$ (Theorem 13.21.44). For the free Lie conformal algebra on one weight-1 generator at level k (Heisenberg at level k): $\kappa = k$ (Chapter E). For Virasoro: the weight-1 space is empty, and the anomaly $\kappa = c/2$ comes from the weight-2 generator via the d log pole-order reduction (the bar propagator has weight 1; Remark 13.13.21).

Part (ii). The shadow depth of $V(R)$ is determined by the vanishing pattern $\{S_r(V(R))\}_{r \geq 2}$ (Definition 13.22.121). For an abelian R (class G): the λ -bracket has no Lie component, so the OPE of $V(R)$ is purely bilinear. The bar complex is formal (A_∞ operations $m_r = 0$ for $r \geq 3$ on bar cohomology), and all shadow invariants S_r for $r \geq 3$ vanish.

For $R = \text{Cur}(\mathfrak{g})$ (class L): the Lie bracket of $\mathfrak{g}$ generates a nonzero cubic shadow S_3 via tree-level degree-3 Feynman graphs. The Jacobi identity of $\mathfrak{g}$ forces the quartic shadow $S_4 = 0$ (the one-loop quartic graph sum vanishes by the Jacobi identity applied to the four-valent vertex), so the tower terminates at degree 3.

For class C ($\beta\gamma$ at weight ≥ 2): the quartic contact invariant $Q^{\text{contact}} \neq 0$ (from the higher-pole structure), but a rank-one rigidity argument (Theorem F.13.12) shows that the self-bracket of the quartic class exits the complex, terminating the tower at degree 4.

For class M (Virasoro, $\mathcal{W}_N$): the self-OPE has poles of order ≥ 4 (for Virasoro: $T_{(3)}T = c/2$), producing nonzero shadow invariants at every degree. The discriminant $\Delta = 8\kappa S_4 \neq 0$ (Theorem 13.22.160), which by the Riccati algebraicity theorem (Theorem 13.22.137) forces the shadow obstruction tower to be infinite.

Part (iii). Functoriality at the level of κ follows from the degree-2 naturality of the bar construction: a morphism $f: R_1 \rightarrow R_2$ induces a morphism $V(f): V(R_1) \rightarrow V(R_2)$ of vertex algebras, hence a morphism $B(V(f)): B(V(R_1)) \rightarrow B(V(R_2))$ of bar complexes. At degree 2, this is the map on self-pairings induced by f , which sends κ_{R_1} to κ_{R_2} .

For part (a): the subalgebra inclusion $\mathfrak{h} \hookrightarrow \mathfrak{g}$ induces $\text{Cur}(\mathfrak{h}) \hookrightarrow \text{Cur}(\mathfrak{g})$ at the same level, and the induced map on envelopes is the inclusion $V_k(\mathfrak{h}) \hookrightarrow V_k(\mathfrak{g})$. The shadow map sends $\kappa(\mathfrak{h}, k)$ to $\kappa(\mathfrak{g}, k)$ by restricting the supertrace from $\mathfrak{g}$ to $\mathfrak{h}$ (the Casimir correction restricts compatibly).

For part (b): the DS reduction at the level of Lie conformal algebras is the BRST quotient $R_f = H_{\text{BRST}}^0(\text{Cur}(\mathfrak{g}), \chi_f)$. The shadow map sends $\kappa(\widehat{\mathfrak{g}}_k) = \dim(\mathfrak{g})(k + h^\vee)/(2h^\vee)$ to the $\mathcal{W}$ -algebra modular characteristic $\kappa(\mathcal{W}_k) = \rho \cdot c_{\mathcal{W}}$, where $\rho = H_N - 1 = \sum_{i=1}^{N-1} 1/(i+1)$ is the anomaly ratio and $c_{\mathcal{W}}$ is the $\mathcal{W}$ -algebra central charge. The compatibility $\kappa(\mathcal{W}_k) = \rho \cdot c_{\mathcal{W}}$ is verified by explicit computation for $\mathfrak{sl}_2$ ($\rho = 1/2, c_{\mathcal{W}} = c_{\text{Vir}}, \kappa = c/2$) and $\mathfrak{sl}_3$ ($\rho = 5/6$, verified in the compute module `factorization_envelope_shadow.py`). $\square$

14.12 THE GRAPH COMPLEX AND DEFORMATION THEORY OF THE SHADOW OBSTRUCTION TOWER

The shadow obstruction tower of a modular Koszul algebra encodes the finite-order projections of the universal Maurer–Cartan element $\Theta_{\mathcal{A}}$. The *deformations* of the shadow obstruction tower (the infinitesimal variations of the shadow invariants $(S_r)_{r \geq 2}$ as the algebra $\mathcal{A}$ varies) are controlled by the Kontsevich graph complex. This is a consequence of two theorems: (1) the shadow invariants map to specific cocycle components in the graph complex GC_2 via the Kontsevich formality quasi-isomorphism, and (2) the cohomology $H^0(\text{GC}_2)$ is isomorphic to the Grothendieck–Teichmüller Lie algebra grt_1 (Willwacher [444]).

Conjecture 14.12.1 (Graph complex controls shadow obstruction tower deformations;). Let GC_n denote the Kontsevich graph complex, whose chain groups are spanned by isomorphism classes of connected graphs with all vertex valences ≥ 3 and whose differential is edge contraction. The cohomological degree of a graph Γ is $|\Gamma| = |E(\Gamma)| - 2|V(\Gamma)|$.

(i) (Shadow-to-graph-complex map.) There exists a Lie algebra map

$$\Phi: \mathfrak{g}_{\mathcal{A}}^{\text{mod}} \longrightarrow \text{GC}_2$$

from the modular convolution algebra to the graph complex, induced by the Kontsevich formality quasi-isomorphism $\mathcal{U}: T_{\text{poly}} \xrightarrow{\sim} D_{\text{poly}}$ applied to the E_2 structure on the bar complex. Under Φ , the odd-degree shadow invariants $S_{2k+1}(\mathcal{A})$ for $k \geq 1$ map to the wheel cocycles $\sigma_{2k+1} \in H^*(\text{GC}_2)$:

$$\Phi(S_{2k+1}(\mathcal{A})) = a_{2k+1}(\mathcal{A}) \cdot [\sigma_{2k+1}],$$

where $a_{2k+1}(\mathcal{A}) \in \mathbb{C}$ is a scalar coefficient depending on the algebra $\mathcal{A}$, and σ_{2k+1} is represented by the wheel graph W_{2k+1} ($2k+1$ spokes, $2k+2$ vertices, $2(2k+1)$ edges, loop order $2k+1$). The even-degree shadows $S_{2k}(\mathcal{A})$ map to exact forms in GC_2 (boundaries, not cocycles).

- (ii) (Willwacher’s theorem and $\mathbf{grt}_1$.) By Willwacher [444], there is an isomorphism of graded Lie algebras

$$H^0(\mathrm{GC}_2) \cong \mathbf{grt}_1,$$

where $\mathbf{grt}_1$ is the Grothendieck–Teichmüller Lie algebra. The generators of $\mathbf{grt}_1$ are the Deligne–Drinfeld elements σ_{2k+1} for $k \geq 1$, each corresponding to the odd zeta value $\zeta(2k+1)$. The known dimensions of $\mathbf{grt}_1$ at each weight (Ihara, Schneps, Brown) are:

weight	3	4	5	6	7	8	9	10	11	12	13	14
dim	1	0	1	0	1	1	1	1	2	2	3	3

At even weights, all elements arise from Lie brackets: $[\sigma_3, \sigma_5]$ at weight 8, $[\sigma_3, \sigma_7]$ at weight 10. At weight 12, the two brackets $[\sigma_3, \sigma_9]$ and $[\sigma_5, \sigma_7]$ satisfy an Ihara relation, leaving one independent bracket; the cusp form $\Delta_{12} \in S_{12}(\mathrm{SL}_2(\mathbb{Z}))$ contributes a second generator at depth 2, giving $\dim \mathbf{grt}_1(12) = 2$. The first odd weight with depth-3 contributions is weight 11: $\dim \mathbf{grt}_1(11) = 2$ (σ_{11} at depth 1 and $[\sigma_3, [\sigma_3, \sigma_5]]$ at depth 3).

- (iii) (Depth classification via truncation.) The shadow depth classification (Definition 13.22.121) corresponds to the truncation level in $\mathbf{grt}_1$:

Class	$r_{\max}$	$\mathbf{grt}_1$ components	Families
G	2	none	Heisenberg, lattice
L	3	σ_3 only	affine Kac–Moody
C	4	σ_3 only	$\beta\gamma$
M	∞	all σ_{2k+1}	Virasoro, $\mathcal{W}_N$

The GC_2 components of an algebra of depth d are supported on wheel cocycles σ_{2k+1} arising from odd-degree shadow invariants S_{2k+1} with $2k+1 \leq d$. For class G ($d = 2$), no wheel cocycle component is activated. For class L ($d = 3$) and class C ($d = 4$), only σ_3 is activated (the even-degree shadow S_4 maps to a boundary, not a cocycle). For class M, all wheel cocycles σ_{2k+1} are nonzero.

- (iv) (Deformation control.) The space of infinitesimal deformations of the shadow obstruction tower of $\mathcal{A}$ (varying the algebra $\mathcal{A}$ within the moduli of modular Koszul algebras) is controlled by $\mathbf{grt}_1$ via the map Φ : a deformation of $\mathcal{A}$ that changes $S_{2k+1}(\mathcal{A})$ activates the corresponding σ_{2k+1} component in $\mathbf{grt}_1$. The $\mathbf{grt}_1$ relations (e.g., the Ihara relation at weight 12) impose constraints on which shadow obstruction towers can arise from actual algebras: not every sequence $(a_3, a_5, a_7, \dots)$ is realizable.

Remark 14.12.2 (Evidence). **Part (i).** The Kontsevich formality theorem [275, 273] provides an L_∞ quasi-isomorphism $\mathcal{U}: T_{\mathrm{poly}}(\mathbb{R}^d) \rightarrow D_{\mathrm{poly}}(\mathbb{R}^d)$ from polyvector fields to polydifferential operators, constructed as a sum over graphs Γ in a variant of the graph complex with weights given by configuration-space integrals. At $d = 2$, this is the formality of the E_2 operad (Kontsevich–Tamarkin). The bar complex $B(\mathcal{A})$ carries an E_2 structure (Proposition A.16.1(i)), and the modular convolution algebra $\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}}$ is built from the

bar complex. The formality map $\mathcal{U}$ induces a Lie algebra map from the Maurer–Cartan moduli of $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ to the Maurer–Cartan moduli of the graph complex.

The image of the shadow invariant $S_r(\mathcal{A})$ under Φ is computed as follows. At odd degree $r = 2k + 1$: the shadow S_{2k+1} is a degree- $(2k + 1)$ scalar in $\text{Def}_{\text{cyc}}^{\text{mod}}(\mathcal{A})$ (Definition 14.5.12). The formality map evaluates this scalar on the Kontsevich graph weights, which at loop order $2k + 1$ are dominated by the wheel graph W_{2k+1} . The wheel graph W_{2k+1} is a cocycle in GC_2 for odd $2k + 1$ (and not a cocycle for even values): the differential $d(W_{2k+1}) = \sum_e \pm W_{2k+1}/e$ vanishes because the dihedral $\mathbb{Z}_2$ symmetry of W_{2k+1} pairs the edge-contraction terms with opposite signs when $2k + 1$ is odd. The coefficient $a_{2k+1}(\mathcal{A})$ is the shadow coefficient $S_{2k+1}(\mathcal{A})$ itself, evaluated through the formality integral.

At even degree $r = 2k$: the wheel graph W_{2k} is *not* a cocycle (the dihedral cancellation fails for even spoke count), so the image $\Phi(S_{2k})$ is a coboundary in GC_2 . It carries information at the chain level but vanishes in cohomology.

Part (ii). This is Willwacher’s theorem [444], which we do not reprove. The key inputs are: (a) the identification of $H^0(\text{GC}_2)$ with the Lie algebra of homotopy automorphisms of the E_2 operad, (b) the identification of this automorphism group with the prounipotent Grothendieck–Teichmüller group GRT_1 (Drinfeld [137]), and (c) the explicit construction of the wheel cocycles σ_{2k+1} as generators. The dimension table is confirmed by the computations of Ihara, Schneps, and Brown, with the weight-11 relation verified by direct graph-complex computation (see the compute module `kontsevich_graph_complex.py` for explicit enumeration up to loop order 5).

Part (iii). The correspondence between shadow depth and `grt1` truncation follows directly from parts (i) and (ii). An algebra of class G has $S_r = 0$ for all $r \geq 3$, so no wheel cocycle component is activated. An algebra of class L has $S_3 \neq 0$ but $S_r = 0$ for $r \geq 4$; the only activated component is σ_3 (weight 3). Class C activates σ_3 only: the shadow obstruction tower terminates at degree 4, and the even-degree shadow S_4 maps to a boundary in GC_2 (not a cocycle), so no additional cocycle component beyond σ_3 is activated. Class M algebras (Virasoro, $\mathcal{W}_N$) have $S_r \neq 0$ for all r (by the infinite shadow obstruction tower, Theorem 13.22.137), so all wheel cocycles σ_{2k+1} are activated.

The numerical verification: for Virasoro at central charge c , the shadow coefficients are computed recursively (Theorem 13.22.137) with seeds $S_2 = c/2$, $S_3 = 2$, $S_4 = 10/(c(5c + 22))$, and the higher S_r are nonzero rational functions of c for all $r \geq 5$. At odd degrees, the nonvanishing of $S_{2k+1}(c)$ for generic c is verified symbolically in the compute module `kontsevich_graph_complex.py` (function `virasoro_shadow_exact`).

Part (iv). A one-parameter family $\mathcal{A}_t$ of modular Koszul algebras determines a path $t \mapsto \Theta_{\mathcal{A}_t}$ in the Maurer–Cartan moduli of $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$. Under Φ , the tangent vector Θ maps to a tangent vector in the GC_2 Maurer–Cartan moduli, which at the cohomological level is an element of `grt1`. The projection to the σ_{2k+1} component is $\dot{a}_{2k+1} = (d/dt)S_{2k+1}(\mathcal{A}_t)$. The `grt1` relations impose constraints: the Ihara relation at weight 12 gives a linear dependence among the brackets $[\sigma_3, \sigma_9]$ and $[\sigma_5, \sigma_7]$, constraining the deformation of S_3S_9 and S_5S_7 jointly. For a path lying entirely within the standard families, the shadow coefficients $S_r(c)$ are determined by a single parameter c , so the tangent vector is one-dimensional and the `grt1` relations are automatically satisfied. The constraint becomes nontrivial for multi-parameter deformations (e.g., deforming both the central charge and the $\mathcal{W}$ -algebra structure simultaneously), where the realizability of a given shadow sequence is constrained by the `grt1` structure.

Remark 14.12.3 (Normalized shadow zeta values). The *normalized shadow zeta values* of an algebra $\mathcal{A}$ of class M are the dimensionless ratios

$$\zeta_r^{\text{sh}}(\mathcal{A}) = \frac{S_r(\mathcal{A})}{|\kappa(\mathcal{A})|^{r/2}}.$$

For the Virasoro algebra at central charge c , these are rational functions of c (computed exactly in `kontsevich_graph_complex.py`, function `shadow_zeta_exact`). The terminology “shadow zeta values” reflects the correspondence $\sigma_{2k+1} \leftrightarrow \zeta(2k+1)$ in `grt1`: the shadow coefficient $S_{2k+1}(\mathcal{A})$ maps to the generator σ_{2k+1} that corresponds to the odd zeta value $\zeta(2k+1)$. The shadow zeta values are *rational* (they are algebraic invariants of the vertex algebra), not transcendental; the connection to the actual zeta values $\zeta(2k+1) \in \mathbb{R}$ is through the graph weights in the Kontsevich integral, which are periods (integrals of algebraic forms over semi-algebraic sets) that evaluate to multiple zeta values.

Chapter 15

Chiral modules and geometric resolutions

The bar complex of a chiral algebra $\mathcal{A}$ on a curve X is built from configuration spaces of unmarked points; each point carries a copy of $\mathcal{A}$. A module $\mathcal{M}$ introduces a distinguished point carrying different data: the module structure. The module bar complex $\overline{B}_{\mathcal{A}}(\mathcal{M})$ is then defined on the pointed configuration space $\overline{C}_{n,1}(X)$, where the first point carries $\mathcal{M}$ and the remaining n points carry $\mathcal{A}$. This complex is a comodule over the bar coalgebra $\overline{B}(\mathcal{A})$, and it computes spaces of conformal blocks, BGG resolutions, and character formulas from configuration-space geometry.

Three results organize the chapter. First, on the quadratic genus-0 E_1 complete/conilpotent lane, the module bar construction implements a complete/conilpotent comparison (Theorem 11.6.2): complete $\mathcal{A}$ -modules correspond to conilpotent $\overline{B}(\mathcal{A})$ -comodules, and derived Ext groups are computed on the bar-comodule side. Outside this lane, the intrinsic bar-coalgebra/comodule formulation is the correct object; a stronger module-category equivalence requires additional hypotheses beyond Theorem B. Second, the module-level Verdier intertwining (Theorem 15.1.22) exchanges module bar complexes of a Koszul pair $(\mathcal{A}, \mathcal{A}^!)$, yielding conformal block identities and dimension invariance under level shifting. Third, the Drinfeld–Sokolov reduction functor commutes with the bar construction (Theorem 15.10.1), so that $\mathcal{W}$ -algebra module resolutions are obtained by BRST reduction of affine Kac–Moody bar complexes.

15.1 FACTORIZATION MODULES: DEFINITIONS AND CATEGORIES

A module over a factorization algebra is itself a factorization algebra on a pointed space: the marked point carries the module data, the remaining points carry algebra data (Voronov [391], Costello–Gwilliam [92], Ayala–Francis [30]). The bar complex $\overline{B}(\mathcal{A}, \mathcal{M})$ lives on such pointed configuration spaces, and its Verdier dual is a comodule over $\overline{B}(\mathcal{A})$. On the proved quadratic genus-0 E_1 surface, this leads to the complete/conilpotent module comparison of Theorem 11.6.2. More generally, the module bar construction provides the intrinsic coalgebra-side object, while broader representation-category equivalences require additional hypotheses and are treated only on the specific lanes where they are established.

Definition 15.1.1 (Factorization module). Let $\mathcal{F}$ be a factorization algebra on a manifold M with values in a symmetric monoidal ∞ -category $\mathcal{V}$, and let $x \in M$ be a point. A *factorization module* over $\mathcal{F}$ supported at x is a rule $\mathcal{M}$ that assigns:

1. To each open disk $D \ni x$: an object $\mathcal{M}(D) \in \mathcal{V}$.

2. To each finite collection of pairwise disjoint opens $U_1, \dots, U_n \subset D$ with $U_i \cap \{x\} = \emptyset$ for all i and $x \in D$: an *action map*

$$\alpha_{U_1, \dots, U_n}^D : \mathcal{F}(U_1) \otimes \cdots \otimes \mathcal{F}(U_n) \otimes \mathcal{M}(D) \longrightarrow \mathcal{M}(D),$$

compatible with the factorization structure of $\mathcal{F}$ on $M \setminus \{x\}$.

These data satisfy associativity and unit axioms parallel to (FA2)–(FA5) of Definition 3.10.3, with $\mathcal{M}$ replacing $\mathcal{F}$ at the marked point x .

Remark 15.1.2 (The Swiss-cheese picture). When $M = \mathbb{R}^n$ and $x = 0$, the collection of disks around the origin with disjoint smaller disks away from the origin defines the *Swiss-cheese operad* SC_n of Voronov [391]. Algebras over SC_n are pairs (A, M) where A is an E_n -algebra and M is an A -module in an appropriate homotopical sense. Definition 15.1.1 globalizes this to arbitrary manifolds.

Definition 15.1.3 (Chiral module). Let $\mathcal{A}$ be a chiral algebra (= E_∞ -chiral algebra, Definition 3.11.1) on a smooth curve X . A *chiral $\mathcal{A}$ -module* supported at $x \in X$ is a $\mathcal{D}_X$ -module $\mathcal{M}$ together with a chiral action map

$$\alpha : j_* j^*(\mathcal{A} \boxtimes \mathcal{M}) \longrightarrow \Delta_! \mathcal{M}$$

(where $j : X^2 \setminus \Delta \hookrightarrow X^2$ is the complement of the diagonal) satisfying:

(i) *Associativity*: the two compositions $\mathcal{A} \boxtimes \mathcal{A} \boxtimes \mathcal{M} \rightrightarrows \Delta_!^{(3)} \mathcal{M}$ agree;

(ii) *Unit*: the composition $\omega_X \boxtimes \mathcal{M} \xrightarrow{\eta \boxtimes \text{id}} \mathcal{A} \boxtimes \mathcal{M} \xrightarrow{\alpha} \Delta_! \mathcal{M}$ equals the canonical map.

This is the $\mathcal{D}$ -module counterpart of a module over a vertex algebra [40, §3.6].

Definition 15.1.4 (E_1 -chiral module). Let $\mathcal{A}$ be an E_1 -chiral algebra (Definition 3.11.3) on X . An E_1 -chiral $\mathcal{A}$ -module is a $\mathcal{D}_X$ -module $\mathcal{M}$ equipped with a chiral action

$$\alpha : j_* j^*(\mathcal{A} \boxtimes \mathcal{M}) \longrightarrow \Delta_! \mathcal{M}$$

satisfying associativity and unitality as in Definition 15.1.3, but indexed by *ordered* configurations: the action of n copies of $\mathcal{A}$ on $\mathcal{M}$ is parameterized by the ordered configuration space $\bar{C}_{n,1}(X) := \{(z_1, \dots, z_n; w) \in X^{n+1} \mid z_i \neq z_j, z_i \neq w\}$ with no Σ_n -equivariance imposed.

In vertex algebra language, $\mathcal{M}$ is a module over a nonlocal vertex algebra: it carries a state-field map $Y_{\mathcal{M}} : \mathcal{A} \rightarrow \text{End}(\mathcal{M})[[z, z^{-1}]]$ satisfying weak associativity (the module Borchers identity) but not the commutativity condition $Y_{\mathcal{M}}(a, z)Y_{\mathcal{M}}(b, w) \sim Y_{\mathcal{M}}(b, w)Y_{\mathcal{M}}(a, z)$.

Definition 15.1.5 (Module categories). For a chiral algebra $\mathcal{A}$ on X , we define the following categories of modules. These are distinct from the open-sector factorization dg-category $\mathcal{C}_{\text{op}}$ of the open/closed package (Theorem A.17.10, §A.17), which is the primitive object on the open side; the symmetric and ordered module categories below are coupling categories naturally acted upon by the chiral algebra and play a different structural role.

- (i) $\text{Mod}_{\mathcal{A}}$: the dg category of chiral $\mathcal{A}$ -modules (Definition 15.1.3), with morphisms the $\mathcal{D}_X$ -module maps compatible with the chiral action. This is the *symmetric* (i.e. Σ_n -equivariant) module category, indexed by unordered configuration spaces, and is a stable ∞ -category when $\mathcal{V} = \text{Ch}(\mathbb{C})$.

- (ii) $\text{Mod}_{\mathcal{A}}^{\mathbf{E}_1}$: the dg category of $\mathbf{E}_1$ -chiral $\mathcal{A}$ -modules (Definition 15.1.4), when $\mathcal{A}$ is $\mathbf{E}_1$ -chiral. This is the *line-operator* module category, indexed by ordered configuration spaces with no Σ_n -equivariance, and carries the braid group action underlying the Drinfeld–Kohno theorem. There is a forgetful functor $\text{Mod}_{\mathcal{A}} \rightarrow \text{Mod}_{\mathcal{A}}^{\mathbf{E}_1}$ when $\mathcal{A}$ is $\mathbf{E}_{\infty}$ -chiral; this functor is generally NOT an equivalence, reflecting the genuine difference between symmetric and ordered factorization data.
- (iii) $D(\text{Mod}_{\mathcal{A}})$: the derived category, obtained by inverting quasi-isomorphisms. We assume throughout that $\text{Mod}_{\mathcal{A}}$ is *compactly generated*: i.e., it is generated under filtered colimits by the compact objects $\text{Mod}_{\mathcal{A}}^c$. This holds whenever $\mathcal{A}$ is finitely generated as a chiral algebra (the free modules $\text{Free}_{\mathcal{A}}(V)$ for finite-dimensional V are compact generators).

Remark 15.1.6 (Tensor structure on module categories). For a rational vertex algebra V , the module category Mod_V carries a braided tensor structure via the fusion product (Huang–Lepowsky–Zhang [227]), with braiding from the monodromy of conformal blocks on $\mathbb{P}^1$. For $\widehat{\mathfrak{g}}_k$ at positive integer level, this is identified with the quantum group tensor product on $C(U_q(\mathfrak{g}))$ via the KL equivalence (Theorem G.11.6).

PROPOSITION 15.1.7 (*Fusion product of Heisenberg Fock modules*;). The fusion product of Fock modules over the Heisenberg algebra $\mathcal{H}_k$ is:

$$F_{\lambda} \boxtimes_{\mathcal{H}_k} F_{\mu} \cong F_{\lambda+\mu}.$$

The braiding isomorphism $\sigma : F_{\lambda} \boxtimes F_{\mu} \xrightarrow{\sim} F_{\mu} \boxtimes F_{\lambda}$ is multiplication by $e^{2\pi i \lambda \mu / k}$ (the monodromy of the intertwining operator around $z = 0$).

Proof. The intertwining operator $\mathcal{Y} : F_{\lambda} \otimes F_{\mu} \rightarrow F_{\lambda+\mu}((z))$ is given by

$$\mathcal{Y}(|\lambda\rangle, z) = z^{\lambda \mu / k} \exp\left(\lambda \sum_{n>0} \frac{J_{-n}}{n} z^n\right) \exp\left(-\lambda \sum_{n>0} \frac{J_n}{n} z^{-n}\right),$$

where $|\lambda\rangle$ is the highest weight vector of F_{λ} (Definition E.3.18). The fusion product is the image of $\mathcal{Y}$ under analytic continuation (in the sense of [227]), which is isomorphic to $F_{\lambda+\mu}$: the charge is additive ($J_0(|\lambda\rangle \boxtimes |\mu\rangle) = (\lambda + \mu)(|\lambda\rangle \boxtimes |\mu\rangle)$) and the Fock space structure is generated by J_{-n} for $n \geq 1$.

The braiding comes from the monodromy of the factor $z^{\lambda \mu / k}$: analytically continuing $z \mapsto e^{2\pi i} z$ gives the phase $e^{2\pi i \lambda \mu / k}$. Since $\mathcal{H}_k$ is abelian, this determines the braiding completely.

In the bar-cobar framework, the fusion product is realized on the configuration space $C_2(X)$: two Fock modules at points z_1, z_2 are fused by integrating the intertwining operator over a small circle $|z_1 - z_2| = \varepsilon$ and taking $\varepsilon \rightarrow 0$. The charge additivity follows from the residue calculus on the boundary stratum $D_{12} = \{z_1 = z_2\} \subset \overline{C}_2(X)$. $\square$

Remark 15.1.8 (Fusion under Koszul duality). Under the module Koszul duality of Corollary E.3.15, $F_{\lambda}^! \boxtimes_{\mathcal{H}^!} F_{\mu}^! \cong F_{\lambda+\mu}^!$: the fusion product is preserved. The braiding phase $e^{2\pi i \lambda \mu / k}$ transforms to $e^{-2\pi i \lambda \mu / k}$ (the sign change reflects the curvature reversal $\kappa \mapsto -\kappa$ on the Koszul dual side). This reflects the general principle that Koszul duality exchanges a braided tensor category with its reverse braiding.

Definition 15.1.9 (*Module Koszul duality functor*). For a Koszul dual pair $(\mathcal{A}, \mathcal{A}^!)$, the *module Koszul duality functor* $\Phi : \text{Mod}_{\mathcal{A}}^{\text{compl}} \rightarrow \text{CoMod}_{\mathcal{B}(\mathcal{A})}^{\text{conil}}$ is:

On objects. For an $\mathcal{A}$ -module $\mathcal{M}$, the module bar complex $\Phi(\mathcal{M}) := \bar{B}(\mathcal{A}; \mathcal{M}) = \bigoplus_{n \geq 0} (s^{-1} \bar{\mathcal{A}})^{\otimes n} \otimes \mathcal{M} \otimes \Omega_{\log}^n(\bar{C}_{n,1}(X))$ with the module bar differential $d = d_{\text{alg-alg}} + d_{\text{alg-mod}}$ (residues at algebra–algebra and algebra–module collisions). The coalgebra $\bar{B}(\mathcal{A})$ coacts on $\Phi(\mathcal{M})$ via the deconcatenation coproduct on the algebra tensor factors.

On morphisms. For $f: \mathcal{M} \rightarrow \mathcal{N}$ an $\mathcal{A}$ -module map, $\Phi(f) = \text{id}_{\bar{B}} \otimes f$: the bar resolution is natural in the module slot, and $\text{id} \otimes f$ is a comodule map because f commutes with the $\mathcal{A}$ -action.

Functoriality. $\Phi(\text{id}) = \text{id}$ and $\Phi(g \circ f) = \Phi(g) \circ \Phi(f)$ by naturality of the tensor product. The functor is exact because the bar resolution is levelwise flat (free $\mathcal{A}$ -modules in each bar degree).

Example. For $\mathcal{A} = \widehat{\mathfrak{g}}_k$ and $\mathcal{M} = V_\Lambda$ (a highest-weight module), the degree-1 term of $\Phi(V_\Lambda)$ is $s^{-1}\bar{\mathfrak{g}}_k \otimes V_\Lambda \otimes \Omega_{\log}^1(\bar{C}_{1,1}(X))$, and the $d_{\text{alg-mod}}$ differential sends $s^{-1}J^a \otimes v \otimes \eta_{z,x}$ to $T_\Lambda^a(v)$, the representation matrix acting on v .

PROPOSITION 15.1.10 (*Module bar-comodule comparison on the quadratic E_1 lane;*). Assume $\mathcal{A}$ lies on the quadratic genus-0 E_1 complete/conilpotent lane of Theorem 11.6.2. Then Φ is the module bar functor implementing the complete/conilpotent comparison

$$\Phi: \text{Mod}_{\mathcal{A}}^{\text{compl}} \xrightarrow{\sim} \text{CoMod}_{\bar{B}(\mathcal{A})}^{\text{conil}}.$$

The quasi-inverse is the cobar functor $\Psi(\mathcal{N}) = \Omega(\bar{B}(\mathcal{A}); \mathcal{N})$. When $\mathcal{A}^\dagger = \bar{B}(\mathcal{A})^\vee$ is finite-type graded, one further obtains $\text{Mod}_{\mathcal{A}}^{\text{compl}} \simeq \text{Mod}_{\mathcal{A}^\dagger}^{\text{compl}}$; without finite-type, the intermediate comodule step is essential (Positselski [350, §4]).

Proof. This is the module-level comparison of Theorem 11.6.2, rewritten in the notation of the present chapter. The module bar functor $\Phi = \bar{B}(\mathcal{A}; -)$ gives the complete module to conilpotent bar-comodule equivalence, the quasi-inverse is the module cobar functor Ψ , and the further rewrite on the graded-dual algebra side is available only when the finite-type identification $\bar{B}(\mathcal{A})^\vee \cong \mathcal{A}^\dagger$ is justified. $\square$

Construction 15.1.11 (*Module categories as MC twisting*). The category of $\mathcal{A}$ -modules admits a convolution-algebraic description:

- (i) An $\mathcal{A}$ -module structure on $\mathcal{M}$ is an MC element in $\text{hom}_\alpha(\bar{B}(\mathcal{A}), \text{End}(\mathcal{M}))$.
- (ii) On any lane where Proposition 15.1.10 applies, the bar-cobar twisting datum exchanges $\mathcal{A}$ -modules with bar-comodules; only after finite-type dualization may one rewrite the target as a category of $\mathcal{A}^\dagger$ -modules.
- (iii) The dg-shifted Yangian $Y_{\mathcal{A}}^{\text{dg}}$ acts on line operators through the genus-0 convolution algebra. On finite-type dualized lanes, its completed module category may be rewritten in terms of modules over the graded dual algebra $\mathcal{A}^\dagger$.

Verification. Part (i): the convolution algebra $\text{hom}_\alpha(\bar{B}(\mathcal{A}), \text{End}(\mathcal{M}))$ carries a dg Lie structure from the bar coproduct and endomorphism composition. An MC element ϕ satisfying $d\phi + \frac{1}{2}[\phi, \phi] = 0$ encodes the A_∞ -module structure maps $m_{n|1}: \mathcal{A}^{\otimes n} \otimes \mathcal{M} \rightarrow \mathcal{M}$, and the MC equation is equivalent to the A_∞ -module relations. Part (ii) follows from Proposition 15.1.10: the bar-cobar twisting morphism $\tau: \bar{B}(\mathcal{A}) \rightarrow \mathcal{A}$ induces Φ by twisting the comodule structure. Part (iii): the dg-shifted Yangian $Y_{\mathcal{A}}^{\text{dg}}$ (Definition O.13.112) is the pronilpotent completion of the genus-0 convolution algebra. On the finite-type dualized lanes singled out by Theorem 11.6.2, its completed module category may be rewritten using the graded dual algebra $\mathcal{A}^\dagger$. $\square$

THEOREM 15.1.12 (*Lax monoidal structure of the module bar functor;*). Let $\mathcal{A}$ lie on a module-theoretic lane where Proposition 15.1.10 applies and suppose the relevant fusion products are defined on the complete module category. Then the module bar functor

$$\Phi: \text{Mod}_{\mathcal{A}}^{\text{compl}} \xrightarrow{\sim} \text{CoMod}_{\bar{B}(\mathcal{A})}^{\text{conil}}$$

is *lax monoidal* with respect to fusion on the module side and cotensor product on the bar-comodule side: there is a natural transformation

$$\mu_{M,N} : \Phi(M \boxtimes_{\mathcal{A}} N) \longrightarrow \Phi(M) \square_{\bar{B}(\mathcal{A})} \Phi(N) \quad (15.1)$$

and $\mu_{M,N}$ is a quasi-isomorphism when M and N are Koszul modules and the required Künneth/Tor-independence hypotheses hold. When $\bar{B}(\mathcal{A})$ is finite-type graded so that $\bar{B}(\mathcal{A})^\vee \cong \mathcal{A}^!$, the induced complete module comparison on the graded-dual side inherits the same lax monoidal structure after dualization.

Proof. Step 1: Construction of $\mu_{M,N}$. The bar construction on the fusion product $M \boxtimes_{\mathcal{A}} N$ is computed on the configuration space $C_n(X)$ with two marked points. By the factorization property of the bar complex (Definition 6.1.15), the summand of $\bar{B}(M \boxtimes N)$ where p points cluster near the first marked point and q points near the second yields $\bar{B}_p(M) \otimes \bar{B}_q(N)$ on $\bar{C}_p(X) \times \bar{C}_q(X)$. The Alexander–Whitney map assembles these summands into the cotensor product $\bar{B}(M) \square_{\bar{B}(\mathcal{A})} \bar{B}(N)$, defining $\mu_{M,N}$.

Step 2: Quasi-isomorphism for Koszul modules. When M is a Koszul module, the bar spectral sequence $E_2^{p,q} = \text{Ext}_{\mathcal{A}}^p(\mathbf{1}, M)$ degenerates. The Künneth theorem on $\bar{C}_p(X) \times \bar{C}_q(X)$ then gives $H^*(\bar{B}(M \boxtimes N)) \cong H^*(\bar{B}(M)) \otimes_{H^*(\bar{B}(\mathcal{A}))} H^*(\bar{B}(N))$ provided the Tor-independence hypothesis holds on the chosen lane. Under that hypothesis, $\mu_{M,N}$ induces an isomorphism on cohomology.

Step 3: Dualized module-side reformulation. If $\bar{B}(\mathcal{A})$ is finite-type graded, then cotensor products of conilpotent comodules dualize to the corresponding completed tensor products on graded-dual modules. The same lax monoidal structure therefore transports to the graded-dual module comparison whenever the identification $\bar{B}(\mathcal{A})^\vee \cong \mathcal{A}^!$ is available. $\square$

Remark 15.1.13 (Braiding reversal is proved on the DK surfaces). The theorem above records only the general lax monoidal bar-comodule compatibility. Braiding reversal is a stronger statement and, on the current proved surface, is established only on the specific affine/Yangian Drinfeld–Kohno comparison lanes where KZ monodromy and Verdier orientation reversal are both identified explicitly (Theorems O.13.5 and O.13.9).

Remark 15.1.14 (Towards chain-level / evaluation-locus derived Drinfeld–Kohno). The mechanism above (Verdier duality reverses collision cycle orientation, hence inverts the R -matrix monodromy) admits a homotopy-coherent enhancement. Ordered configuration spaces on the line carry the braid group action (Arnol’d), and bar-cobar duality implements Verdier duality on these configuration spaces. The *chain-level / evaluation-locus derived Drinfeld–Kohno theorem* (Theorems O.13.5 and O.13.9) proves that this mechanism, composed with the Kazhdan–Lusztig equivalence, yields a chain-level derived equivalence with braiding reversal $R_q \mapsto R_{q^{-1}}$, both for affine algebras and for Yangians on the evaluation locus. This is the theorematic DK-o/DK-i package. The later DK stages (extension beyond the evaluation locus, the factorization-level Kazhdan bridge, and the dg-shifted comparison) remain conjectural; see Conjecture K.7.1 and §O.13 for the full treatment.

Remark 15.1.15 (Quantum groups and braiding reversal). For $\mathcal{A} = \widehat{\mathfrak{g}}_k$ at positive integer level, monoidal module Koszul duality combined with KL gives:

$$\begin{array}{ccc} \mathcal{O}_k^{\text{int}}(\widehat{\mathfrak{g}}) & \xrightarrow[\sim]{\Phi_{\text{KL}}} & C(U_q(\mathfrak{g})) \\ \Phi \downarrow & & \downarrow q \mapsto q^{-1} \\ \mathcal{O}_{k'}(\widehat{\mathfrak{g}}) & \xrightarrow[\sim]{\Phi_{\text{KL}}} & C(U_{q^{-1}}(\mathfrak{g})) \end{array}$$

where $q = e^{\pi i/(k+h^\vee)}$ and $k' = -k - 2h^\vee$. Since $k' < 0$, the bottom-left entry is the full category $\mathcal{O}$ (KL–Finkelberg category [257]). The vertical arrow reverses the braiding ($R_q \mapsto R_{q^{-1}}$) while preserving the tensor product.

PROPOSITION 15.1.16 (*Derived Ext exchange on the quadratic E_1 lane;*). Assume $\mathcal{A}$ lies on the quadratic genus-0 E_1 complete/conilpotent lane of Theorem 11.6.2. For complete $\mathcal{A}$ -modules M, N , write $M^\dagger = \Phi(M)$ and $N^\dagger = \Phi(N)$ for the corresponding conilpotent bar-comodules. Then

$$\mathrm{Ext}_{\mathcal{A}}^n(M, N) \cong \mathrm{Hom}_{D(\mathrm{CoMod}_{\overline{B}(\mathcal{A})}^{\mathrm{conil}})}(M^\dagger, N^\dagger[n]) \quad (15.2)$$

for all $n \geq 0$. When the finite-type graded-dual identification $\overline{B}(\mathcal{A})^\vee \cong \mathcal{A}^\dagger$ is available, one may further reinterpret the right-hand side on the completed $\mathcal{A}^\dagger$ -module side, but that extra dual-algebra rewrite is not part of this proposition.

Proof. This is the derived Ext comparison of Theorem 11.6.2(ii), rewritten in the notation of the present chapter. On the proved quadratic genus-0 E_1 lane, the module bar functor $\Phi = \overline{B}(\mathcal{A}; -)$ identifies complete $\mathcal{A}$ -modules with conilpotent bar-comodules, and the theorem states precisely that derived extensions on the module side are computed by derived morphisms in the bar-comodule category with the same order of arguments. The last sentence is the same finite-type caveat already recorded in Proposition 15.1.10: only after the graded-dual identification $\overline{B}(\mathcal{A})^\vee \cong \mathcal{A}^\dagger$ is justified may one translate the comodule target into a completed dual-algebra statement. $\square$

Remark 15.1.17 (*Deformation–extension duality on the bar-comodule surface*). Equation (15.2) says that first-order extensions of $\mathcal{A}$ -modules are controlled by the dual bar-comodule deformation theory on the proved quadratic genus-0 E_1 lane. This is the intrinsic theorematic content. Any further translation into dual-algebra language, into Tor over $\mathcal{A}^\dagger$, or into singular-vector bookkeeping on the dual algebra side, requires the additional finite-type dualization data that identifies the relevant bar-comodules with complete $\mathcal{A}^\dagger$ -modules. In the curved case, the appropriate analogues live in Positselski’s coderived/curved framework [350].

15.1.1 CONFORMAL BLOCKS AND THE BAR COMPLEX

Definition 15.1.18 (*Space of conformal blocks*). For the Heisenberg algebra, conformal blocks are spaces of Fock-space coinvariants; the genus- g partition function $Z_g(\mathcal{H}_k)$ computed in §2.11 is a section of the corresponding bundle over $\overline{\mathcal{M}}_g$. The general definition is as follows.

Let $\mathcal{A}$ be a chiral algebra on a smooth projective curve X of genus g , and let $\mathcal{M}_1, \dots, \mathcal{M}_r$ be $\mathcal{A}$ -modules inserted at distinct points $x_1, \dots, x_r \in X$. The *space of conformal blocks* is the space of coinvariants:

$$\mathbb{V}(\mathcal{A}; \mathcal{M}_1, \dots, \mathcal{M}_r; X) = H^0(X \setminus \{x_1, \dots, x_r\}, \mathcal{A}) \Big| \mathcal{M}_1 \otimes \dots \otimes \mathcal{M}_r.$$

Here the left action is by the residues of the chiral bracket along the insertions x_i . When $r = 0$ (no module insertions), $\mathbb{V}(\mathcal{A}; X) = H^0(X, \mathcal{A}) \setminus 1$ is the *vacuum conformal block*.

PROPOSITION 15.1.19 (*Conformal blocks via the bar complex;*). For a Koszul chiral algebra $\mathcal{A}$ on a curve X of genus g with module insertions $\mathcal{M}_1, \dots, \mathcal{M}_r$, the space of conformal blocks is computed by the bar complex on X :

$$\mathbb{V}(\mathcal{A}; \mathcal{M}_1, \dots, \mathcal{M}_r; X) \cong H^0(\mathrm{Tot} \, \overline{B}(\mathcal{M}_1, \dots, \mathcal{M}_r; X))$$

where $\overline{B}(\mathcal{M}_1, \dots, \mathcal{M}_r; X)$ is the bar complex on $\overline{C}_{n+r}(X)$ with module data at the first r marked points and algebra data at the remaining n points.

Proof. The bar complex on $\overline{C}_{n+r}(X)$ computes the derived coinvariants of $\mathcal{A}$ acting on $\mathcal{M}_1 \otimes \cdots \otimes \mathcal{M}_r$. The n -th term of the bar complex is:

$$\bar{B}_n(\vec{\mathcal{M}}; X) = \Gamma(\overline{C}_{n+r}(X), j_* j^*(\mathcal{M}_1 \boxtimes \cdots \boxtimes \mathcal{M}_r \boxtimes \mathcal{A}^{\boxtimes n}) \otimes \Omega_{\log}^n)$$

where $j: C_{n+r}(X) \hookrightarrow \overline{C}_{n+r}(X)$ and $\Omega_{\log}^n$ are the logarithmic forms with poles along the boundary divisors. The differential is $d = d_{\text{config}} + d_{\text{internal}}$ as in Definition 6.1.15, with d_{config} encoding the chiral bracket residues of $\mathcal{A}$ acting on each $\mathcal{M}_i$.

By the Koszul property, the spectral sequence associated to the bar filtration degenerates at E_2 , and the E_1 page computes $H^*(X \setminus \{x_i\}, \mathcal{A}) \setminus \mathcal{M}_1 \otimes \cdots \otimes \mathcal{M}_r$, which is precisely the conformal block. The E_2 degeneration ensures that $H^0(\text{Tot } \bar{B})$ is exactly the conformal block space, without higher corrections. $\square$

Remark 15.1.20 (Conformal blocks and Koszul duality). The Verdier intertwining $\mathbb{D}_{\text{Ran}} \bar{B}(\mathcal{A}) \simeq \mathcal{A}^!$ (Theorem 11.1.84) acts at the algebra level. To obtain a conformal-block identity

$$\mathbb{V}(\mathcal{A}; \vec{\mathcal{M}}; X) \cong \mathbb{V}(\mathcal{A}^!; \vec{\mathcal{M}}^!; X),$$

one needs the *module-level* Verdier intertwining: the functor $\mathbb{D}_{\text{Ran}}$ must exchange the module bar complex $\bar{B}(\mathcal{A}; \vec{\mathcal{M}})$ with $\bar{B}(\mathcal{A}^!; \vec{\mathcal{M}}^!)$ compatibly with the pointed configuration space $\overline{C}_{n,r}(X)$. The algebra-level theorem supplies the compatibility on the $\mathcal{A}$ -tensor factors; the module-level extension requires that each $\mathcal{M}_i$ and its dual $\mathcal{M}_i^!$ are related by a Koszul-module pairing (Definition 15.1.21). Under this hypothesis, the conformal-block identity holds and gives a geometric proof that $\dim \mathbb{V}$ is invariant under $k \mapsto -k - 2h^\vee$, distinct from the classical level-rank duality ([37], [333]). The full module-level Verdier intertwining is Theorem 15.1.22.

Definition 15.1.21 (Koszul module pair). Let $(\mathcal{A}, \mathcal{A}^!)$ be a chiral Koszul pair (Definition 11.1.15). A *Koszul module pair* $(\mathcal{M}, \mathcal{M}^!)$ consists of an $\mathcal{A}$ -module $\mathcal{M}$ and an $\mathcal{A}^!$ -module $\mathcal{M}^!$ such that the module bar complex

$$\bar{B}(\mathcal{A}; \mathcal{M}) = \bigoplus_{n \geq 0} (s^{-1} \bar{\mathcal{A}})^{\otimes n} \otimes \mathcal{M} \otimes \Omega_{\log}^n(\overline{C}_{n,1}(X))$$

satisfies $H^*(\bar{B}(\mathcal{A}; \mathcal{M})) \cong \mathcal{M}^!$ as a $\bar{B}(\mathcal{A})$ -comodule. Just as $H^*(\bar{B}(\mathcal{A}))$ is the dual coalgebra of $\mathcal{A}$ and $\bar{B}(\mathcal{A})$ is the bar coalgebra computing it (Convention 6.0.2), $\bar{B}(\mathcal{A}; \mathcal{M})$ computes the Koszul dual comodule of $\mathcal{M}$.

THEOREM 15.1.22 (Module-level Verdier intertwining;). Let $(\mathcal{A}, \mathcal{A}^!)$ be a chiral Koszul pair (Definition 11.1.15) on a smooth projective curve X , and let $\mathcal{M}_1, \dots, \mathcal{M}_r$ be Koszul $\mathcal{A}$ -modules with Koszul dual $\mathcal{A}^!$ -modules $\mathcal{M}_1^!, \dots, \mathcal{M}_r^!$ (Definition 15.1.21). Then Verdier duality on $\overline{C}_{n,r}(X)$ exchanges the module bar complexes:

$$\mathbb{D}_{\overline{C}_{n,r}(X)} \bar{B}_n(\mathcal{A}; \vec{\mathcal{M}}; X) \simeq \bar{B}_n(\mathcal{A}^!; \vec{\mathcal{M}}^!; X) \quad (15.3)$$

compatibly with the bar differential and the pointed-configuration structure maps. On H^0 , this induces:

$$\mathbb{V}(\mathcal{A}; \vec{\mathcal{M}}; X) \cong \mathbb{V}(\mathcal{A}^!; \vec{\mathcal{M}}^!; X)^\vee. \quad (15.4)$$

Proof. The pointed configuration space $\overline{C}_{n,r}(X)$ parameterizes n algebra insertions and r module insertions with collision patterns encoded by boundary divisors. The module bar complex

$\bar{B}_n(\mathcal{A}; \vec{\mathcal{M}}; X) = \Gamma(\bar{C}_{n,r}(X), \mathcal{M}_1 \boxtimes \cdots \boxtimes \mathcal{M}_r \boxtimes \mathcal{A}^{\boxtimes n} \otimes \Omega_{\log}^n)$ is a holonomic $\mathcal{D}$ -module on $\bar{C}_{n,r}(X)$ (extending Lemma 7.0.12 to the pointed setting).

Step 1: Verdier duality on algebra factors. On the n algebra-insertion factors, Verdier duality acts by Theorem 7.0.36: $\mathbb{D}$ exchanges the logarithmic forms η_{ij} with the distributional sections $\delta_{D_{ij}}$, and maps $\mathcal{A}^{\boxtimes n}$ to $(\mathcal{A}^!)^{\boxtimes n}$ via the Koszul pairing $\mathcal{A} \otimes \mathcal{A}^! \rightarrow \omega_X$.

Step 2: Verdier duality on module factors. At each module insertion x_i , the Koszul-module pairing $\mathcal{M}_i \otimes \mathcal{M}_i^! \rightarrow \omega_X$ (Definition 15.1.21) provides the local Verdier data. The collision divisors D_{x_i, z_j} (where an algebra point collides with a module point) contribute residues of the $\mathcal{A}$ -action on $\mathcal{M}_i$; under Verdier duality, these become residues of the $\mathcal{A}^!$ -action on $\mathcal{M}_i^!$, by functoriality of the chiral bracket under the Koszul pairing.

Step 3: Compatibility with the differential. The module bar differential has two types of residue: algebra–algebra collisions (controlled by Step 1) and algebra–module collisions (controlled by Step 2). Both types are intertwined by $\mathbb{D}$ because the Koszul-module pairing is compatible with the chiral bracket:

$$\langle d_{\text{bar}} m, m^! \rangle = -\langle m, d_{\text{bar}}^! m^! \rangle$$

(the adjoint-connection identity of Theorem 7.0.36, Step 2, applied to each collision divisor). Combining Steps 1–3 yields the identification (15.3) on $\bar{C}_{n,r}(X)$: the Verdier dual of the module bar complex of $\mathcal{A}$ on $(\vec{\mathcal{M}})$ is the module bar complex of $\mathcal{A}^!$ on $(\vec{\mathcal{M}}^!)$, regarded as a holonomic $\mathcal{D}$ -module. In the homotopy module-algebra notation of Convention 6.0.2, $\mathbb{D}\bar{B}_n(\mathcal{A}; \vec{\mathcal{M}}) \simeq \bar{B}_n(\mathcal{A}^!; \vec{\mathcal{M}}^!)$, which agrees with $\mathcal{A}_{\infty,n}^!(\vec{\mathcal{M}}^!)$ as a factorization algebra on the proved Verdier-intertwining surface.

Step 4: Descent to conformal blocks. Taking H^0 of (15.3) and using the bar-complex computation of conformal blocks (Proposition 15.1.19) gives:

$$\mathbb{V}(\mathcal{A}; \vec{\mathcal{M}}; X) = H^0(\bar{B}(\mathcal{A}; \vec{\mathcal{M}}; X)) \cong H^0(\mathbb{D}\bar{B}(\mathcal{A}^!; \vec{\mathcal{M}}^!; X))^\vee = \mathbb{V}(\mathcal{A}^!; \vec{\mathcal{M}}^!; X)^\vee.$$

The duality in the second step is $H^0(\mathbb{D}C) \cong H^{\dim}(C)^\vee$ for a holonomic complex C on the smooth variety $\bar{C}_{n,r}(X)$; the Koszul concentration ensures $H^{\dim} = H^0$ (all cohomology in a single degree). $\square$

COROLLARY 15.1.23 (*Dimension invariance under Koszul duality*;). For $\mathcal{A} = \widehat{\mathfrak{g}}_k$ and integrable modules at positive integer level:

$$\dim \mathbb{V}(\widehat{\mathfrak{g}}_k; \vec{\Lambda}; \Sigma_g) = \dim \mathbb{V}(\widehat{\mathfrak{g}}_{-k-2h^\vee}; \vec{\Lambda}^!; \Sigma_g).$$

Proof. Apply Theorem 15.1.22 with $\mathcal{A}^! = \widehat{\mathfrak{g}}_{-k-2h^\vee}$ (Theorem G.7.1). The isomorphism (15.4) preserves dimension. $\square$

Definition 15.1.24 (*Bundle of conformal blocks*). Let $\mathcal{A}$ be a rational chiral algebra and $\Lambda_1, \dots, \Lambda_r$ a collection of highest weights. As the pointed curve $(X; x_1, \dots, x_r)$ varies over the moduli space $\mathcal{M}_{g,r}$, the spaces of conformal blocks (Definition 15.1.18) assemble into a vector bundle

$$\mathbb{V}(\mathcal{A}; \Lambda_1, \dots, \Lambda_r) \rightarrow \mathcal{M}_{g,r}$$

of finite rank, called the *bundle of conformal blocks* (or *bundle of vacua*).

- (i) The bundle carries a projective flat connection: the *Knizhnik–Zamolodchikov–Bernard (KZB) connection*, whose horizontal sections satisfy the KZB equations.

- (ii) The rank of $\mathbb{V}$ is independent of the genus- g curve X and depends only on the algebra $\mathcal{A}$, the weights Λ_i , and the genus g .
- (iii) The factorization property of $\mathcal{A}$ implies a *factorization* of the bundle under degeneration: when X degenerates to a nodal curve $X_0 = X_1 \cup_P X_2$, the fiber satisfies

$$\mathbb{V}(\mathcal{A}; \vec{\Lambda}; X_0) \cong \bigoplus_{\mu \in \text{Irr}(\mathcal{A})} \mathbb{V}(\mathcal{A}; \vec{\Lambda}_1, \mu; X_1) \otimes \mathbb{V}(\mathcal{A}; \mu^*, \vec{\Lambda}_2; X_2).$$

PROPOSITION 15.1.25 (*KZB connection from the bar complex*;). The projective flat connection on $\mathbb{V}(\mathcal{A}; \vec{\Lambda})$ arises from the bar complex as follows. The bar complex $\bar{B}(\vec{\mathcal{M}}; X)$ of Proposition 15.1.19 depends on the complex structure of X through the propagator $\eta_{ij} \in \Omega^1(\bar{C}_2(X))$. The variation of η_{ij} with respect to moduli $t_\alpha \in T\mathcal{M}_{g,r}$ yields:

$$\nabla_{\partial/\partial t_\alpha} = \partial_{t_\alpha} + \sum_{i < j} \text{Res}_{D_{ij}} \frac{\partial \eta_{ij}}{\partial t_\alpha},$$

where the residue operator acts on bar complex terms on $\bar{C}_{n+r}(X)$. Flatness $[\nabla_\alpha, \nabla_\beta] = 0$ follows from $d^2 = 0$ on the bar complex (Theorem 6.1.21): the flatness obstruction equals the commutator of bar differentials, which vanishes.

For $\mathcal{A} = \widehat{\mathfrak{g}}_k$ on $\mathbb{P}^1$, on the affine Kac–Moody comparison surface this genus-0 specialization identifies with the KZ connection $\nabla_i = \partial_{z_i} + \frac{1}{k+h^\vee} \sum_{j \neq i} \frac{\Omega_{ij}}{z_i - z_j}$, where $\Omega_{ij} = \sum_a T_i^a \otimes T_j^a$ is the Casimir element.

Proof. The bar complex $\bar{B}(\vec{\mathcal{M}}; X)$ is a complex of sheaves on $\mathcal{M}_{g,r}$ (via the universal curve $\pi: C_{g,r} \rightarrow \mathcal{M}_{g,r}$), and its cohomology sheaf $R^0\pi_*(\bar{B})$ is the bundle $\mathbb{V}$. The Gauss–Manin connection on $R^0\pi_*(\bar{B})$ is the KZB connection.

The propagator η_{ij} on $\bar{C}_2(X)$ is the unique logarithmic 1-form with simple pole along the diagonal D_{ij} and residue +1 (the Cauchy kernel on the curve). On $\mathbb{P}^1$: $\eta_{ij} = dz_i/(z_i - z_j)$. Its variation $\partial_{t_\alpha} \eta_{ij}$ contributes a term to the connection that acts on $\mathcal{M}_i \otimes \mathcal{M}_j$ via the chiral bracket; this is the Casimir insertion $\Omega_{ij}/(k+h^\vee)$ (the factor $(k+h^\vee)^{-1}$ is the inverse of the quadratic pole coefficient in the OPE).

Flatness: $[\nabla_\alpha, \nabla_\beta]$ involves $\partial_\alpha \partial_\beta \eta_{ij} - \partial_\beta \partial_\alpha \eta_{ij} = 0$ (symmetry of second derivatives) plus commutators of residue operators. The commutator of residue operators at D_{ij} and D_{kl} vanishes when $\{i, j\} \cap \{k, l\} = \emptyset$ (disjoint divisors). When $\{i, j\} \cap \{k, l\} \neq \emptyset$, the commutator is a residue at the codimension-2 stratum $D_{ij} \cap D_{kl}$, which is controlled by $d^2 = 0$ on the bar complex. $\square$

THEOREM 15.1.26 (*Verlinde formula via the bar complex* [388];). Let $\mathcal{A} = \widehat{\mathfrak{g}}_k$ at positive integer level k , with integrable highest weights $\Lambda_1, \dots, \Lambda_r$. The dimension of the space of conformal blocks on a genus- g curve is:

$$\dim \mathbb{V}(\widehat{\mathfrak{g}}_k; \Lambda_1, \dots, \Lambda_r; \Sigma_g) = \sum_{\mu \in P_+^k} \prod_{i=1}^r \frac{S_{\Lambda_i, \mu}}{S_{0, \mu}} \cdot (S_{0, \mu})^{2-2g} \quad (15.5)$$

where $S_{\Lambda, \mu}$ is the modular S -matrix of $\widehat{\mathfrak{g}}_k$:

$$S_{\Lambda, \mu} = C \sum_{w \in W} \varepsilon(w) e^{-2\pi i \langle w(\Lambda + \rho), \mu + \rho \rangle / (k+h^\vee)}, \quad C = \frac{i^{|\Delta^+|}}{|P/(k+h^\vee)Q|^{1/2}}.$$

Proof. The proof assembles three ingredients.

Step 1: Factorization reduction. By the factorization property of conformal blocks (Definition 15.1.24(iii)), the genus- g conformal block decomposes under degeneration to a maximally degenerate curve (a tree of $\mathbb{P}^1$'s with g self-intersections):

$$\dim \mathbb{V}(g, \vec{\Lambda}) = \sum_{\mu_1, \dots, \mu_g \in \text{Irr}} \prod_{\text{vertices}} N_{\Lambda_a \Lambda_b}^{\Lambda_c} \quad (15.6)$$

where $N_{\Lambda\mu}^\nu$ are the fusion coefficients (= dimensions of genus-0 three-point conformal blocks).

Step 2: Diagonalization via the S -matrix. The fusion coefficients are diagonalized by the modular S -matrix: the Verlinde formula for fusion coefficients gives

$$N_{\Lambda\mu}^\nu = \sum_{\sigma \in P_+^k} \frac{S_{\Lambda, \sigma} S_{\mu, \sigma} \overline{S_{\nu, \sigma}}}{S_{0, \sigma}}.$$

Substituting into (15.6) and summing over the internal weights $\mu_1, \dots, \mu_g$ using the orthogonality $\sum_{\mu} S_{\mu, \sigma} \overline{S_{\mu, \tau}} = \delta_{\sigma, \tau}$, the sum telescopes to the claimed formula (15.5).

Step 3: Bar complex interpretation. In the bar-cobar framework, each ingredient has a geometric counterpart:

- The fusion coefficients $N_{\Lambda\mu}^\nu$ are computed by the bar complex on $\overline{C}_3(\mathbb{P}^1)$ (Proposition 15.1.19 with $g = 0, r = 3$).
- The modular S -matrix is the monodromy of the KZB connection (Proposition 15.1.25) around the A -cycle of a genus-1 curve.
- The factorization property is the bar complex's factorization along boundary strata of $\overline{C}_{n+r}(X)$ (Definition 6.1.15).

The Koszul property ensures that the bar spectral sequence degenerates, so the rank of $\mathbb{V}$ is computed exactly by the E_2 page. $\square$

Remark 15.1.27 (Verlinde formula and Koszul duality). The Verlinde formula (15.5) applies at positive integer level k ; the Koszul dual level $k' = -k - 2h^\vee < 0$ has no integrable highest weights, so Verlinde does not directly apply there. The complementarity theorem (Theorem 13.15.14) nonetheless constrains conformal block dimensions at level k' through the center:

$$\mathcal{Q}_g(\widehat{\mathfrak{g}}_k) + \mathcal{Q}_g(\widehat{\mathfrak{g}}_{k'}^\dagger) = H^*(\mathcal{M}_g, Z(\widehat{\mathfrak{g}}_k)).$$

At positive integer level, the Verlinde dimensions are computed exactly via the bar complex (Theorem 15.1.26).

15.1.2 CONFORMAL BLOCK RANKS UNDER KOSZUL DUALITY

Conjecture 15.1.28 (Conditional conformal-block comparison from braided categorical duality;). Let $(\mathcal{A}, \mathcal{A}^\dagger)$ be a Koszul pair of chiral algebras, both rational and C_2 -cofinite, with finitely many simple modules. Assume in addition that there is a braided tensor equivalence

$$\Phi: \mathcal{C}_{\mathcal{A}} \xrightarrow{\sim} \mathcal{C}_{\mathcal{A}^\dagger}^{\text{rev}}$$

between their semisimple module categories, compatible with the bijection on simple objects supplied by the conditional highest-weight bar/Koszul t-structure comparison (Proposition 15.1.35). Denote by $\Phi: \text{Irr}(\mathcal{A}) \xrightarrow{\sim} \text{Irr}(\mathcal{A}^!)$ the bijection on simple modules. Then the conformal block ranks satisfy:

- (i) (Genus 0) The fusion coefficients are preserved: $N_{\Lambda\mu}^\nu(\mathcal{A}) = N_{\Phi(\Lambda)\Phi(\mu)}^{\Phi(\nu)}(\mathcal{A}^!)$.
- (ii) (Genus g) In the semisimple factorization regime, the pointed genus- g conformal block dimensions agree:

$$\dim \mathbb{V}(\mathcal{A}; \vec{\Lambda}; \Sigma_g) = \dim \mathbb{V}(\mathcal{A}^!; \Phi(\vec{\Lambda}); \Sigma_g).$$

Remark 15.1.29 (Evidence). For (i): by hypothesis, Φ is a braided tensor equivalence on the semisimple module categories. Since Φ is a tensor functor, it preserves the fusion product: $\Phi(\mathcal{L}(\Lambda) \boxtimes \mathcal{L}(\mu)) \cong \Phi(\mathcal{L}(\Lambda)) \boxtimes \Phi(\mathcal{L}(\mu))$. In particular, $N_{\Lambda\mu}^\nu = \dim \text{Hom}_{\mathcal{A}}(\mathcal{L}(\nu), \mathcal{L}(\Lambda) \boxtimes \mathcal{L}(\mu)) = \dim \text{Hom}_{\mathcal{A}^!}(\Phi(\mathcal{L}(\nu)), \Phi(\mathcal{L}(\Lambda)) \boxtimes \Phi(\mathcal{L}(\mu))) = N_{\Phi(\Lambda)\Phi(\mu)}^{\Phi(\nu)}$.

For (ii): in the rational semisimple regime, the pointed genus- g conformal block dimensions are computed by the factorization formula (15.6), i.e. by gluing genus-0 three-point blocks along a pants decomposition. Since part (i) identifies the fusion coefficients on every vertex after transporting labels by Φ , the resulting factorization sum is identical on the two sides.

Remark 15.1.30 (Conformal block comparison and complementarity). Proposition 15.1.28 is now explicitly a conditional categorical comparison, not a theorematic output of the general bar-cobar package. It is consistent with complementarity (Theorem 13.15.14): when the S -matrices satisfy $S_{\Lambda,\mu}^{\mathcal{A}} = S_{\Phi(\Lambda),\Phi(\mu)}^{\mathcal{A}^!}$ (as for specific Feigin–Frenkel / KL-type surfaces where such categorical input is available), Verlinde yields identical ranks directly. The “both rational and C_2 -cofinite” hypothesis is essential: Koszul duality can map rational to non-rational (e.g., $V_1(\mathfrak{sl}_2)$ rational, $V_{-3}(\mathfrak{sl}_2)$ not). A direct KZB-connection comparison under Koszul duality is not proved here in this generality.

Remark 15.1.31 (DS reduction and conformal-block comparison). The BRST reduction statement above identifies $\mathcal{W}^k(\mathfrak{g})$ conformal blocks with BRST-reduced Kac–Moody conformal blocks. This is compatible with the expectation that any semisimple categorical conformal-block comparison, when available on the affine side, should descend through BRST reduction. However, no general descended conformal-block duality theorem is proved here beyond those explicit categorical input surfaces.

15.1.3 CONFORMAL BLOCKS FROM THE BAR COMPLEX: THE STANDARD FAMILIES

15.1.3.1 Kac–Moody at positive integer level

Let $\mathcal{A} = \widehat{\mathfrak{g}}_k$ with $k \in \mathbb{Z}_{>0}$ and $\mathfrak{g}$ simple. Insert integrable highest-weight modules $V_{\Lambda_1}, \dots, V_{\Lambda_r}$ at distinct points $x_1, \dots, x_r \in \mathbb{P}^1$. The module bar complex (Proposition 15.1.19) is:

$$\bar{B}_n(\widehat{\mathfrak{g}}_k; \vec{V}_\Lambda; \mathbb{P}^1) = \Gamma(\bar{C}_{n,r}(\mathbb{P}^1), V_{\Lambda_1} \boxtimes \dots \boxtimes V_{\Lambda_r} \boxtimes \widehat{\mathfrak{g}}_k^{\boxtimes n} \otimes \Omega_{\log}^n).$$

The bar differential has two components:

1. *Algebra–algebra collisions* ($z_i \rightarrow z_j, i, j > r$): extract the Lie bracket $[J^a, J^b] = f^{ab}{}_c J^c$ via the simple-pole residue, and the Killing form $k\kappa^{ab}$ via the double-pole residue.
2. *Algebra–module collisions* ($z_i \rightarrow x_j, i > r, j \leq r$): extract the $\widehat{\mathfrak{g}}_k$ -action on V_{Λ_j} via $\text{Res}_{z_i=x_j} [J^a(z_i) \cdot v_j \cdot \eta_{i,x_j}] = T_j^a \cdot v_j$, where T_j^a is the representation matrix in V_{Λ_j} .

The resulting H^0 is the space of coinvariants $\widehat{\mathfrak{g}}_k(X \setminus \{x_i\}) \backslash V_{\Lambda_1} \otimes \cdots \otimes V_{\Lambda_r}$: the conformal block in the sense of Tsuchiya–Ueno–Yamada [412].

Example 15.1.32 (Three-point function on $\mathbb{P}^1$). For $\widehat{\mathfrak{sl}}_2$ at level k with three fundamental modules V_1, V_1, V_1 at $0, 1, \infty$, the bar complex on $\overline{C}_{n,3}(\mathbb{P}^1)$ has:

- $\bar{B}_0 = V_1 \otimes V_1 \otimes V_1$: the raw tensor product (dimension 8).
- $d: \bar{B}_0 \rightarrow 0$: the coinvariant quotient by the action of $\mathfrak{sl}_2[z, z^{-1}]$ on $\mathbb{P}^1 \setminus \{0, 1, \infty\}$.

The Casimir element $\Omega = e \otimes f + f \otimes e + \frac{1}{2}h \otimes h$ acts on pairs of V_1 factors. The coinvariant space is $\dim \mathbb{V} = 1$ for $k \geq 1$ (the unique $\mathfrak{sl}_2$ -invariant in $V_1^{\otimes 3}$), confirming $N_{1,1}^0 = 1$ in the Verlinde formula.

15.1.3.2 Virasoro

For the Virasoro algebra Vir_c , the conformal block at genus 0 with r highest-weight module insertions $M_{h_1}, \dots, M_{h_r}$ at $z_1, \dots, z_r \in \mathbb{P}^1$ is computed by the bar complex on pointed configuration spaces, with the bar differential extracting the Virasoro action via:

$$\text{Res}_{z=z_i} [T(z) \cdot v_i \cdot \eta_{z,z_i}] = L_{-1}^{(i)} v_i.$$

The Sugawara Casimir $\Omega_{ij}^{\text{Vir}} = \sum_{n \in \mathbb{Z}} L_n^{(i)} \otimes L_{-n}^{(j)} \cdot (z_i - z_j)^n$ enters the KZ-type connection on the conformal block bundle.

At central charge $c = c_{p,q} = 1 - 6(p - q)^2/(pq)$ (minimal models), the conformal block spaces are finite-dimensional and computed by the Feigin–Fuchs resolution, which the bar spectral sequence recovers: the E_1 page is the Verma module coinvariant, and the d_1 differential implements the BGG resolution (Theorem 15.6.2). The surviving $E_2 = E_\infty$ gives the finite-dimensional conformal block.

15.1.3.3 $\mathcal{W}$ -algebras via Drinfeld–Sokolov

For $\mathcal{W}^k(\mathfrak{g}) = H_{\text{DS}}^0(\widehat{\mathfrak{g}}_k)$ (the principal Drinfeld–Sokolov reduction), the bar complex intertwines with the BRST reduction:

$$\bar{B}(\mathcal{W}^k(\mathfrak{g}); \vec{\mathcal{M}}; X) \simeq H_{Q_{\text{DS}}}^0(\bar{B}(\widehat{\mathfrak{g}}_k; \vec{\mathcal{N}}; X)),$$

where $\mathcal{N}_i$ are the $\widehat{\mathfrak{g}}_k$ -modules inducing $\mathcal{M}_i$ under DS reduction. The conformal blocks of $\mathcal{W}^k(\mathfrak{g})$ are therefore the BRST-reduced conformal blocks of $\widehat{\mathfrak{g}}_k$:

$$\mathbb{V}(\mathcal{W}^k; \vec{\mathcal{M}}; X) = H_{Q_{\text{DS}}}^0(\mathbb{V}(\widehat{\mathfrak{g}}_k; \vec{\mathcal{N}}; X)).$$

For $\mathfrak{g} = \mathfrak{sl}_2$, this gives Virasoro conformal blocks at $c = 1 - 6(k + 1)^2/(k + 2)$; for $\mathfrak{g} = \mathfrak{sl}_N$, it gives $\mathcal{W}_N$ conformal blocks. The Koszul dual level shift $k \mapsto -k - 2h^\vee$ commutes with DS (Theorem 15.10.1), so the conformal block comparison discussed in Remark 15.1.31 is expected to descend through the BRST reduction on surfaces where the required categorical hypotheses are known.

15.1.3.4 Cosets

For a conformal embedding $\mathcal{B} \hookrightarrow \mathcal{A}$ (e.g., the diagonal $\widehat{\mathfrak{g}}_k \hookrightarrow \widehat{\mathfrak{g}}_{k_1} \otimes \widehat{\mathfrak{g}}_{k_2}$ with $k = k_1 + k_2$), the coset $\mathcal{A}/\mathcal{B}$ has conformal blocks computed by the *relative bar complex*:

$$\bar{B}(\mathcal{A}/\mathcal{B}; \vec{\mathcal{M}}; X) := \bar{B}(\mathcal{A}; \vec{\mathcal{M}}; X) \otimes_{\bar{B}(\mathcal{B})} \mathbb{C},$$

the bar complex of $\mathcal{A}$ with $\mathcal{B}$ -coinvariants imposed. The conformal blocks decompose as:

$$\mathbb{V}(\mathcal{A}; \vec{\Lambda}; X) \cong \bigoplus_{\vec{\mu}} \mathbb{V}(\mathcal{A}/\mathcal{B}; \vec{\Lambda}/\vec{\mu}; X) \otimes \mathbb{V}(\mathcal{B}; \vec{\mu}; X),$$

the branching rule realized at the bar-complex level by the Künneth decomposition on $\overline{C}_{n,r}(X)$. The coset Koszul dual $(\mathcal{A}/\mathcal{B})^\dagger$ is computed from $\bar{B}(\mathcal{A}/\mathcal{B})^\vee$: the Verdier dual of the relative bar coalgebra.

Example 15.1.33 (GKO coset $\widehat{\mathfrak{sl}}_{2,k} \otimes \widehat{\mathfrak{sl}}_{2,1}/\widehat{\mathfrak{sl}}_{2,k+1}$). The Goddard–Kent–Olive coset realizes the Virasoro minimal model $\mathcal{M}(k+2, k+3)$ at $c = 1 - 6/((k+2)(k+3))$. At the bar-complex level: the relative bar complex of the coset is the BRST reduction of the tensor-product bar complex by the diagonal $\widehat{\mathfrak{sl}}_2$ action. The Verlinde dimensions of the coset conformal blocks match the minimal model fusion rules; this is a bar-complex proof of the GKO correspondence.

15.1.3.5 Yangians and quantum groups

For the E_1 -chiral Yangian $Y(\mathfrak{g})^{\text{ch}}$ on a pointed curve $(X; x_1, \dots, x_r)$, the module bar complex is built on *ordered* configuration spaces $\widetilde{C}_{n,r}(X)$ (no Σ_n -equivariance). The conformal blocks are:

$$\mathbb{V}^{E_1}(Y(\mathfrak{g}); V_{\Lambda_1}(a_1), \dots, V_{\Lambda_r}(a_r); X) = H^0(\bar{B}_n^{E_1}(Y(\mathfrak{g}); \vec{V}(a); X)),$$

where $V_{\Lambda_i}(a_i)$ are evaluation modules at spectral parameters $a_1, \dots, a_r$.

The KZ connection on these conformal blocks (with Casimir insertion $\Omega_{ij}/(a_i - a_j)$ from the rational R -matrix) has monodromy valued in the braid group B_r . The Drinfeld–Kohno theorem (Theorem O.13.9) identifies this monodromy with the R -matrix representation of $U_q(\mathfrak{g})$ on $V_{\Lambda_1} \otimes \dots \otimes V_{\Lambda_r}$. At the bar-complex level, the identification is:

$$\text{Mon}_{B_r}(\mathbb{V}^{E_1}(Y(\mathfrak{g}); \vec{V}(a); \mathbb{P}^1)) \cong V_{\Lambda_1} \otimes \dots \otimes V_{\Lambda_r} \in \text{Rep}(U_q(\mathfrak{g})),$$

where the braiding on the left (from the ordered bar-complex propagator η_{ij}) equals the R -matrix braiding on the right (from the quantum group).

Remark 15.1.34 (Chiral homology as the derived conformal block). The conformal block $\mathbb{V} = H^0(\bar{B}(\mathcal{A}; \vec{\mathcal{M}}; X))$ is the degree-0 piece of a richer object: the full chiral homology $H_{\text{ch}}^*(\mathcal{A}; \vec{\mathcal{M}}; X) = H^*(\bar{B}(\mathcal{A}; \vec{\mathcal{M}}; X))$. The higher cohomology $H^{>0}$ detects:

1. *Obstructions to flatness* of the conformal block bundle (the KZB connection is flat on H^0 , but the higher H^i carry the obstruction classes from the Leray spectral sequence of the universal curve).
2. *Derived coinvariants*: for non-rational algebras (e.g., $\widehat{\mathfrak{g}}_k$ at admissible level), $H^{>0} \neq 0$ and the derived conformal blocks carry the logarithmic structure of non-semisimple modules.
3. *Genus corrections*: at genus $g \geq 1$, the higher chiral homology groups H_{ch}^i receive contributions from $H^i(\bar{\mathcal{M}}_g, \mathcal{Z}_{\mathcal{A}})$ via the genus spectral sequence (Theorem 13.15.23).

For Koszul algebras, the E_2 collapse (Lemma 13.18.8) forces $H^{>0} = 0$: the conformal block IS the full chiral homology. Off the Koszul locus, the higher chiral homology groups are the derived obstruction spaces of Theorem 13.15.14.

15.1.4 DERIVED CATEGORIES AND T-STRUCTURES

Conjecture 15.1.35 (Conditional highest-weight Koszul t-structure from bar linearity;). Let $(\mathcal{A}, \mathcal{A}^!)$ be a Koszul pair of chiral algebras. Assume the module-category t -exactness package of Conjecture 12.14.1 on the chosen lane, and suppose in addition that the module bar functor of Remark 15.1.9 restricts to a triangulated equivalence

$$\Phi: D^b(\mathcal{O}_k) \xrightarrow{\sim} \mathcal{D}_{k'}^{\text{bar}}$$

onto a highest-weight target subcategory on the bar/comodule side. Assume also that for every simple $\mathcal{L}(\lambda) \in \mathcal{O}_k$, the bar resolution is linear: the term $\bar{B}_n(\mathcal{L}(\lambda))$ is concentrated in internal degree $n + h(\lambda)$. Then internal degree defines a Koszul t-structure on $\mathcal{D}_{k'}^{\text{bar}}$, characterized by

$$\mathcal{D}_{\text{Kosz}}^{\leq 0} = \{M^\bullet \in \mathcal{D}_{k'}^{\text{bar}} : H^n(M^\bullet) \text{ is concentrated in internal degrees } \geq n \text{ for all } n\},$$

and each $\Phi(\mathcal{L}(\lambda))$ lies in its heart. If, in addition, that heart is realized by an honest highest-weight category on the target side, then its simple objects are naturally identified with those of $\mathcal{O}_k$.

Remark 15.1.36 (Evidence). By hypothesis, the module bar functor already restricts to the displayed triangulated comparison on the chosen highest-weight lane. What remains is the internal-degree statement. For a simple object $\mathcal{L}(\lambda) \in \mathcal{O}_k$, linearity says that $\bar{B}_n(\mathcal{L}(\lambda))$ sits in internal degree $n + h(\lambda)$, so the resulting complex is concentrated on the diagonal singled out by the usual Koszul-degree convention. This is precisely the condition that places $\Phi(\mathcal{L}(\lambda))$ in the heart of the internal-degree t-structure written above.

Extension-closure and stability under cones then transport the standard t-structure on $D^b(\mathcal{O}_k)$ to the corresponding highest-weight target subcategory. Any further identification of that heart with an honest abelian highest-weight category on the target side is extra categorical input and is therefore stated conditionally rather than proved here.

Remark 15.1.37 (Geometric interpretation of the conditional t-structure comparison). On any highest-weight lane where Proposition 15.1.35 applies, the standard t-structure corresponds to filtration by bar degree (number of configuration space points), while the transported bar/Koszul t-structure corresponds to filtration by *internal degree* (total conformal weight). On specific Kazhdan–Lusztig-type surfaces, this transported t-structure can match the canonical-basis t-structure on the quantum-group side, but no unconditional theorem of that form is proved here.

15.2 HIGHEST WEIGHT MODULES

Affine Kac–Moody, Virasoro, and $\mathcal{W}$ -algebras carry a conformal grading; their module theory is governed by highest weight representations.

Definition 15.2.1 (Weight grading and highest weight modules). Let $\mathcal{A}$ be a chiral algebra equipped with a conformal vector (a Virasoro subalgebra generated by $T(z) = \sum_n L_n z^{-n-2}$). A *weight grading* on an $\mathcal{A}$ -module $\mathcal{M}$ is a decomposition $\mathcal{M} = \bigoplus_h \mathcal{M}_h$ into generalized eigenspaces of L_0 .

A module $\mathcal{M}$ is *highest weight* of weight λ (encoding the L_0 -eigenvalue h together with any additional Cartan data) if $\mathcal{M} = \mathcal{A} \cdot v_\lambda$ is generated by a vector v_λ satisfying:

- (i) $\mathcal{A}_{>0} \cdot v_\lambda = 0$ (annihilation by positive modes);
- (ii) $L_0 \cdot v_\lambda = h \cdot v_\lambda$ (weight condition);
- (iii) for affine algebras, $\mathfrak{h} \cdot v_\lambda = \lambda|_{\mathfrak{h}} \cdot v_\lambda$ (Cartan eigenvalue).

Definition 15.2.2 (Verma module). The *Verma module* $\mathcal{M}(\lambda)$ is the universal highest weight module of weight λ : it is induced from the one-dimensional representation of the non-negative subalgebra $\mathcal{A}_{\geq 0} = \mathcal{A}_0 \oplus \mathcal{A}_{>0}$ on which v_λ has weight λ and $\mathcal{A}_{>0}$ acts by zero:

$$\mathcal{M}(\lambda) = \text{Ind}_{\mathcal{A}_{\geq 0}}^{\mathcal{A}} \mathbb{C}_\lambda = U(\mathcal{A}_{<0}) \otimes_{\mathbb{C}} \mathbb{C}_\lambda.$$

Every highest weight module of weight λ is a quotient of $\mathcal{M}(\lambda)$. The unique simple quotient is $\mathcal{L}(\lambda) = \mathcal{M}(\lambda) / \mathcal{J}(\lambda)$, where $\mathcal{J}(\lambda)$ is the maximal proper submodule.

Definition 15.2.3 (Shapovalov form). The *Shapovalov form* on $\mathcal{M}(\lambda)$ is the unique symmetric bilinear form $\langle \cdot, \cdot \rangle_\lambda: \mathcal{M}(\lambda) \times \mathcal{M}(\lambda) \rightarrow \mathbb{C}$ satisfying $\langle v_\lambda, v_\lambda \rangle_\lambda = 1$ and the contravariance property

$$\langle a_n \cdot u, w \rangle_\lambda = \langle u, a_{-n} \cdot w \rangle_\lambda$$

for all modes a_n of generating fields. Equivalently, $\langle u, w \rangle_\lambda = \varepsilon(u \cdot \sigma(w))$, where σ is the anti-involution sending $a_n \mapsto a_{-n}$ and ε is the counit $\mathcal{M}(\lambda) \rightarrow \mathbb{C}_\lambda$.

The form is non-degenerate on the weight- $(h+n)$ subspace $\mathcal{M}(\lambda)_{h+n}$ if and only if $\mathcal{M}(\lambda)$ has no singular vectors of weight $h+n$. The *Kac determinant* $\det \langle \cdot, \cdot \rangle_{\lambda, n}$ on this subspace admits a product formula ([238], Theorem 9.1; [239], Lecture 4) whose vanishing locus determines the reducibility of $\mathcal{M}(\lambda)$.

PROPOSITION 15.2.4 (Generic irreducibility [238, 162];). For the affine algebras $\widehat{\mathfrak{g}}_k$, the Virasoro algebra Vir_c , and the $\mathcal{W}$ -algebras $\mathcal{W}^k(\mathfrak{g})$: the Verma module $\mathcal{M}(\lambda)$ is irreducible for generic values of the level/central charge and the highest weight. Precisely, the Kac determinant is a non-trivial polynomial in the parameters, so its vanishing defines a proper subvariety of the parameter space.

The reducibility locus includes:

- (i) *Minimal model values:* $c_{p,q} = 1 - 6(p-q)^2/pq$ for Vir_c (Feigin–Fuchs [162]);
- (ii) *Admissible levels:* $k = -h^\vee + p/q$ for $\widehat{\mathfrak{g}}_k$ (Kac–Wakimoto [241]);
- (iii) *Critical level:* $k = -h^\vee$ for $\widehat{\mathfrak{g}}_k$ (the Sugawara construction is undefined; see Remark 7.1.12).

Remark 15.2.5 (Connection to Koszul duality). Generic irreducibility is the representation-theoretic counterpart of the Koszul property. At generic level, the Ext groups

$$\text{Ext}_{\mathcal{O}}^q(\mathcal{M}(\lambda), \mathcal{M}(\mu)) = 0, \quad q > 0, \lambda \neq \mu,$$

vanish between distinct Verma modules, ensuring bar spectral sequence degeneration at E_2 (cf. Theorem 12.5.1). At special levels (critical, admissible, minimal model), Verma modules become reducible, Ext groups become non-trivial, and the bar complex acquires higher-order obstructions.

15.2.1 CATEGORY $\mathcal{O}$ AND STRUCTURAL RESULTS

Definition 15.2.6 (Category $\mathcal{O}$ for affine Lie algebras). Let $\widehat{\mathfrak{g}} = \mathfrak{g}[t, t^{-1}] \oplus \mathbb{C}K \oplus \mathbb{C}d$ be an untwisted affine Lie algebra at level k (i.e., K acts as $k \cdot \text{id}$). *Category $\mathcal{O}_k(\widehat{\mathfrak{g}})$* is the full subcategory of $\widehat{\mathfrak{g}}$ -modules M satisfying:

- (i) M is finitely generated over $\widehat{\mathfrak{g}}$;
- (ii) $\mathfrak{h} \oplus \mathbb{C}d$ acts semisimply on M (i.e., M decomposes into weight spaces $M = \bigoplus_{\lambda} M_{\lambda}$ with $\dim M_{\lambda} < \infty$);

(iii) $\mathfrak{n}_+[t] \oplus \mathfrak{n}_+ \oplus \mathfrak{h}[t] \cdot t$ acts locally nilpotently on M .

The objects of $\mathcal{O}_k$ include all Verma modules $\mathcal{M}(\lambda)$ and their simple quotients $\mathcal{L}(\lambda)$ (Definition 15.2.2).

Definition 15.2.7 (Integrable modules). The *integrable* subcategory $\mathcal{O}_k^{\text{int}}(\widehat{\mathfrak{g}}) \subset \mathcal{O}_k(\widehat{\mathfrak{g}})$ consists of modules on which the Chevalley generators e_i, f_i ($i = 0, \dots, \text{rk } \mathfrak{g}$) act locally nilpotently. For k a non-negative integer, $\mathcal{O}_k^{\text{int}}$ is a semisimple abelian category with simple objects the integrable highest-weight modules $L(\Lambda)$, Λ dominant of level k ; there are finitely many such (their number equals the cardinality of P_+^k/W , where P_+^k is the set of level- k dominant weights). This is the starting point for the Verlinde formula (see Part II for explicit computations).

Definition 15.2.8 (Weyl modules). For a dominant integral weight Λ of level k , the *Weyl module* (or *standard module*) is the maximal integrable quotient of the Verma module:

$$V(\Lambda) = \mathcal{M}(\Lambda) \Big/ \sum_{i=0}^r \langle f_i^{\langle \Lambda, \alpha_i^\vee \rangle + 1} \cdot v_\Lambda \rangle.$$

At integrable level, $V(\Lambda)$ coincides with the simple module $L(\Lambda)$ (the Weyl module is irreducible). At non-integral or non-dominant levels, $V(\Lambda)$ and $L(\Lambda)$ may differ.

In the bar-cobar framework, the Weyl module is the natural “free” object: the bar complex $\bar{B}^{\text{ch}}(\widehat{\mathfrak{g}}_k, V(\Lambda))$ computes $\text{Ext}_{\mathcal{O}_k}^*(V(\Lambda), -)$, and the bar spectral sequence degenerates at E_2 precisely when $V(\Lambda)$ is Koszul.

THEOREM 15.2.9 (Kazhdan–Lusztig equivalence [257];). Let k be a non-negative integer and set $q = e^{\pi i/(k+h^\vee)}$. There is an equivalence of braided tensor categories

$$\Phi_{\text{KL}}: \mathcal{O}_k^{\text{int}}(\widehat{\mathfrak{g}}) \xrightarrow{\sim} C(U_q(\mathfrak{g})),$$

where $C(U_q(\mathfrak{g}))$ denotes the *semisimplified tilting category* of $U_q(\mathfrak{g})$ at the root of unity q . The equivalence sends the integrable module $L(\Lambda)$ to the simple tilting module $T_q(\Lambda)$ and identifies the fusion product $\boxtimes_{\widehat{\mathfrak{g}}_k}$ with the fusion tensor product on C .

The equivalence sends the braiding (monodromy of conformal blocks on $\mathbb{P}^1$) to the R -matrix braiding on $C(U_q(\mathfrak{g}))$.

References. For $\mathfrak{g} = \mathfrak{sl}_N$, this is proved by Kazhdan–Lusztig [257] via a deformation argument comparing the monodromy representation of the KZ connection with the quasi- R -matrix of $U_q(\mathfrak{g})$. Finkelberg [165] extended the result to arbitrary semisimple $\mathfrak{g}$. The braided tensor structure on $\mathcal{O}_k^{\text{int}}$ is constructed by Huang–Lepowsky–Zhang [227] using intertwining operators and analytic continuation. $\square$

Remark 15.2.10 (Categorical precision). The KL target is *not* the full $\text{Rep}(U_q(\mathfrak{g}))$ (non-semisimple at root of unity) but the semisimplified quotient of the tilting category by negligible morphisms. The resulting modular tensor category $C(U_q(\mathfrak{g}))$ is semisimple with $|P_+^k|$ simple objects, matching integrable modules at level k .

Remark 15.2.11 (Koszul duality and $q \leftrightarrow q^{-1}$). The level shift $k \leftrightarrow -k - 2h^\vee$ (Theorem G.7.1) sends $q \mapsto q^{-1}$ (Theorem G.11.6), identifying chiral Koszul duality with the Drinfeld–Jimbo bar involution:

$$\begin{array}{ccc} \mathcal{O}_k^{\text{int}} & \xrightarrow{\Phi_{\text{KL}}} & C(U_q(\mathfrak{g})) \\ \text{Koszul} \downarrow & & \downarrow q \mapsto q^{-1} \\ \mathcal{O}_{-k-2h^\vee}^{\text{int}} & \xrightarrow{\Phi_{\text{KL}}} & C(U_{q^{-1}}(\mathfrak{g})) \end{array}$$

Commutativity on simple objects: both sides send $L(\Lambda)$ to $T_{q^{-1}}(\Lambda)$; on tensor products, from braiding reversal.

Definition 15.2.12 (Contragredient module). For $M \in \mathcal{O}_k(\widehat{\mathfrak{g}})$, the *contragredient* (restricted dual) module is

$$M^\vee = \bigoplus_{\lambda} M_{\lambda}^*,$$

the graded dual (direct sum of duals of weight spaces), equipped with the $\widehat{\mathfrak{g}}$ -action $(a \cdot f)(m) = f(\sigma(a) \cdot m)$ where σ is the Chevalley anti-involution $\sigma(e_i) = f_i$, $\sigma(f_i) = e_i$, $\sigma(h) = h$, $\sigma(d) = d$, $\sigma(K) = K$.

The contragredient satisfies:

- (i) $\mathcal{M}(\lambda)^\vee \cong \mathcal{M}(\lambda)$ (Verma modules are self-contragredient);
- (ii) $\mathcal{L}(\lambda)^\vee \cong \mathcal{L}(\lambda)$ (simple modules are self-contragredient);
- (iii) the Shapovalov form (Definition 15.2.3) realizes the natural pairing $M \otimes M^\vee \rightarrow \mathbb{C}$.

Remark 15.2.13 (Contragredient modules and Koszul duality). The contragredient $(-)^\vee$ on $\mathcal{O}_k$ operates *within* a fixed level; Koszul duality sends complete $\widehat{\mathfrak{g}}_k$ -modules to conilpotent bar-comodules on the dual-side genus-0 lane (Theorem 11.6.2). Thus it compares structures at *different* levels $k' = -k - 2h^\vee$, while the contragredient remains internal to level k . Both preserve highest weight labels but act on different structures.

THEOREM 15.2.14 (BGG reciprocity for affine algebras [48, 253];). In category $\mathcal{O}_k(\widehat{\mathfrak{g}})$ at generic level, each simple module $\mathcal{L}(\lambda)$ has a projective cover $P(\lambda)$ satisfying the *BGG reciprocity*:

$$[P(\lambda) : \mathcal{M}(\mu)] = [\mathcal{M}(\mu) : \mathcal{L}(\lambda)]$$

where $[P : \mathcal{M}]$ denotes the Verma module multiplicity in a Verma flag of the projective, and $[\mathcal{M} : \mathcal{L}]$ denotes the composition factor multiplicity.

Equivalently, the Grothendieck group $K_0(\mathcal{O}_k)$ has two natural bases: the Verma modules $\{[\mathcal{M}(\lambda)]\}$ and the simple modules $\{[\mathcal{L}(\lambda)]\}$. The transition matrix between them is upper-triangular (with respect to the partial order on weights), and BGG reciprocity states that the inverse transition matrix is the *transpose* of the transition matrix.

This is proved for finite-dimensional semisimple Lie algebras by Bernstein–Gel’fand–Gel’fand [48] and extended to symmetrizable Kac–Moody algebras by Rocha-Caridi–Wallach and Kashiwara–Tanisaki [253].

Remark 15.2.15 (BGG reciprocity and the bar-cobar resolution). The projective cover $P(\lambda)$ is the bar resolution of $\mathcal{L}(\lambda)$ by Verma modules (Theorem 15.6.5, Step 1), so $[P(\lambda) : \mathcal{M}(\mu)]$ counts bar complex multiplicities. For a Koszul algebra, $[P(\lambda) : \mathcal{M}(\mu)] = \dim \operatorname{Ext}_{\mathcal{O}}^*(\mathcal{L}(\lambda), \mathcal{L}(\mu))$ and BGG reciprocity becomes self-duality of the bar complex under the Shapovalov form.

Remark 15.2.16 (BGG reciprocity from bar spectral sequence). The bar spectral sequence provides a refinement of BGG reciprocity. The E_2 page $E_2^{p,q} = H^q(B^p(\mathcal{A}))$ of the bar filtration encodes the module multiplicities in each bar degree: $E_2^{p,0}$ is the space of weight- p bar generators, and $E_2^{p,q}$ for $q > 0$ measures syzygies. At admissible levels, the rationality of $L_k(\mathfrak{g})$ (Theorem G.11.18) gives finite-dimensionality of the relevant fixed conformal-weight sectors of $E_r^{p,q}$ (Corollary G.11.21). A deeper question is whether the BGG multiplicities (specifically the Kazhdan–Lusztig polynomials $P_{w,w'}(q) = \sum_i q^i \dim \operatorname{Ext}_{\mathcal{O}}^i(\mathcal{M}(w \cdot \lambda), \mathcal{L}(w' \cdot \lambda))$) can be read off from the E_2 page of the bar spectral sequence. This would require a wall-crossing analysis for the spectral sequence as the level crosses admissible values, which remains open.

Definition 15.2.17 (Tilting modules). A module $T \in \mathcal{O}_k(\widehat{\mathfrak{g}})$ is *tilting* if both T and $T^\vee$ (the contragredient) admit a Verma flag:

$$0 = T_0 \subset T_1 \subset \cdots \subset T_r = T \quad \text{with} \quad T_i/T_{i-1} \cong \mathcal{M}(\mu_i) \text{ for each } i.$$

For each dominant weight λ , there exists a unique indecomposable tilting module $T(\lambda)$ with highest weight λ . At integrable level k , the indecomposable tilting modules $\{T(\Lambda) : \Lambda \in P_+^k\}$ form a complete set of projective objects in the fusion category $\mathcal{O}_k^{\text{int}}(\widehat{\mathfrak{g}})$ (Andersen [8], Soergel [380]).

PROPOSITION 15.2.18 (Tilting modules and the bar complex;). For an indecomposable tilting module $T(\lambda)$ over $\widehat{\mathfrak{g}}_k$ at generic level:

- (i) The bar complex $\bar{B}^{\text{ch}}(\widehat{\mathfrak{g}}_k, T(\lambda))$ is *self-dual* under the Verdier involution: $\bar{B}(T(\lambda))^\vee \cong \bar{B}(T(\lambda))$.
- (ii) The Verma flag multiplicities are: $[T(\lambda) : \mathcal{M}(\mu)] = \dim \text{Hom}_{\mathcal{O}}(P(\mu), T(\lambda)) = [\mathcal{M}(\mu) : \mathcal{L}(\lambda)]$ where the last equality is BGG reciprocity (Theorem 15.2.14).
- (iii) [Category: semisimplified tilting $\mathcal{C}(U_q(\mathfrak{g}))$.] Under the Kazhdan–Lusztig equivalence

$$\Phi_{\text{KL}} : \mathcal{O}_k^{\text{int}} \xrightarrow{\sim} \mathcal{C}(U_q(\mathfrak{g})),$$

the tilting module $T(\Lambda)$ maps to the indecomposable tilting module $T_q(\Lambda) \in \mathcal{C}(U_q(\mathfrak{g}))$.

Proof. (i) follows from the self-contragredience $T(\lambda)^\vee \cong T(\lambda)$ (the defining property of tilting modules), combined with the compatibility of the bar construction with contragredience.

(ii) is a direct consequence of BGG reciprocity: a projective $P(\mu)$ has a Verma flag with multiplicities $[P(\mu) : \mathcal{M}(\nu)] = [\mathcal{M}(\nu) : \mathcal{L}(\mu)]$, and $T(\lambda)$, being both Verma-filtered and co-Verma-filtered, has multiplicities equal to the composition multiplicities by the double-flag property.

(iii) follows from the uniqueness of indecomposable tilting modules with a given highest weight: the KL functor preserves highest weights and the Verma flag structure (it sends $\mathcal{M}(\Lambda)$ to the quantum Verma module $M_q(\Lambda)$), so it must send tilting to tilting. □

Remark 15.2.19 (Affine DK scope for tilting modules). The proposition above records only the bar-complex self-duality, Verma-flag multiplicities, and the external Kazhdan–Lusztig transport to semisimplified quantum-group tilting modules. It does *not* prove that the general module bar functor of Theorem 15.1.12 sends affine tilting modules to tilting modules at the dual level. Such a statement would require a separate categorical comparison on the affine Drinfeld–Kohno surface, not merely the lax monoidal bar-comodule theorem.

PROPOSITION 15.2.20 (Verma module bar complex;). Let $\mathcal{M}(\lambda)$ be the Verma module over $\widehat{\mathfrak{g}}_k$ at generic level k . The geometric bar complex (Definition 15.3.2) takes the form:

$$\bar{B}_n^{\text{ch}}(\widehat{\mathfrak{g}}_k, \mathcal{M}(\lambda)) = \Gamma(\bar{\mathcal{C}}_{n+2}(X), j_* j^*(\widehat{\mathfrak{g}}_k \boxtimes \bar{\boxtimes}^n \boxtimes \mathcal{M}(\lambda)) \otimes \Omega_{\log}^n).$$

This complex is acyclic at generic level (Proposition 15.2.4: Verma modules are irreducible, so the bar complex has no higher cohomology). At special levels where the Verma module is reducible, $H^1(\bar{B}_\bullet(\widehat{\mathfrak{g}}_k, \mathcal{M}(\lambda)))$ is generated by the singular vectors of $\mathcal{M}(\lambda)$: each singular vector $v_\mu \in \mathcal{M}(\lambda)_\mu$ satisfying $\widehat{\mathfrak{g}}_{>0} \cdot v_\mu = 0$ contributes a class in H^1 at conformal weight $|\mu|$.

Proof. At generic level, $\mathcal{M}(\lambda)$ is irreducible (Proposition 15.2.4), so it is a free module over $U(\widehat{\mathfrak{g}}_{<0})$. The bar complex is then acyclic by the standard contracting homotopy (§15.3 below).

At special level, the maximal submodule $\mathcal{J}(\lambda) \subset \mathcal{M}(\lambda)$ is non-zero. Each inclusion $\mathcal{M}(\mu) \hookrightarrow \mathcal{M}(\lambda)$ of a Verma submodule (generated by a singular vector of weight μ) produces a class in H^1 of the bar complex: the inclusion $\iota : v_\mu \hookrightarrow \mathcal{M}(\lambda)$ satisfies $d_{\text{bar}}(\iota) = 0$ (since v_μ is annihilated by $\widehat{\mathfrak{g}}_{>0}$) and is non-trivial in cohomology (since v_μ is not in the image of d_{bar} from $\bar{B}_2$: this would require v_μ to factor through the chiral product, which contradicts primitivity of singular vectors).

The vanishing locus of the Shapovalov form (Definition 15.2.3) determines which weight spaces have singular vectors, and the Kac determinant formula $\det \langle -, - \rangle_{\lambda, n}$ gives the multiplicity. In the bar-cobar framework, the Kac determinant is the determinant of the pairing between $\bar{B}_1$ and $\bar{B}^1$ at conformal weight n : its vanishing detects the failure of bar-complex acyclicity, which is the bar-cobar translation of Verma module reducibility. $\square$

Definition 15.2.21 (Kazhdan–Lusztig polynomials). The *Kazhdan–Lusztig polynomials* $P_{y,w}(q) \in \mathbb{Z}[q]$, indexed by pairs of elements y, w in the (affine) Weyl group with $y \leq w$ in the Bruhat order, are defined by the recursive formula:

$$P_{y,w}(q) = q^{(\ell(w)-\ell(y)-1)/2} P_{y,sw}(q^{-1}) + q^{(\ell(w)-\ell(y))/2} P_{sy,sw}(q^{-1}) - \sum_{y \leq z < sw} \mu(z, sw) q^{(\ell(w)-\ell(z))/2} P_{y,z}(q)$$

with initial conditions $P_{w,w} = 1$ and $P_{y,w} = 0$ for $y \not\leq w$, where s is a simple reflection with $sw < w$ and $\mu(z, w) = \deg P_{z,w}$ is the leading coefficient (see Kazhdan–Lusztig [256]).

The representation-theoretic significance: for category $\mathcal{O}$ of a symmetrizable Kac–Moody algebra, the composition multiplicities satisfy

$$[\mathcal{M}(w \cdot \lambda) : \mathcal{L}(y \cdot \lambda)] = P_{y,w}(1)$$

as conjectured by Kazhdan–Lusztig [256] and proved by Beilinson–Bernstein [39] and Brylinski–Kashiwara [74] (for finite type) and Kashiwara–Tanisaki [253] (for affine type).

Remark 15.2.22 (Kazhdan–Lusztig polynomials and the bar spectral sequence). The Koszul resolution of $\mathcal{L}(\lambda)$ (Theorem 15.4.2) is the BGG resolution with n -th term $\bigoplus_{\ell(w)=n} \mathcal{M}(w \cdot \lambda)$; inverting the Verma character matrix recovers $P_{y,w}(1)$. For Koszul algebras, the full q -polynomial $P_{y,w}(q) = \sum_i \dim \text{Ext}_{\mathcal{O}}^i(\mathcal{M}(w \cdot \lambda), \mathcal{L}(y \cdot \lambda)) q^{i/2}$ is read from the E_2 page of the bar spectral sequence (BGS [41]).

Example 15.2.23 (KL polynomials for $\widehat{\mathfrak{sl}}_2$). The affine Weyl group of $\widehat{\mathfrak{sl}}_2$ is $\mathcal{W} = \mathbb{Z} \rtimes \mathbb{Z}/2$, generated by reflections s_0 (affine) and s_1 (finite). Elements of minimal length in each coset $\mathcal{W}/\langle s_1 \rangle$ are parameterized by $n \in \mathbb{Z}_{\geq 0}$ with $\ell(w_n) = n$, where $w_n = s_0 s_1 s_0 \cdots$ (n factors). The Bruhat order is the linear order $w_0 < w_1 < w_2 < \cdots$.

For this linear Bruhat order, the KL polynomials are:

$$P_{w_m, w_n}(q) = \begin{cases} 1 & \text{if } m = n, \\ 0 & \text{if } m > n, \\ 1 & \text{if } n - m = 1 \text{ (adjacent),} \\ \sum_{j=0}^{\lfloor (n-m-1)/2 \rfloor} q^j & \text{in general.} \end{cases}$$

In particular, the polynomials are truncated geometric series of degree $\lfloor (n-m-1)/2 \rfloor$, and the evaluation $P_{w_m, w_n}(1) = \lceil (n-m)/2 \rceil$ counts the total composition factor multiplicity.

Bar spectral sequence interpretation. By Remark 15.2.22, $P_{w_m, w_n}(q) = \sum_i \dim \operatorname{Ext}_O^i(\mathcal{M}(w_n \cdot \lambda), \mathcal{L}(w_m \cdot \lambda)) q^{i/2}$. The formula $P_{w_m, w_n}(q) = \sum_{j=0}^{\lfloor (n-m-1)/2 \rfloor} q^j$ says that the Ext groups between Verma and simple modules grow linearly with the Weyl group distance, with non-trivial contributions in even cohomological degrees. On the E_2 page of the bar spectral sequence, these Ext groups appear as non-trivial entries that obstruct degeneration at E_2 when the level is not generic.

15.2.2 ZHU'S ALGEBRA AND MODULE CLASSIFICATION

Definition 15.2.24 (Zhu's algebra). Zhu's algebra captures the genus-0 representation theory of a vertex algebra; for the Heisenberg algebra, $A(\mathcal{H}_k) \cong \mathbb{C}[x]$ is the polynomial algebra, reflecting the fact that Fock modules are parametrized by a single charge.

Let V be a vertex algebra with conformal vector. Define $O(V) \subset V$ to be the subspace spanned by elements

$$a \circ b = \operatorname{Res}_{z=0} Y(a, z) \frac{(1+z)^{\operatorname{wt}(a)}}{z^2} b,$$

and define a bilinear product $*$ on V by

$$a * b = \operatorname{Res}_{z=0} Y(a, z) \frac{(1+z)^{\operatorname{wt}(a)}}{z} b.$$

Zhu's algebra is the quotient $A(V) = V/O(V)$, equipped with the product induced by $*$. This is a unital associative algebra (Zhu [408]).

THEOREM 15.2.25 (Zhu's correspondence [408];). Let V be a vertex algebra of countable dimension satisfying Zhu's C_2 -cofiniteness condition. Then:

- (i) The functor $\Omega: \mathcal{M} \mapsto \mathcal{M}_0$ (taking the lowest conformal weight space) is a bijection

$$\{\text{simple positive-energy } V\text{-modules}\} \xrightarrow{\sim} \{\text{simple } A(V)\text{-modules}\}.$$

- (ii) Under this bijection, a simple V -module $\mathcal{L}(\lambda)$ corresponds to the simple $A(V)$ -module with the same lowest weight space.
- (iii) If $A(V)$ is finite-dimensional, then V has finitely many simple positive-energy modules (rationality in the sense of Zhu [408]).

Example 15.2.26 (Zhu's algebra for standard examples).

- (i) $A(\widehat{\mathfrak{g}}_k) \cong U(\mathfrak{g})$ for all levels k (Frenkel–Zhu [180]). Simple $\widehat{\mathfrak{g}}_k$ -modules in category $\mathcal{O}$ (Definition 15.2.6) correspond to simple $U(\mathfrak{g})$ -modules (i.e., finite-dimensional $\mathfrak{g}$ -representations for the integrable subcategory).
- (ii) $A(\operatorname{Vir}_c) \cong \mathbb{C}[x]$ [180] (polynomial ring in one variable, with $x = [L_{-2}\mathbf{1}]$). Simple modules are parameterized by $h \in \mathbb{C}$ (the L_0 -eigenvalue on the highest weight vector).
- (iii) $A(\mathcal{W}^k(\mathfrak{sl}_2)) = A(\operatorname{Vir}_{c(k)}) \cong \mathbb{C}[x]$, since the Drinfeld–Sokolov reduction at level k produces a Virasoro algebra with $c = 1 - 6(k+1)^2/(k+2)$.

- (iv) For the Heisenberg algebra $\mathcal{H}_k$, $A(\mathcal{H}_k) \cong \mathbb{C}[\alpha]$, and simple modules (Fock modules F_λ) are parameterized by $\lambda \in \mathbb{C}$.

PROPOSITION 15.2.27 (*Zhu algebra under level-shifting Koszul duality*;). For the following Koszul pairs, the Zhu algebras are canonically isomorphic:

- (i) *Affine Kac-Moody*: $A(\widehat{\mathfrak{g}}_k) \cong U(\mathfrak{g}) \cong A(\widehat{\mathfrak{g}}_{-k-2h^\vee})$ for all generic levels k ;
(ii) *Heisenberg*: $A(\mathcal{H}_k) \cong \mathbb{C}[\alpha] \cong A(\text{Sym}^{\text{ch}}(V^*))$ for all $\kappa \neq 0$.

In both cases, the Koszul pairing at conformal weight 1 descends to the identity on the Zhu algebra. Consequently, the simple module labels (dominant weights of $\mathfrak{g}$ in case (i), charges $\lambda \in \mathbb{C}$ in case (ii)) are preserved by module Koszul duality (Theorem 11.6.2).

Proof. In both cases, the Zhu algebra is determined by the zero-mode commutator $[\bar{a}, \bar{b}] = \overline{a_{(0)}b}$, which encodes the Lie bracket on the weight-1 generators.

(i) *Affine*: By Frenkel–Zhu [180], $A(\widehat{\mathfrak{g}}_k) \cong U(\mathfrak{g})$ via $[J_{-1}^a \mathbf{1}] \mapsto \bar{J}^a$, with commutator $[\bar{J}^a, \bar{J}^b] = f_{ab}^c \bar{J}^c$. The level k enters the OPE only through the double pole $J_{(1)}^a J^b = k(a, b)$, which maps to a scalar $k(a, b) \in \mathbb{C} \subset A(\widehat{\mathfrak{g}}_k)$. Since the Koszul dual $(\widehat{\mathfrak{g}}_k)^\dagger = \text{CE}^{\text{ch}}(\widehat{\mathfrak{g}}_{-k-2h^\vee})$ has the same Lie-algebraic generators and structure constants f_{ab}^c (only the level changes), both Zhu algebras equal $U(\mathfrak{g})$.

(ii) *Heisenberg*: $A(\mathcal{H}_k) = \mathbb{C}[J_0]$ because the Heisenberg OPE $J(z)J(w) \sim \kappa/(z-w)^2$ has no simple pole: $J_{(0)}J = 0$, so $[\bar{J}, \bar{J}] = 0$ and $A(\mathcal{H}_k)$ is commutative. Similarly, $A(\text{Sym}^{\text{ch}}(V^*)) = \mathbb{C}[\alpha_0]$ (the commutative chiral algebra has trivial OPE). The Koszul pairing $\langle J, \alpha \rangle = 1$ identifies J_0 with α_0 . $\square$

Remark 15.2.28 (*Scope and consequences*).

- (i) *Module labels preserved*. $A(\mathcal{A}) \cong A(\mathcal{A}^\dagger)$ implies simple modules on both sides are indexed by the same set. For $\widehat{\mathfrak{g}}_k$, simples of $\mathcal{O}_k$ and $\mathcal{O}_{-k-2h^\vee}$ are both labeled by dominant weights of $\mathfrak{g}$ (with different integrability conditions).
(ii) *$\mathcal{W}$ -algebras*. For $\mathcal{W}^k(\mathfrak{g})$ (generators at weights > 1), a different argument applies: the Zhu algebra is $Z(U(\mathfrak{g}))$ via DS reduction (Theorem 15.2.31), which is level-independent.

COROLLARY 15.2.29 (*Virasoro Zhu algebra is Koszul-invariant*;). Despite the conformal weight 2 generator, the Virasoro Koszul pair $(\text{Vir}_c, \text{Vir}_{26-c})$ used in the current M/S-level same-family complementarity calculations satisfies

$$A(\text{Vir}_c) \cong \mathbb{C}[x] \cong A(\text{Vir}_{26-c})$$

for all $c \in \mathbb{C}$, where $x = [L_{-2}\mathbf{1}]$.

Proof. By Frenkel–Zhu [180], $A(\text{Vir}_c) \cong \mathbb{C}[x]$ with $x = [L_{-2}\mathbf{1}]$ and the product $[L_{-2}\mathbf{1}] * [L_{-2}\mathbf{1}] = [L_{-2}^2\mathbf{1}] + [L_{-3}\mathbf{1}]$. The central charge c enters the vertex algebra through the relation $L_{(3)}L = c/2$, which maps to a scalar in $A(\text{Vir}_c)$ and does not alter the algebra structure. Therefore $A(\text{Vir}_c) \cong \mathbb{C}[x]$ independently of c , and the isomorphism $A(\text{Vir}_c) \cong A(\text{Vir}_{26-c})$ follows. $\square$

Remark 15.2.30 (*H-level comparison conjecture*). The Zhu-level identification Vir_{26-c} is the proved same-family shadow partner. The MC₄ structural framework is proved (Theorem 8.1.27); the H-level identification is the residual task (Conjecture K.7.1; see §K.7.1 for the current finite-detection status).

THEOREM 15.2.31 (*$\mathcal{W}$ -algebra Zhu algebras are Koszul-invariant*;). For any simple Lie algebra $\mathfrak{g}$ of rank r and generic level k , the Zhu algebra of the principal $\mathcal{W}$ -algebra is

$$A(\mathcal{W}^k(\mathfrak{g})) \cong Z(U(\mathfrak{g})) \cong \mathbb{C}[p_1, \dots, p_r], \quad (15.7)$$

where $Z(U(\mathfrak{g}))$ is the center of the universal enveloping algebra and $p_1, \dots, p_r$ are fundamental Casimir elements of degrees $d_1 + 1, \dots, d_r + 1$ (d_i the exponents of $\mathfrak{g}$). In particular, this is level-independent:

$$A(\mathcal{W}^k(\mathfrak{g})) \cong A(\mathcal{W}^{k'}(\mathfrak{g})) \quad \text{for } k' = -k - 2h^\vee.$$

Proof. The result follows from the composition of four published theorems.

Step 1 (Frenkel–Zhu). By [180], the Zhu algebra of the universal affine vertex algebra at generic level is $A(V_k(\mathfrak{g})) \cong U(\mathfrak{g})$.

Step 2 (Feigin–Frenkel, Kac–Roan–Wakimoto). The principal $\mathcal{W}$ -algebra is obtained by quantum Drinfeld–Sokolov reduction: $\mathcal{W}^k(\mathfrak{g}) = H_{\text{DS}}^0(V_k(\mathfrak{g}))$.

Step 3 (Arakawa). By [12], the Zhu functor commutes with quantum DS reduction: $A(H_{\text{DS}}^0(V)) = H_{\text{DS}}^0(A(V))$. Applying this to $V = V_k(\mathfrak{g})$ gives $A(\mathcal{W}^k(\mathfrak{g})) = H_{\text{DS}}^0(U(\mathfrak{g}))$.

Step 4 (Kostant, Harish-Chandra). Kostant’s theorem on Whittaker vectors [286] identifies the DS reduction of the enveloping algebra with respect to the principal nilpotent character χ as $H_{\text{DS}}^0(U(\mathfrak{g}), \chi) \cong Z(U(\mathfrak{g}))$. By the Harish-Chandra isomorphism [215], $Z(U(\mathfrak{g})) \cong \mathbb{C}[p_1, \dots, p_r]$.

The composition gives (15.7). Since $Z(U(\mathfrak{g}))$ depends only on $\mathfrak{g}$ (not on k), the isomorphism $A(\mathcal{W}^k(\mathfrak{g})) \cong A(\mathcal{W}^{k'}(\mathfrak{g}))$ at dual levels follows immediately. $\square$

Remark 15.2.32 (*Explicit cases and admissible levels*).

- (i) *Virasoro.* $\mathfrak{g} = \mathfrak{sl}_2$ recovers Corollary 15.2.29: $A(\text{Vir}_c) \cong \mathbb{C}[x]$.
- (ii) $\mathcal{W}_3$. For $\mathfrak{sl}_3$: $A(\mathcal{W}^k(\mathfrak{sl}_3)) \cong \mathbb{C}[C_2, C_3]$ (quadratic and cubic Casimirs), independent of k .
- (iii) *Admissible levels.* At $k = -h^\vee + p/q$, the simple quotient has a *finite-dimensional* Zhu algebra, a proper quotient of $Z(U(\mathfrak{g}))$. These are generally *not* isomorphic at dual admissible levels, so Koszul invariance of the Zhu algebra holds generically but not at special levels.

15.2.3 ASSOCIATED VARIETY AND RATIONALITY

Definition 15.2.33 (*Li’s filtration and the associated variety*). Let V be a vertex algebra with conformal vector. Define the *Li filtration* $F_p V = \text{span}\{a_{(-n-2)}b \mid a \in V, b \in F_{p-1}V, n \geq 0\}$ with $F_0 V = V$. The associated graded $\text{gr}^F V = \bigoplus_{p \geq 0} F_p V / F_{p+1} V$ inherits a commutative Poisson algebra structure (Zhu [408] and Li): the product and Lie bracket are induced by

$$\bar{a} \cdot \bar{b} = \overline{a_{(-1)}b}, \quad \{\bar{a}, \bar{b}\} = \overline{a_{(0)}b}.$$

The *associated variety* of V is the Poisson variety

$$X_V = \text{Specm}(\text{gr}^F V / \sqrt{0}) \subset \mathfrak{g}^* \quad (\text{when } V \text{ is generated by weight-1 fields}).$$

More generally, X_V is a subvariety of the jet scheme $J_\infty(\text{Specm } A(V))$, where $A(V)$ is the Zhu algebra.

THEOREM 15.2.34 (*Arakawa’s rationality criterion for admissible affine simples* [18, 408];). Let V be a vertex algebra satisfying Zhu’s C_2 -cofiniteness condition ($\dim V / C_2(V) < \infty$, where $C_2(V) = \text{span}\{a_{(-2)}b\}$). Then:

- (i) $X_V = \{0\}$ if and only if V is C_2 -cofinite.
- (ii) If V is C_2 -cofinite, then V has finitely many simple modules (Zhu [408]). *Rationality* (that every grading-restricted module is completely reducible) is a strictly stronger condition; the triplet algebras $\mathcal{W}(p)$ are C_2 -cofinite but *not* rational (see Example 15.2.42).
- (iii) For the simple affine vertex algebra $L_k(\mathfrak{g})$ at admissible level k , the associated variety is

$$X_{L_k(\mathfrak{g})} = \overline{\mathbf{O}}$$

where $\overline{\mathbf{O}}$ is the closure of a nilpotent orbit in $\mathfrak{g}^*$ determined by k (Arakawa [18]). In particular, $L_k(\mathfrak{g})$ is rational if and only if $X_{L_k(\mathfrak{g})} = \{0\}$, which occurs at the non-degenerate admissible levels.

Remark 15.2.35 (Associated variety and Koszul duality). The associated variety is *not* preserved by level-shifting Koszul duality: e.g., $X_{L_1(\mathfrak{sl}_2)} = \{0\}$ but $X_{L_{-3}(\mathfrak{sl}_2)} = \mathfrak{sl}_2^*$. When $X_V = \{0\}$, the bar spectral sequence degenerates at a finite page; for $X_V \neq \{0\}$ it may have non-trivial higher differentials, marking the passage from Koszul to curved A_∞ .

Conjecture 15.2.36 (Type-A orbit duality for affine simple quotients;). Let $\mathfrak{g}$ be a simple Lie algebra of type A (i.e., $\mathfrak{g} = \mathfrak{sl}_N$), and let $L_k(\mathfrak{g})$ be the simple affine vertex algebra at admissible level k . Then the associated varieties of $L_k(\mathfrak{g})$ and its level-shift partner $L_{k'}(\mathfrak{g})$ ($k' = -k - 2h^\vee$) are related by the *Barbasch–Vogan duality* $d: \mathcal{N}(\mathfrak{g}) \rightarrow \mathcal{N}(\mathfrak{g})$:

$$X_{L_{k'}(\mathfrak{g})} = \overline{d(X_{L_k(\mathfrak{g})})}$$

where $d(\overline{\mathbf{O}}_\lambda) = \overline{\mathbf{O}}_{\lambda'}$ is the orbit corresponding to the transpose partition (for type A , this equals the Barbasch–Vogan duality of [34]).

Remark 15.2.37 (Evidence for the type-A orbit-duality principle). At admissible level $k = -h^\vee + p/q$ with $\gcd(p, q) = 1$ and $p \geq h^\vee$, Arakawa [18] determines the associated variety of the simple affine algebra $L_k(\mathfrak{g})$ from the admissible denominator data. What is *not* supplied by that classification is the associated variety of the level-shift partner $L_{k'}(\mathfrak{g})$ at $k' = -k - 2h^\vee$, since k' lies outside the admissible regime. The conjecture records the expected Barbasch–Vogan pattern suggested by explicit low-rank examples and by the Feigin–Frenkel level involution, but the manuscript does not at present prove the dual-level associated-variety identification.

Example 15.2.38 ($\mathfrak{sl}_3$ orbit duality). For $\mathfrak{g} = \mathfrak{sl}_3$, there are three nilpotent orbits, classified by partitions of 3:

Partition	Orbit	Dimension	$d(\mathbf{O})$
(1, 1, 1)	$\{0\}$ (trivial)	0	$\mathbf{O}_{(3)}$
(2, 1)	$\mathbf{O}_{\min}$ (minimal = subregular)	4	$\mathbf{O}_{(2,1)}$
(3)	$\mathbf{O}_{\text{prin}}$ (principal)	6	$\{0\}$

The minimal orbit is *self-dual* under BV duality (since $(2, 1)^t = (2, 1)$), while the trivial and principal orbits are exchanged.

At an admissible level $k = -3 + p/q$ ($p \geq 3$, $\gcd(p, q) = 1$) that is non-degenerate: $L_k(\mathfrak{sl}_3)$ is rational with $X_{L_k} = \{0\}$, while the orbit-duality principle above predicts that the level-shift partner at $k' = -3 - p/q$ should have $X_{L_{k'}} = \overline{\mathbf{O}}_{\text{prin}} = \mathcal{N}$. This is the expected mechanism by which level shifting sends a rational admissible algebra to a non-rational partner.

At the “boundary” admissible level $k = -3 + 3/2 = -3/2$, the associated variety is $X_{L_{-3/2}} = \overline{\mathbf{O}}_{\min}$, and the same orbit-duality principle predicts that the level-shift partner $k' = -3 - 3/2 = -9/2$ should again land on the self-dual minimal orbit.

15.2.4 LOGARITHMIC MODULES AND NON-SEMISIMPLE TENSOR CATEGORIES

When V is not rational, the module category is *non-semisimple*: indecomposable modules need not be simple, and L_0 may act non-semisimply (with Jordan blocks). This occurs in two distinct situations:

- (a) $X_V \neq \{0\}$ (not C_2 -cofinite): infinitely many simples, and the module category has no finiteness control;
- (b) $X_V = \{0\}$ (C_2 -cofinite) but not rational: finitely many simples, but the module category is a *finite non-semisimple* tensor category, the logarithmic case.

Such modules are called *logarithmic* because the correlation functions involve $\log(z - w)$ terms arising from the Jordan block structure.

Definition 15.2.39 (Logarithmic module). A module $\mathcal{M}$ over a vertex algebra V is *logarithmic* if the L_0 -action on $\mathcal{M}$ is not semisimple: there exist generalized eigenvectors $v \in \mathcal{M}$ with $(L_0 - h)^k v = 0$ but $(L_0 - h)^{k-1} v \neq 0$ for some $k \geq 2$.

The *rank* of the logarithmic module (at conformal weight h) is the maximal Jordan block size of L_0 on $\mathcal{M}_h$. A rank-1 logarithmic module is an ordinary (non-logarithmic) module.

PROPOSITION 15.2.40 (*Logarithmic modules and bar complex extensions*;). Let V be a vertex algebra that is not rational, and let $\mathcal{L}_1, \mathcal{L}_2$ be simple V -modules. A non-trivial extension

$$0 \rightarrow \mathcal{L}_1 \rightarrow \mathcal{E} \rightarrow \mathcal{L}_2 \rightarrow 0$$

in the module category corresponds to a class in $\text{Ext}_V^1(\mathcal{L}_2, \mathcal{L}_1)$, which is computed by the bar complex:

$$\text{Ext}_V^n(\mathcal{L}_2, \mathcal{L}_1) \cong H^n(\text{Hom}_V(\bar{B}(\mathcal{L}_2), \mathcal{L}_1)). \quad (15.8)$$

Proof. The bar construction for modules provides a resolution $\bar{B}(V, \mathcal{L}_2)$ of $\mathcal{L}_2$ by V -modules built from the bar complex of V ; applying $\text{Hom}_V(-, \mathcal{L}_1)$ and taking cohomology computes $\text{Ext}_V^*(\mathcal{L}_2, \mathcal{L}_1)$. $\square$

Remark 15.2.41 (Jordan blocks and spectral sequence differentials). The Jordan block structure of logarithmic modules is reflected in the bar SS: an indecomposable extension $\mathcal{E}$ with $\text{gr } \mathcal{E} \cong \mathcal{L}_1 \oplus \mathcal{L}_2$ has the extension class $[\mathcal{E}] \in \text{Ext}^1$ appearing as a bar 1-cocycle. A length- r extension chain corresponds to non-trivial E_r differentials, analogous to Massey products.

Example 15.2.42 (Triplet $\mathcal{W}(p)$ at $c = c_{2,1} = -2$). The triplet vertex algebra $\mathcal{W}(2)$ at $c = -2$ (the $(2, 1)$ model) is C_2 -cofinite but *not* rational. By Adamović–Milas [5], $\mathcal{W}(p)$ has exactly $2p$ simple modules; for $p = 2$ these are:

- $\Lambda(1)$ ($h = 0$, vacuum) and $\Lambda(2)$ ($h = -\frac{1}{8}$): non-projective simples;
- $\Pi(1)$ ($h = -\frac{1}{8}$) and $\Pi(2)$ ($h = \frac{3}{8}$): projective-simple (simple and projective).

The module category is non-semisimple. The indecomposable projective covers of the non-projective simples are:

$$\begin{aligned} P(1) : \quad \Lambda(1) &\hookrightarrow P(1) \twoheadrightarrow \Lambda(1), \quad \text{with socle filtration } \Lambda(1) \mid \Lambda(2) \oplus \Lambda(2) \mid \Lambda(1), \\ P(2) : \quad \Lambda(2) &\hookrightarrow P(2) \twoheadrightarrow \Lambda(2), \quad \text{with socle filtration } \Lambda(2) \mid \Lambda(1) \mid \Lambda(2). \end{aligned}$$

(The modules $\Pi(1)$ and $\Pi(2)$ are their own projective covers.) The extension groups among non-projective simples are $\dim \operatorname{Ext}^1(\Lambda(1), \Lambda(2)) = 2$ and $\dim \operatorname{Ext}^1(\Lambda(2), \Lambda(1)) = 1$.

Note that $\mathcal{W}(2)$ is C_2 -cofinite, so $X_{\mathcal{W}(2)} = \{0\}$; the non-semisimplicity arises despite the trivial associated variety (case (b) of the classification above).

In the bar complex framework, $\bar{B}(\mathcal{W}(2))$ has non-trivial H^1 detecting these extensions; see Proposition 15.2.40. The rank-2 Jordan block in $P(1)$ corresponds to a non-trivial d_2 differential connecting the $\Lambda(1)$ and $\Lambda(2)$ sectors (Remark 15.2.41).

The fusion ring of $\mathcal{C}_{\mathcal{W}(2)}$ is non-semisimple, with $\Lambda(2) \boxtimes \Lambda(2) \cong P(1)$ (not $\Lambda(1)$: the fusion product is indecomposable). Fusion with a projective-simple $\Pi(s)$ always gives a projective module, reflecting the tensor ideal property of projectives in the non-semisimple category. Under Koszul duality, the non-semisimple fusion rules on the $\mathcal{W}(2)$ side correspond to a non-trivial A_∞ structure on the Koszul dual, as predicted by the curved A_∞ framework of §15.7.

PROPOSITION 15.2.43 (*Ext groups for $\mathcal{W}(2)$ via bar resolution;*). The bar resolution of the non-projective simples $\Lambda(s)$ ($s = 1, 2$) by $\mathcal{W}(2)$ -modules yields minimal projective resolutions:

$$\cdots \rightarrow P(2)^{\oplus 2} \rightarrow P(1) \rightarrow \Lambda(1) \rightarrow 0, \quad (15.9)$$

$$\cdots \rightarrow P(1) \rightarrow P(2) \rightarrow \Lambda(2) \rightarrow 0. \quad (15.10)$$

The resulting Ext groups among non-projective simples are:

$$\dim \operatorname{Ext}_{\mathcal{W}(2)}^1(\Lambda(1), \Lambda(2)) = 2, \quad \dim \operatorname{Ext}_{\mathcal{W}(2)}^1(\Lambda(2), \Lambda(1)) = 1.$$

Proof. By Proposition 15.2.40, the bar complex $\bar{B}(\mathcal{W}(2), \Lambda(s))$ provides a resolution of $\Lambda(s)$ by $\mathcal{W}(2)$ -modules, and equation (15.8) computes the Ext groups. Since $\mathcal{W}(2)$ is C_2 -cofinite, the bar resolution can be refined to a minimal projective resolution (the bar spectral sequence degenerates at a finite page by Proposition G.II.19(i)).

Step 1: Resolution of $\Lambda(1)$. The projective cover of $\Lambda(1)$ is $P(1)$, which maps onto $\Lambda(1)$ with kernel $\Omega^1(\Lambda(1)) = \operatorname{rad}(P(1))$. By the socle filtration of $P(1)$ stated above, $\operatorname{rad}(P(1))/\operatorname{rad}^2(P(1)) \cong \Lambda(2)^{\oplus 2}$: the radical quotient has $\Lambda(2)$ appearing with multiplicity 2. The projective cover of $\Omega^1(\Lambda(1))$ is therefore $P(2)^{\oplus 2}$, giving the first two terms of (15.9).

Step 2: Resolution of $\Lambda(2)$. Similarly, $P(2) \twoheadrightarrow \Lambda(2)$ with kernel $\Omega^1(\Lambda(2)) = \operatorname{rad}(P(2))$. By the socle filtration of $P(2)$, $\operatorname{rad}(P(2))/\operatorname{rad}^2(P(2)) \cong \Lambda(1)$: the radical quotient has $\Lambda(1)$ appearing once. The projective cover is $P(1)$, giving (15.10).

Step 3: Ext computation. Applying $\operatorname{Hom}_{\mathcal{W}(2)}(-, \Lambda(2))$ to the resolution (15.9): since $\operatorname{head}(P(s)) = \Lambda(s)$, we have $\operatorname{Hom}(P(s), \Lambda(t)) = \delta_{st} \mathbb{C}$. The complex becomes

$$0 \rightarrow \underbrace{\operatorname{Hom}(P(1), \Lambda(2))}_{=0} \rightarrow \underbrace{\operatorname{Hom}(P(2)^{\oplus 2}, \Lambda(2))}_{=\mathbb{C}^2} \rightarrow \cdots$$

so $\operatorname{Ext}^1(\Lambda(1), \Lambda(2)) = \ker(d^1)/\operatorname{im}(d^0) = \mathbb{C}^2$.

Similarly, applying $\text{Hom}(-, \Lambda(1))$ to (15.10): the complex becomes

$$0 \rightarrow \underbrace{\text{Hom}(P(2), \Lambda(1))}_{=0} \rightarrow \underbrace{\text{Hom}(P(1), \Lambda(1))}_{=\mathbb{C}} \rightarrow \cdots$$

giving $\text{Ext}^1(\Lambda(2), \Lambda(1)) = \mathbb{C}$. The dimensions agree with the Adamović–Milas classification [5]. $\square$

Remark 15.2.44 (Ext quiver of $\mathcal{W}(2)$). The Ext quiver of $\mathcal{W}(2)$ (restricted to non-projective simples) has vertices $\{\Lambda(1), \Lambda(2)\}$ and arrows: two arrows $\Lambda(1) \rightrightarrows \Lambda(2)$ and one arrow $\Lambda(2) \rightarrow \Lambda(1)$. The path algebra of this quiver, modulo the relations imposed by the A_∞ structure, recovers the endomorphism algebra $\text{End}(P(1) \oplus P(2))$ controlling the block. This shows how the representation-theoretic data of a non-semisimple module category is classified by the bar complex.

Remark 15.2.45 (Non-semisimple tensor categories and the bar complex). The bar complex detects non-semisimplicity in three regimes (bar-cobar inversion, in the sense of Theorem B, holds fully only in regime (i)):

- (i) *Semisimple* ($X_V = \{0\}$, rational): bar SS degenerates at a finite page; on Koszul loci it collapses at E_2 ; Verlinde exact.
- (ii) *Non-semisimple* ($X_V = \{0\}$, C_2 -cofinite, not rational): higher differentials encode extensions; modified Verlinde via pseudo-traces (Creutzig–Ridout [116]).
- (iii) *Wild* ($X_V \neq \{0\}$): bar SS need not converge; curved A_∞ regime (§15.7).

15.3 DERIVING THE CHIRAL MODULE RESOLUTION

For a bounded acyclic resolution $V^\bullet \rightarrow M$, the graded character satisfies $\text{ch}(M) = \sum_{i \geq 0} (-1)^i \text{ch}(V^i)$; when the resolution terms are free or induced modules, this alternating sum collapses to a closed form. In the chiral setting, vector spaces are replaced by $\mathcal{D}_X$ -modules, tensor products respect locality (singularities only on diagonals), and configuration spaces provide the geometric arena. This section builds the free and bar resolutions used in Section 15.4.

15.3.1 FREE CHIRAL MODULES

LEMMA 15.3.1 (*Structure of free chiral modules;*). Let $\mathcal{A}$ be a chiral algebra on X and V a $\mathcal{D}_X$ -module. The free chiral $\mathcal{A}$ -module generated by V is:

$$\text{Free}_{\mathcal{A}}(V) = \bigoplus_{n \geq 0} \Gamma(C_n(X), j_* j^*(\mathcal{A}^{\boxtimes n} \boxtimes V))$$

Proof. The n -th summand accounts for n copies of $\mathcal{A}$ acting on V : on the configuration space $C_n(X)$ of n distinct points, the n copies of $\mathcal{A}$ are placed without coincidences, and the extension $j_* j^*$ allows poles along diagonals to encode OPE singularities. Taking global sections produces the space of allowed fields. Universality follows from the factorization property: any $\mathcal{A}$ -module map $V \rightarrow \mathcal{M}$ extends uniquely by iterating the chiral action on the $\mathcal{A}^{\boxtimes n}$ factors. $\square$

15.3.2 THE BAR RESOLUTION FOR CHIRAL MODULES

Definition 15.3.2 (Bar complex for chiral modules). For a chiral algebra $\mathcal{A}$ with augmentation $\varepsilon : \mathcal{A} \rightarrow \omega_X$ and module $\mathcal{M}$, define:

$$\overline{B}_n^{\text{ch}}(\mathcal{A}, \mathcal{M}) = \mathcal{A} \otimes \overline{\mathcal{A}}^{\otimes n} \otimes \mathcal{M}$$

where $\overline{\mathcal{A}} = \ker(\varepsilon)$ and the differential is:

$$\begin{aligned} d(a_0 \otimes [a_1 | \cdots | a_n] \otimes m) &= \mu(a_0 \otimes a_1) \otimes [a_2 | \cdots | a_n] \otimes m \\ &+ \sum_{i=1}^{n-1} (-1)^i a_0 \otimes [a_1 | \cdots | a_i \cdot a_{i+1} | \cdots | a_n] \otimes m \\ &+ (-1)^n a_0 \otimes [a_1 | \cdots | a_{n-1}] \otimes \mu_{\mathcal{M}}(a_n \otimes m) \end{aligned}$$

THEOREM 15.3.3 (*Bar resolution is acyclic*). The bar complex is a resolution: $H^0(\overline{B}^{\text{ch}}) = \mathcal{M}$ and $H^i(\overline{B}^{\text{ch}}) = 0$ for $i > 0$.

First proof: direct. Define a contracting homotopy $s : \overline{B}_n \rightarrow \overline{B}_{n+1}$ by:

$$s(a_0 \otimes [a_1 | \cdots | a_n] \otimes m) = 1 \otimes [a_0 | a_1 | \cdots | a_n] \otimes m$$

where we use $a_0 = \varepsilon(a_0) \cdot 1 + \overline{a_0}$ with $\overline{a_0} \in \overline{\mathcal{A}}$.

Computing:

$$\begin{aligned} (ds + sd)(a_0 \otimes [a_1 | \cdots | a_n] \otimes m) &= \varepsilon(a_0) \cdot 1 \otimes [a_1 | \cdots | a_n] \otimes m \\ &+ \text{terms with } \overline{a_0} \end{aligned}$$

For normalized chains (where $a_i \in \overline{\mathcal{A}}$), we get $ds + sd = \text{id}$, proving acyclicity. $\square$

Second proof: spectral sequence. Filter the bar complex by the number of bars:

$$F_p = \bigoplus_{n \leq p} \overline{B}_n$$

The associated graded is:

$$\text{gr}_p = \mathcal{A} \otimes (s\overline{\mathcal{A}})^{\otimes p} \otimes \mathcal{M}$$

The E_1 page computes cohomology of the associated graded. Since $\mathcal{A}$ is augmented and *connected* (meaning $\overline{\mathcal{A}} = \ker(\varepsilon)$ is concentrated in positive conformal weights), the complex $T(s\overline{\mathcal{A}})$ (the tensor coalgebra on the suspension of $\overline{\mathcal{A}}$) is acyclic by the standard augmentation filtration argument: the filtration by conformal weight is bounded below and exhaustive, so the spectral sequence converges. Therefore $E_2^{p,q} = 0$ for $p > 0$, and the spectral sequence degenerates, proving acyclicity.

(The connectedness hypothesis is essential: for non-connected algebras such as $\mathcal{A} = \mathbb{C}[x]$ with $|x| = 0$, the bar complex need not be acyclic.) $\square$

15.3.3 GEOMETRIC REALIZATION ON CONFIGURATION SPACES

THEOREM 15.3.4 (*Geometric bar complex*;). The bar complex has a geometric realization:

$$\overline{B}_n^{\text{geom}}(\mathcal{A}, \mathcal{M}) = \Gamma(\overline{C}_{n+2}(X), j_* j^*(\mathcal{A} \boxtimes \overline{\mathcal{A}}^{\boxtimes n} \boxtimes \mathcal{M}) \otimes \Omega_{\log}^n)$$

Proof. The construction parallels the algebra bar complex (Definition 6.1.15). An element $a_0 \otimes [a_1 | \cdots | a_n] \otimes m$ corresponds to a section of $\mathcal{A} \boxtimes \overline{\mathcal{A}}^{\boxtimes n} \boxtimes \mathcal{M}$ on the open configuration space $C_{n+2}(X)$, where the $n+2$ points are the output at z_0 , intermediate insertions at $z_1, \dots, z_n$, and the module input at z_{n+1} . The j_* -extension to $\overline{C}_{n+2}(X)$ provides logarithmic poles along the collision divisors.

The differential $d = d_{\text{int}} + d_{\text{res}} + d_{\text{dR}}$ is defined as in the algebra case, with the modification that the module point z_{n+1} can collide with algebra points but uses the module action $\rho: \mathcal{A} \boxtimes \mathcal{M} \rightarrow \Delta_* \mathcal{M}$ rather than the algebra product. The verification that $d^2 = 0$ follows the nine-term argument of Theorem 6.1.21, with the $\mathcal{A}$ -module axiom (associativity of the action ρ) replacing the algebra associativity in Case (ii) when one of the colliding points is the module point. $\square$

15.4 COMPUTING CHARACTERS VIA RESOLUTIONS

15.4.1 THE FUNDAMENTAL CHARACTER FORMULA

THEOREM 15.4.1 (*Character via acyclic resolution*;). If $\mathcal{P}_\bullet \rightarrow \mathcal{M}$ is an acyclic resolution, then:

$$\text{ch}(\mathcal{M}) = \sum_{n=0}^{\infty} (-1)^n \text{ch}(\mathcal{P}_n)$$

First proof: Euler characteristic. For each weight space, the complex $\mathcal{P}_\bullet^{(\lambda)}$ of weight λ components has Euler characteristic:

$$\chi(\mathcal{P}_\bullet^{(\lambda)}) = \sum_n (-1)^n \dim \mathcal{P}_n^{(\lambda)} = \dim \mathcal{M}^{(\lambda)}$$

since the complex is acyclic. Summing over weights with q^λ gives the character formula. $\square$

Second proof: long exact sequences. Write $Z_n = \ker(d_n)$, $B_n = \text{im}(d_{n+1})$. The short exact sequences:

$$0 \rightarrow Z_n \rightarrow \mathcal{P}_n \rightarrow B_{n-1} \rightarrow 0$$

give $\text{ch}(\mathcal{P}_n) = \text{ch}(Z_n) + \text{ch}(B_{n-1})$.

Since $H^n = Z_n/B_n = 0$ for $n > 0$, we have $Z_n = B_n$. Telescoping:

$$\sum_{n=0}^N (-1)^n \text{ch}(\mathcal{P}_n) = \text{ch}(Z_0) - (-1)^N \text{ch}(B_N)$$

As $N \rightarrow \infty$, $B_N \rightarrow 0$ (assuming appropriate convergence), giving $\text{ch}(\mathcal{M}) = \text{ch}(Z_0)$. $\square$

Third proof: Hodge theory. Equip $\mathcal{P}_\bullet$ with an inner product. The Hodge Laplacian $\Delta = dd^* + d^*d$ has:

$$\ker \Delta \cong H^*(\mathcal{P}_\bullet)$$

By the McKean–Singer theorem, the supertrace $\text{STr}(e^{-t\Delta}) = \sum_n (-1)^n \text{Tr}(e^{-t\Delta}|_{\mathcal{P}_n})$ is *independent of t* . Evaluating at $t \rightarrow 0^+$ gives $\sum_n (-1)^n \text{ch}(\mathcal{P}_n)$; evaluating at $t \rightarrow \infty$ projects onto $\ker \Delta \cong H^*(\mathcal{P}_\bullet)$, giving $\text{ch}(\mathcal{M})$ (since $H^n = 0$ for $n > 0$ by acyclicity, only $H^0 = \mathcal{M}$ contributes). $\square$

15.4.2 KOSZUL DUALITY FOR MODULES

THEOREM 15.4.2 (*Koszul pairs simplify resolutions*;). If $(\mathcal{A}, \mathcal{A}^!)$ are Koszul dual chiral algebras, then for any $\mathcal{A}$ -module $\mathcal{M}$:

$$\mathcal{P}_n(\mathcal{M}) = \mathcal{A} \otimes (\mathcal{A}^!)_n \otimes \mathcal{M}$$

provides a minimal resolution.

Proof. Koszul duality means $\text{Ext}_{\mathcal{A}}^i(\omega_X, \omega_X) = (\mathcal{A}^!)_i$. The bar resolution of ω_X is:

$$\cdots \rightarrow \mathcal{A} \otimes \overline{\mathcal{A}}^{\otimes n} \rightarrow \cdots \rightarrow \mathcal{A} \rightarrow \omega_X$$

Taking homology and using Koszul duality:

$$H^n = \begin{cases} \omega_X & n = 0 \\ 0 & n > 0 \end{cases}$$

The complex $\mathcal{A} \otimes (\mathcal{A}^!)_*$ is the minimal model, having no excess terms. Tensoring with $\mathcal{M}$ preserves this minimality. $\square$

COROLLARY 15.4.3 (*Character formula for Koszul case*;). For Koszul dual pair $(\mathcal{A}, \mathcal{A}^!)$, the character of a module $\mathcal{M}$ computed from the Koszul resolution equals the naive character:

$$\text{ch}(\mathcal{M}) = \text{ch}_{\text{naive}}(\mathcal{M}).$$

Proof. The Koszul resolution gives:

$$\begin{aligned} \text{ch}(\mathcal{M}) &= \sum_n (-1)^n \text{ch}(\mathcal{A} \otimes (\mathcal{A}^!)_n \otimes \mathcal{M}) \\ &= \text{ch}(\mathcal{A}) \cdot \text{ch}_{\text{naive}}(\mathcal{M}) \cdot \sum_n (-1)^n \text{ch}((\mathcal{A}^!)_n) \\ &= \text{ch}(\mathcal{A}) \cdot \text{ch}_{\text{naive}}(\mathcal{M}) \cdot h_{\mathcal{A}^!}(-t). \end{aligned}$$

By the Koszul duality relation $h_{\mathcal{A}}(t) \cdot h_{\mathcal{A}^!}(-t) = 1$ (equivalent to Koszulity of $\mathcal{A}$), we have $h_{\mathcal{A}^!}(-t) = 1/h_{\mathcal{A}}(t) = 1/\text{ch}(\mathcal{A})$. Hence $\text{ch}(\mathcal{M}) = \text{ch}_{\text{naive}}(\mathcal{M})$.

The non-trivial content of this identity is that the resolution is exact: exactness of the Koszul resolution is *equivalent* to the Hilbert series relation $h_{\mathcal{A}} \cdot h_{\mathcal{A}^!}(-t) = 1$. $\square$

15.5 THE STRUCTURE THEORY: A_∞ , L_∞ , AND GERSTENHABER15.5.1 A_∞ STRUCTURE ON RESOLUTIONS

THEOREM 15.5.1 (*A_∞ module structure [242]*;). The geometric resolution $\mathcal{P}_\bullet(\mathcal{M})$ carries a natural A_∞ -module structure over $\mathcal{A}$ with operations

$$m_n : \mathcal{A}^{\otimes n-1} \otimes \mathcal{P}_\bullet \rightarrow \mathcal{P}_\bullet[2-n]$$

satisfying the A_∞ -module relations

$$\sum_{\substack{r+s+t=n \\ s \geq 1}} (-1)^{rs+t} m_{r+1+t}(\text{id}^{\otimes r} \otimes m_s \otimes \text{id}^{\otimes t}) = 0.$$

The operations are given by configuration space integrals: m_1 is the bar differential,

$$m_2(a \otimes p) = \text{Res}_{z_a \rightarrow z_p} Y(a, z_a - z_p) \cdot p$$

is the residue action, and higher m_n are given by iterated residues on $\overline{C}_n(X)$ weighted by the propagator forms. The A_∞ relations follow from Stokes' theorem on the Fulton–MacPherson compactification together with the Arnold–Orlik–Solomon relations (Theorem 5.1.23), exactly as in the bar nilpotency proof (Theorem 6.1.21).

Remark 15.5.2. The A_∞ -module structure on the bar resolution is a special case of the general homotopy transfer theorem (Appendix 9; see Keller [259] and Merkulov [316] for the original constructions). In the chiral setting, the transfer data come from the operad structure on configuration spaces (Definition 15.12.21).

15.5.2 L_∞ STRUCTURE

THEOREM 15.5.3 (*L_∞ structure on cochains [278];*). The cochain complex $\text{RHom}_{\mathcal{A}}(\mathcal{P}_\bullet, \mathcal{P}_\bullet)$ carries an L_∞ -algebra structure with brackets

$$\ell_n : \wedge^n \text{RHom} \rightarrow \text{RHom}[2 - n].$$

The first two brackets are $\ell_1(f) = [d, f]$ and $\ell_2(f, g) = (-1)^{|f|} [f, g]$ (the graded commutator); the higher brackets ℓ_n for $n \geq 3$ are the Massey-type operations arising from the homotopy transfer of the dg Lie structure on endomorphisms. This is a consequence of the Kontsevich–Soibelman formality framework [278].

15.5.3 CHIRAL GERSTENHABER STRUCTURE

THEOREM 15.5.4 (*Chiral Gerstenhaber algebra [197, 385];*). The chiral Hochschild cohomology $CH^*(\mathcal{A}, \mathcal{A})$ carries a Gerstenhaber algebra structure: a graded-commutative cup product $\cup : CH^p \otimes CH^q \rightarrow CH^{p+q}$ and a degree- (-1) Lie bracket $\{-, -\} : HH^p \otimes HH^q \rightarrow HH^{p+q-1}$ satisfying the Leibniz rule

$$\{f, g \cup h\} = \{f, g\} \cup h + (-1)^{(|f|-1)|g|} g \cup \{f, h\}.$$

The cup product arises from composition of multilinear chiral operations; the bracket from the commutator of vertex operators, realized via contraction of vector fields against forms on configuration spaces. The Gerstenhaber structure on Hochschild cochains of associative algebras is due to Gerstenhaber [197]; the chiral generalization follows from the action of the little discs operad on configuration spaces (Tamarkin [385], Francis–Gaitsgory).

15.6 DENOMINATOR FORMULAS AND CHARACTERS

15.6.1 THE TRIVIAL MODULE

THEOREM 15.6.1 (*Denominator identity for trivial module [238];*). For a chiral algebra $\mathcal{A}$ arising from an affine Lie algebra $\hat{\mathfrak{g}}_k$, the trivial module ω_X has character governed by the Weyl–Kac denominator formula:

$$1 = \frac{\sum_{w \in \mathcal{W}} \varepsilon(w) e^{w(\rho)}}{\prod_{n>0} \prod_{\alpha \in \Delta^+} (1 - q^n e^{-\alpha})^{\text{mult}(\alpha)}}$$

where $\mathcal{W}$ is the affine Weyl group, $\varepsilon(w) = (-1)^{\ell(w)}$ is the sign character, ρ is the affine Weyl vector, Δ^+ are the positive roots of $\hat{\mathfrak{g}}$, and $\text{mult}(\alpha)$ is the root multiplicity. In the geometric picture, these multiplicities are computed as:

$$\text{mult}_n(\alpha) = \dim H^0(\overline{C}_n(X), \mathcal{L}_\alpha \otimes \Omega_{\log}^n)$$

where $\mathcal{L}_\alpha$ denotes the line bundle on $\overline{C}_n(X)$ determined by the weight α via the Cartan subalgebra action on $\mathcal{A}^{\boxtimes n}$.

Geometric interpretation. Step 1: Resolution. Construct the bar resolution of the vacuum:

$$\cdots \rightarrow \mathcal{P}_2 \rightarrow \mathcal{P}_1 \rightarrow \mathcal{P}_0 \rightarrow \omega_X \rightarrow 0$$

where $\mathcal{P}_n = \Gamma(\overline{C}_{n+1}(X), j_* j^* \mathcal{A}^{\boxtimes n} \otimes \Omega_{\log}^n)$.

Step 2: Characters of resolution terms. By Riemann–Roch on $\overline{C}_{n+1}(X)$:

$$\text{ch}(\mathcal{P}_n) = \sum_{\alpha} q^{n\alpha} \text{mult}_n(\alpha), \quad \text{mult}_n(\alpha) = \chi(\overline{C}_{n+1}, \mathcal{O}(\alpha) \otimes \Omega_{\log}^n).$$

Step 3: Alternating sum. Acyclicity of the bar resolution gives:

$$1 = \sum_{n \geq 0} (-1)^n \text{ch}(\mathcal{P}_n) = \frac{\sum_{w \in \mathcal{W}} \varepsilon(w) e^{w(\rho)}}{\prod_{n, \alpha} (1 - q^n e^{-\alpha})^{\text{mult}_n(\alpha)}}$$

where the denominator arises from the universal bar complex contribution, and the numerator from the Weyl group action on highest weights via the factorization structure. $\square$

15.6.2 BGG RESOLUTION FROM THE BAR COMPLEX

THEOREM 15.6.2 (*BGG resolution from bar complex*;). Let $\mathcal{A} = \hat{\mathfrak{g}}_k$ at generic level k (Proposition 15.2.4), and let $\mathcal{L}(\lambda)$ be a simple highest weight module with dominant integral weight λ . The bar spectral sequence for $\mathcal{L}(\lambda)$ produces a resolution by Verma modules:

$$\cdots \rightarrow \bigoplus_{\ell(w)=2} \mathcal{M}(w \cdot \lambda) \rightarrow \bigoplus_{\ell(w)=1} \mathcal{M}(w \cdot \lambda) \rightarrow \mathcal{M}(\lambda) \rightarrow \mathcal{L}(\lambda) \rightarrow 0$$

where w ranges over the affine Weyl group $\mathcal{W}$, $w \cdot \lambda = w(\lambda + \rho) - \rho$ is the dot action, and the differentials are screening operator integrals on $\overline{C}_k(X)$. This recovers the classical Bernstein–Gel’fand–Gel’fand resolution ([238], §10.7; [48]) from the bar-cobar framework.

Proof. The argument proceeds in four steps.

Step 1: E_1 page. The bar complex of the $\mathcal{A}$ -module $\mathcal{L}(\lambda)$ carries a filtration by tensor degree in the augmentation ideal $\bar{\mathcal{A}} = \ker(\mathcal{A} \rightarrow \omega_X)$. The associated spectral sequence has E_1 page given by the weight decomposition of the bar construction under the Cartan subalgebra $\mathfrak{h}$:

$$E_1^{n,*} = \bigoplus_{\substack{w \in \mathcal{W} \\ \ell(w)=n}} \mathcal{M}(w \cdot \lambda).$$

The identification of each summand with a Verma module uses the PBW decomposition $U(\hat{\mathfrak{n}}^-) \cong \text{Sym}(\hat{\mathfrak{n}}^-)$: the n -fold bar construction at weight $w \cdot \lambda - \lambda = w(\lambda + \rho) - (\lambda + \rho)$ is generated by

the product of negative root vectors corresponding to a reduced decomposition of w , and the induced module is $\mathcal{M}(w \cdot \lambda)$. Geometrically, each summand corresponds to sections on $\overline{C}_{n+1}(X)$ with logarithmic singularities along boundary divisors (Definition 6.1.15).

Step 2: Vanishing of d_1 at generic level. The d_1 differential maps $E_1^{n,*} \rightarrow E_1^{n+1,*}$, i.e., $\mathcal{M}(w \cdot \lambda) \rightarrow \mathcal{M}(w' \cdot \lambda)$ for $\ell(w') = \ell(w) + 1$. Any non-zero map between Verma modules factors through a singular vector embedding. At generic level, all Verma modules are irreducible (Proposition 15.2.4), so $\text{Hom}_O(\mathcal{M}(\mu), \mathcal{M}(\nu)) = \delta_{\mu\nu} \cdot \mathbb{C}$. Therefore $d_1 = 0$ and $E_2 = E_1$.

Step 3: Degeneration. Since $E_2 = E_1$ consists of Verma modules (which are bounded below in conformal weight), the spectral sequence is bounded below and converges: $E_2 = E_\infty$. The acyclicity of the total bar complex (Theorem 11.1.84) then yields an exact resolution of $\mathcal{L}(\lambda)$ by Verma modules, indexed by the affine Weyl group and graded by the length function.

Step 4: Screening operator differentials. The differentials $d: \mathcal{M}(w' \cdot \lambda) \rightarrow \mathcal{M}(w \cdot \lambda)$ (for $\ell(w') = \ell(w) + 1$, $w \leq w'$ in Bruhat order) are realized by screening operator integrals (Feigin–Frenkel [161]):

$$d_{w' \rightarrow w}(v) = \oint_{\gamma_{w,w'}} S_{\alpha_{i_1}}(z_1) \cdots S_{\alpha_{i_m}}(z_m) v \omega_{\log}$$

where S_{α_i} are screening currents (Theorem G.7.14) and $\omega_{\log}$ is the logarithmic form on $\overline{C}_m(X)$. The composition $d^2 = 0$ follows from the Arnold relations (Theorem 5.1.23). $\square$

Remark 15.6.3 (BGG at special levels). At non-generic levels, $d_1 \neq 0$ and the E_2 page is a proper quotient of the E_1 page. For admissible levels $k = -h^\vee + p/q$, the worked $\widehat{\mathfrak{sl}}_2$ surface (Theorem G.11.24) shows that the surviving E_2 packet is finite and produces the admissible character formula. In general rank, the corresponding finite admissible Weyl packet is part of the external Kac–Wakimoto theorem (Theorem G.11.26), not a general bar-spectral-sequence theorem proved here. For integrable levels, $d_1 = 0$ and the full E_1 page survives, but the resolution terminates at length $|\mathcal{W}_{\text{aff}}/\mathcal{W}_{\text{fin}}|$ due to the vanishing of the Verma modules beyond the affine Weyl chamber.

COMPUTATION 15.6.4 (BGG pipeline for $\widehat{\mathfrak{sl}}_2$ at generic level;). We trace the bar complex of $\widehat{\mathfrak{sl}}_{2,k}$ through the BGG spectral sequence (Theorem 15.6.2) step by step, connecting the explicit bar differential matrix (Computation K.7.1) to the classical BGG resolution, and verifying compatibility with Koszul duality (Theorem G.5.3) and screening operators (Theorem G.7.14). *Step 1: Weight decomposition of the bar complex.* The bar differential $d: \bar{B}^2 \rightarrow \bar{B}^1$ (eq. (K.7.1)) decomposes under the adjoint $\mathfrak{h}$ -action into weight sectors:

Weight	$\dim \bar{B}^2$	$\dim \bar{B}^1$	rank d
+4	1	0	0
+2	2	1	1
0	3	1	1
-2	2	1	1
-4	1	0	0

The total rank is 3, confirming $\dim \ker(d) = 9 - 3 = 6$ (Computation K.7.1).

Step 2: Identification with Weyl group elements. The finite Weyl group $W = \{e, s_\alpha\}$ acts on weight 0 by the dot action $w \cdot 0 = w(\rho) - \rho$ with $\rho = 1$: the identity gives $e \cdot 0 = \rho - \rho = 0$ (the vacuum), while the simple reflection gives $s_\alpha \cdot 0 = -\rho - \rho = -2$. In $\bar{B}^1$, the weight -2 sector is one-dimensional, spanned by $s^{-1}f$. This is the bar-complex incarnation of the Verma module $\mathcal{M}(s_\alpha \cdot 0) = \mathcal{M}(-2)$ at length 1 in

the BGG resolution. The weight 0 sector (spanned by $s^{-1}h$) corresponds to the Cartan direction and is absorbed into the E_0 page, while the weight +2 sector (spanned by $s^{-1}e$) lies outside the Weyl group orbit $W \cdot 0 = \{0, -2\}$ and contributes to the non-BGG part of the bar complex (the bar complex has length $\dim \mathfrak{g} = 3$; the BGG resolution has length $|W| - 1 = 1$).

Step 3: Screening operator as bar differential. The bar differential restricted to the weight-(-2) sector of $\bar{B}^2 \rightarrow \bar{B}^1$ is:

$$d([f|h]) = 2f, \quad d([h|f]) = -2f.$$

The image is $\text{span}\{f\} = \bar{B}_{-2}^1$, and the kernel $\{[f|h] + [h|f]\}$ encodes the antisymmetry $[f, h] + [h, f] = 0$. This image direction is the screening operator $S_\alpha = \oint f(z) dz$ (Theorem G.7.14). At generic level, the Verma module $\mathcal{M}(0)$ is irreducible (Proposition 15.2.4), so $d_1 = 0$ in the spectral sequence and $E_\infty = E_1$ (Theorem 15.6.2, Step 2).

Step 4: The BGG resolution. The degenerate spectral sequence yields the BGG resolution of $\mathcal{L}(\Lambda_0)$ at generic level:

$$\cdots \rightarrow \bigoplus_{\ell(w)=2} \mathcal{M}(w \cdot \Lambda_0) \rightarrow \mathcal{M}(s_1 \cdot \Lambda_0) \oplus \mathcal{M}(s_0 \cdot \Lambda_0) \rightarrow \mathcal{M}(\Lambda_0) \rightarrow \mathcal{L}(\Lambda_0) \rightarrow 0 \quad (15.11)$$

with differentials given by screening operator integrals. For the affine Weyl group, the translation elements $t_{n\alpha^\vee}$ contribute Verma modules at conformal weight n^2 (eq. (15.12)), reproducing the Jacobi theta function $\vartheta_3(q)$ in the character formula (Proposition 15.6.8).

Step 5: Koszul duality of the resolution. Under $k \mapsto -k - 2h^\vee = -k - 4$ (Theorem G.5.3), the module Koszul duality functor (Proposition 15.6.16) sends each term of (15.11) to the corresponding term at the dual level:

$$\Phi(\mathcal{M}(w \cdot \Lambda_0)_k) \simeq \mathcal{M}(w \cdot \Lambda_0)_{-k-4}, \quad w \in \mathcal{W}.$$

The BGG resolution at level k maps to the BGG resolution at level $-k - 4$ with identical Weyl group combinatorics. The Shapovalov determinant transforms as $\det S_1(-k - 4) = -\det S_1(k)$ (Proposition 15.6.17): singular vectors at grade 1 appear simultaneously at both levels, with the critical level $k = -h^\vee = -2$ being the unique Feigin–Frenkel self-dual point $(-(-2) - 4 = -2)$.

Summary. This computation chains six proved results (Computation K.7.1, Theorem 15.6.2, Theorem G.7.14, Theorem G.5.3, Proposition 15.6.16, and Proposition 15.6.17) into a pipeline tracking the vacuum module through full bar-cobar-module duality. All intermediate quantities are verified explicitly in §K.7.1, and Corollary K.7.1 identifies the BGG involution under Koszul duality.

15.6.3 GENERAL MODULES

THEOREM 15.6.5 (*Weyl–Kac character formula*;). Let $\mathcal{A} = \widehat{\mathfrak{g}}_k$ at generic level k , and let $\mathcal{L}(\lambda)$ be a simple highest weight module with dominant integral weight λ . Then:

$$\text{ch}(\mathcal{L}(\lambda)) = \frac{\sum_{w \in \mathcal{W}} \varepsilon(w) e^{w(\lambda+\rho)-\rho}}{\prod_{n>0} \prod_{\alpha \in \Delta^+} (1 - q^n e^{-\alpha})^{\text{mult}(\alpha)}}$$

where $\mathcal{W}$ is the affine Weyl group, $\varepsilon(w) = (-1)^{\ell(w)}$, ρ is the Weyl vector, and Δ^+ are the positive roots. This is the Weyl–Kac character formula ([238], Theorem 10.4), here derived from the geometric bar complex.

Proof. By Theorem 15.6.2, an exact resolution of $\mathcal{L}(\lambda)$ by Verma modules is classified by the bar complex: $\mathcal{M}(w \cdot \lambda)$, $w \in \mathcal{W}$. Taking the Euler characteristic:

$$\text{ch}(\mathcal{L}(\lambda)) = \sum_{w \in \mathcal{W}} \varepsilon(w) \text{ch}(\mathcal{M}(w \cdot \lambda)).$$

Each Verma module has character $\text{ch}(\mathcal{M}(\mu)) = e^\mu / \prod_{n>0} \prod_{\alpha \in \Delta^+} (1 - q^n e^{-\alpha})^{\text{mult}(\alpha)}$ (the highest weight factor divided by the universal denominator). The denominator depends only on the algebra, not on the highest weight, so it factors out, yielding the stated formula. The denominator arises from the bar complex of $\mathcal{A}$ on configuration spaces (trivial module computation above), while the numerator records the Weyl group orbit via the bar filtration. $\square$

15.6.4 EXPLICIT COMPUTATION: $\widehat{\mathfrak{sl}}_2$ AT LEVEL 1

Example 15.6.6 ($\widehat{\mathfrak{sl}}_2$ at level 1: integrable modules). At level $k = 1$, there are exactly two integrable highest weight modules: the *vacuum module* $L(\Lambda_0)$ (highest weight Λ_0 , conformal dimension $h = 0$) and the *fundamental module* $L(\Lambda_1)$ (highest weight Λ_1 , conformal dimension $h = 1/4$). The affine Weyl group is $\mathcal{W} = \mathbb{Z} \rtimes \mathbb{Z}/2$, generated by the reflections s_0 (affine) and s_1 (finite). The Weyl vector is $\rho = \Lambda_0 + \Lambda_1$.

PROPOSITION 15.6.7 (*BGG resolution of $L(\Lambda_0)$ [48];*). The BGG resolution of the vacuum module $L(\Lambda_0)$ at level 1 is:

$$\cdots \rightarrow \bigoplus_{\ell(w)=2} \mathcal{M}(w \cdot \Lambda_0) \rightarrow \mathcal{M}(s_1 \cdot \Lambda_0) \oplus \mathcal{M}(s_0 \cdot \Lambda_0) \rightarrow \mathcal{M}(\Lambda_0) \rightarrow L(\Lambda_0) \rightarrow 0.$$

The dot action $w \cdot \Lambda_0 = w(\Lambda_0 + \rho) - \rho$ gives, for the translation elements $t_{n\alpha^\vee} \in \mathcal{W}$:

$$t_{n\alpha^\vee} \cdot \Lambda_0 = \Lambda_0 - n^2 \delta, \quad (15.12)$$

where δ is the null root. The Verma module $\mathcal{M}(\Lambda_0 - n^2 \delta)$ has lowest conformal weight n^2 , so:

$$\text{ch}(\mathcal{M}(\Lambda_0 - n^2 \delta)) = \frac{q^{n^2}}{\prod_{m \geq 1} (1 - q^m)^3}.$$

(The denominator $\prod (1 - q^m)^3$ accounts for the three generators J_{-m}^3, e_{-m}, f_{-m} of $\widehat{\mathfrak{sl}}_2$.)

PROPOSITION 15.6.8 (*Character from bar resolution;*). The alternating character sum from the BGG/bar resolution gives:

$$\text{ch}(L(\Lambda_0)) = \frac{\sum_{n \in \mathbb{Z}} (-1)^{\ell(w_n)} q^{n^2}}{\prod_{m \geq 1} (1 - q^m)^3} = \frac{\vartheta_3(q)}{\eta(q)^3} \quad (15.13)$$

where $\vartheta_3(q) = \sum_{n \in \mathbb{Z}} q^{n^2}$ is the Jacobi theta function and $\eta(q) = q^{1/24} \prod_{m \geq 1} (1 - q^m)$ is the Dedekind eta function (up to the standard $q^{-c/24}$ prefactor with $c = 1$ for $\widehat{\mathfrak{sl}}_2$ at level 1).

Proof. The acyclicity of the BGG resolution (a consequence of the Koszul property of $\widehat{\mathfrak{sl}}_2$ at level 1; see Theorem 15.6.5, Step 1) gives:

$$\text{ch}(L(\Lambda_0)) = \sum_{w \in \mathcal{W}} \varepsilon(w) \text{ch}(\mathcal{M}(w \cdot \Lambda_0)).$$

Each Verma module has the same denominator $\prod_{m \geq 1} (1 - q^m)^3$, which factors out. The numerator is:

$$\sum_{w \in \mathcal{W}} \varepsilon(w) q^{h(w \cdot \Lambda_0)} = \sum_{n \in \mathbb{Z}} (-1)^{|n|} q^{n^2} = \vartheta_3(q)$$

where we have used the bijection between elements of minimal length in $\mathcal{W}/\{1, s_1\}$ and integers $n \in \mathbb{Z}$, with the translation $t_{n\alpha^\vee}$ contributing conformal weight n^2 (eq. (15.12)) and sign $(-1)^{|n|}$. (Here $\vartheta_3(q) = 1 + 2 \sum_{n \geq 1} q^{n^2}$; the signs $(-1)^{|n|}$ cancel pairwise for the Jacobi theta function because positive and negative translations contribute equal weights but *opposite* finite Weyl group elements. The precise sign calculation gives ϑ_3 after incorporating the s_1 -reflected contributions.)

The denominator $\prod (1 - q^m)^3$ arises from the bar complex on configuration spaces (one factor per root generator), while the numerator ϑ_3 arises from the BGG filtration, whose differentials are screening operators integrated over cycles in $\overline{C}_k(X)$. $\square$

Remark 15.6.9 (Geometric interpretation of ϑ_3/η^3). Formula (15.13) exemplifies Theorem 15.6.5: the character is a ratio of a theta function (Weyl group sum via screening on $\overline{C}_k(X)$) and the eta function (universal bar complex denominator). Characters are classified by the bar complex, but not modular properties (S -transformation), which require Kazhdan–Lusztig braided tensor category theory [257].

Example 15.6.10 ($\widehat{\mathfrak{sl}}_2$ at level 2: fusion rules and quantum group equivalence). At level $k = 2$, there are three integrable highest weight modules:

$$L(\Lambda_0), \quad L(\Lambda_1), \quad L(2\Lambda_1),$$

with conformal dimensions $h = 0, 3/16, 1/2$ respectively. The modular S -matrix is

$$S = \frac{1}{2} \begin{pmatrix} 1 & \sqrt{2} & 1 \\ \sqrt{2} & 0 & -\sqrt{2} \\ 1 & -\sqrt{2} & 1 \end{pmatrix}.$$

The Verlinde formula gives the fusion rules:

$$\begin{aligned} L(\Lambda_1) \boxtimes L(\Lambda_1) &= L(\Lambda_0) \oplus L(2\Lambda_1), \\ L(\Lambda_1) \boxtimes L(2\Lambda_1) &= L(\Lambda_1), \\ L(2\Lambda_1) \boxtimes L(2\Lambda_1) &= L(\Lambda_0). \end{aligned}$$

The fusion ring has three simple objects; the subring generated by $L(2\Lambda_1)$ is the $\mathbb{Z}/2$ group ring (since $L(2\Lambda_1)^{\boxtimes 2} = L(\Lambda_0)$), while $L(\Lambda_1)$ generates the full ring with the non-group-like rule $L(\Lambda_1)^{\boxtimes 2} = L(\Lambda_0) \oplus L(2\Lambda_1)$. Under the KL equivalence (Theorem 15.2.9) with $q = e^{\pi i/4}$ (a primitive 8th root of unity), $L(\Lambda_0) \leftrightarrow V_q(0)$ (trivial representation), $L(\Lambda_1) \leftrightarrow V_q(\omega_1)$ (fundamental), $L(2\Lambda_1) \leftrightarrow V_q(2\omega_1)$ (adjoint, truncated).

The Koszul dual at level $k' = -k - 2h^\vee = -2 - 4 = -6$ satisfies $q' = e^{\pi i/(k' + h^\vee)} = e^{\pi i/(-4)} = e^{-\pi i/4} = q^{-1}$: the quantum group $U_{q^{-1}}(\mathfrak{sl}_2)$ has the same fusion rules (since q and q^{-1} give isomorphic representation categories) but reversed braiding, as predicted by Remark 15.2.11.

Example 15.6.11 (Fusion via bar complex: $L(\Lambda_1) \boxtimes L(\Lambda_1)$ at level 2). We compute the fusion product $L(\Lambda_1) \boxtimes L(\Lambda_1)$ for $\widehat{\mathfrak{sl}}_2$ at level $k = 2$ using the bar complex on $\overline{C}_2(\mathbb{P}^1)$.

Place the two $L(\Lambda_1)$ -modules at points $z_1, z_2 \in \mathbb{P}^1$. The intertwining operator $\mathcal{Y}$ encodes the fusion; in the bar complex framework, it is computed by the residue of the two-point function on the boundary divisor $D_{12} = \{z_1 = z_2\} \subset \overline{C}_2(\mathbb{P}^1)$.

Step 1: OPE data. The primary field $\phi_j(z)$ of spin j in $L(j\Lambda_1)$ has OPE fusion channel decomposition:

$$\phi_{1/2}(z_1) \phi_{1/2}(z_2) \sim (z_{12})^{-3/8} (\phi_0(z_2) + z_{12} \partial \phi_0 + \cdots) + (z_{12})^{1/8} (\phi_1(z_2) + \cdots)$$

where $z_{12} = z_1 - z_2$, and the two channels correspond to $L(\Lambda_0)$ (identity) and $L(2\Lambda_1)$ (spin-1 representation).

Step 2: Bar complex. On $\overline{C}_2(\mathbb{P}^1) \cong \mathbb{P}^1$ (the blow-up of $(\mathbb{P}^1)^2$ along the diagonal), the bar complex term $\bar{B}_0$ is $L(\Lambda_1) \otimes L(\Lambda_1)$, and the differential $d: \bar{B}_0 \rightarrow \bar{B}_{-1}$ extracts the residue $\text{Res}_{D_{12}}(\eta_{12})$. The kernel of this map in the fusion product is precisely $L(\Lambda_0) \oplus L(2\Lambda_1)$: the two summands arise from the two analytic continuations of the intertwining operator around $z_1 = z_2$.

Step 3: Truncation. At level $k = 2$, the spin-3/2 channel (which would appear for $k \geq 3$) is absent: the bar complex detects this via the vanishing of the corresponding section on $\overline{C}_2(\mathbb{P}^1)$ at the level-dependent boundary stratum. This is the bar complex realization of the truncated Clebsch–Gordan rule at $j'' \leq 2k - j - j' = 2$.

PROPOSITION 15.6.12 (*Ext groups at level 2; .*). For $\widehat{\mathfrak{sl}}_2$ at integrable level $k = 2$, the Ext groups among integrable modules vanish in positive degree:

$$\text{Ext}_{\mathcal{O}_2}^i(L(\Lambda_a), L(\Lambda_b)) = 0, \quad i > 0, \quad a, b \in \{0, 1, 2\Lambda_1\}.$$

Here $\mathcal{O}_2$ denotes the integrable category at level 2.

Proof. At positive integer level, the integrable category $\mathcal{O}_k^{\text{int}}$ is semisimple (Theorem G.II.18 via Kac [238]). Hence all simple modules are projective in the integrable category: $\text{Ext}_{\mathcal{O}_k^{\text{int}}}^i(L(\Lambda), L(\mu)) = 0$ for $i > 0$.

In the bar complex framework, this corresponds to the E_2 degeneration at generic/integrable level (Theorem 15.6.5): the bar spectral sequence collapses because the Verma modules are irreducible (equivalently, the Shapovalov form is non-degenerate). The Ext-vanishing is the module-theoretic statement of the Koszul property. $\square$

PROPOSITION 15.6.13 (*Ext complementarity at dual levels; .*). At the Koszul dual level $k' = -k - 2h^\vee = -6$, the situation reverses in the bar-resolution sense: the dual side acquires non-trivial extension classes.

More precisely, what the rational side sees as semisimplicity (Ext-vanishing), the dual side sees as non-trivial extensions. This follows from two ingredients already established in this chapter:

- (i) *Singular vector locus symmetry* (Corollary 15.6.19): the Feigin–Frenkel involution $\iota: k \mapsto -k - 2h^\vee$ rearranges the zero locus of the Kac–Kazhdan determinant $\det S_n(\lambda, k)$, sending the component $\{\lambda = s-1-r(k+h^\vee)\}$ to $\{\lambda = s-1+r(k+h^\vee)\}$. A Verma module that is irreducible at level k (lying off Σ_n) generically acquires singular vectors at level k' (landing on Σ_n), and vice versa.
- (ii) *Bar resolution* (Proposition 15.II.6): $\text{Ext}_{\mathcal{A}}^n(M, N) \simeq H^n(\text{Hom}_{\mathcal{A}}(B_\bullet(\mathcal{A}) \otimes_{\mathcal{A}} M, N))$. Singular vectors in $\mathcal{M}(\lambda)_k$ produce non-trivial classes in H^1 of the bar complex, hence non-vanishing Ext^1 . Their absence yields $\text{Ext}^1 = 0$.

Concretely, Proposition 15.6.12 gives $\text{Ext}_{\mathcal{O}_2}^i = 0$ for $i > 0$ at level $k = 2$ (semisimplicity), while at the dual level $k' = -6$ the Kac–Kazhdan determinant acquires new zeros by (i), producing the non-trivial Ext^1 classes detected by (ii). This module-level complementarity is parallel to, but logically independent

of, the global complementarity theorem (Theorem 13.15.14), which decomposes the center cohomology $H^*(\overline{\mathcal{M}}_g, \mathcal{Z}(\mathcal{A}))$ rather than the module Ext groups.

Proof. Proposition 15.6.12 gives the level-2 semisimplicity statement: the Kac–Kazhdan determinant has no bar-relevant zeros there, so the bar resolution detects no higher Ext-classes. Corollary 15.6.19 transports that determinant locus under the Feigin–Frenkel involution $k \mapsto -k - 2h^\vee$, so the dual level $k' = -6$ lands on the singular-vector surface. Proposition 15.11.6 identifies those singular vectors with nontrivial cohomology classes in the bar resolution, hence with nonzero Ext¹. This is exactly the stated complementarity between the semisimple side and the extension-rich dual side. $\square$

PROPOSITION 15.6.14 (*Characters under level-shifting Koszul duality*;). Let $\widehat{\mathfrak{g}}_k$ and $\widehat{\mathfrak{g}}_{k'} = (\widehat{\mathfrak{g}}_k)^\dagger$ with $k' = -k - 2h^\vee$ be a Koszul dual pair at generic level. Then:

- (i) The Weyl–Kac character formula has the same structure at both levels: both $\text{ch}(L_k(\lambda))$ and $\text{ch}(L_{k'}(\lambda))$ are governed by the same affine Weyl group and the same structure constants f_{ab}^c . The level enters only through the denominator product, which is independent of the highest weight.
- (ii) The denominator identity transforms as

$$\prod_{n>0} \prod_{\alpha \in \Delta^+} (1 - q^n e^{-\alpha})^{\text{mult}(\alpha)} \xrightarrow{k \mapsto k'} \prod_{n>0} \prod_{\alpha \in \Delta^+} (1 - q^n e^{-\alpha})^{\text{mult}'(\alpha)}$$

where the root multiplicities $\text{mult}'(\alpha) = \text{mult}(\alpha)$ for real roots ($\text{mult} = 1$) and $\text{mult}'(\alpha) = \text{mult}(\alpha) = \text{rk}(\mathfrak{g})$ for imaginary roots. Hence the denominator is level-independent.

- (iii) In particular, the character ratio $\text{ch}(L_k(\lambda))/\text{ch}(L_{k'}(\lambda))$ depends only on the numerators (the Weyl group sums), and for the same highest weight label λ the two characters are *identical*:

$$\text{ch}(L_k(\lambda)) = \text{ch}(L_{k'}(\lambda)).$$

Proof. The Weyl–Kac character (Theorem 15.6.5) depends on the level k only through the structure of the affine Lie algebra $\widehat{\mathfrak{g}}_k$, which determines the root system, Weyl group, and root multiplicities. Since the root system $\Delta(\widehat{\mathfrak{g}})$, the affine Weyl group $\mathcal{W}(\widehat{\mathfrak{g}})$, and the root multiplicities depend only on the underlying finite-dimensional $\mathfrak{g}$ (not on the level), both the numerator and denominator of the character formula are level-independent.

The level appears in the representation theory through the set of *allowed* highest weights: at level k , the dominant integral weights form the level- k alcove $P_+^k = \{\Lambda \mid \langle \Lambda, \theta^\vee \rangle \leq k\}$, where θ is the highest root. Under $k \mapsto k' = -k - 2h^\vee$, the alcove changes (for $k' < 0$ the notion of “integrable” module requires modification; see the admissible modules of Kac–Wakimoto [241]).

For the same formal highest weight λ (viewed as a weight of the finite-dimensional $\mathfrak{g}$), the Weyl–Kac formula produces the same formal power series. This is the character-level manifestation of the Zhu algebra isomorphism $A(\widehat{\mathfrak{g}}_k) \cong U(\mathfrak{g}) \cong A(\widehat{\mathfrak{g}}_{k'})$ (Proposition 15.2.27): the Zhu algebra classifies the lowest weight spaces, and the character is built from the Zhu data by the BGG resolution. $\square$

Remark 15.6.15 (*Character duality in the bar-cobar framework*). The character identity $\text{ch}(L_k(\lambda)) = \text{ch}(L_{k'}(\lambda))$ holds because the bar complexes at levels k and k' have the same graded dimensions (Verma module spaces depend only on $\mathfrak{g}$); the differentials differ but cancel in the Euler characteristic. This does *not* imply $\mathcal{O}_k \simeq \mathcal{O}_{k'}$ (e.g., $k = 1$ is semisimple, $k' = -3$ is not for $\mathfrak{sl}_2$). Any highest-weight categorical comparison requires the extra t -exact bar/Koszul input fenced in Proposition 15.1.35; the general module bar-comodule package alone does not supply an equivalence of categories $\mathcal{O}$.

15.6.5 VACUUM VERMA MODULE UNDER KOSZUL DUALITY

PROPOSITION 15.6.16 (*Vacuum Verma under the module bar functor on the finite-type E_1 lane;*). For $\widehat{\mathfrak{sl}}_2$ at generic level k , on the quadratic genus-0 E_1 finite-type-graded lane of Theorem 11.6.2, the module bar functor $\Phi: \text{Mod}_{\widehat{\mathfrak{sl}}_{2,k}}^{\text{compl}} \rightarrow \text{CoMod}_{\overline{B}(\widehat{\mathfrak{sl}}_{2,k})}^{\text{conil}}$ sends the vacuum Verma to a cofree comodule that, after the graded-dual identification $\overline{B}(\widehat{\mathfrak{sl}}_{2,k})^\vee \cong \widehat{\mathfrak{sl}}_{2,-k-4}$, becomes the vacuum Verma at the Feigin–Frenkel dual level:

$$\Phi(\mathcal{M}(0)_k) \simeq \mathcal{M}(0)_{-k-4} \quad (15.14)$$

where the right-hand side is read in $\text{Mod}_{\widehat{\mathfrak{sl}}_{2,-k-4}}^{\text{compl}}$ via the graded-dual rewrite, and $-k - 2h^\vee = -k - 4$ is the Feigin–Frenkel dual level. Off the finite-type lane, $\Phi(\mathcal{M}(0)_k)$ is the cofree $\overline{B}(\widehat{\mathfrak{sl}}_{2,k})$ -comodule on the vacuum and the algebra-side rewrite is unavailable.

Proof. The proof proceeds in three steps. We work on the finite-type/quadratic lane where Theorem 11.6.2 gives the complete-module/conilpotent-bar-comodule comparison and the graded-dual identification $\overline{B}(\widehat{\mathfrak{sl}}_{2,k})^\vee \cong \widehat{\mathfrak{sl}}_{2,-k-4}$ is justified; off this lane the target should be read as a $\overline{B}(\widehat{\mathfrak{sl}}_{2,k})$ -comodule.

Step 1: Functoriality. The module bar functor $\Phi: \text{Mod}_{\mathcal{A}}^{\text{compl}} \rightarrow \text{CoMod}_{\overline{B}(\mathcal{A})}^{\text{conil}}$ of Definition 15.1.9 sends an $\mathcal{A}$ -module $\mathcal{M}$ to the module bar complex $\overline{B}_{\mathcal{A}}(\mathcal{M})$ over $\mathcal{A} = \widehat{\mathfrak{sl}}_{2,k}$, which is naturally a comodule over the bar coalgebra $\overline{B}(\mathcal{A})$ via deconcatenation on the algebra tensor factors (Theorem 11.6.2).

Step 2: Free modules map to cofree comodules. The vacuum Verma module is the *free* module on the vacuum vector: $\mathcal{M}(0)_k = U(\widehat{\mathfrak{n}}^-)_k \cdot |0\rangle$, where $\widehat{\mathfrak{n}}^-$ is the negative nilpotent subalgebra. On the proved quadratic genus-0 E_1 lane (Proposition 15.1.10), Φ is the complete/conilpotent equivalence and sends the free $\mathcal{A}$ -module on $|0\rangle$ to the cofree $\overline{B}(\mathcal{A})$ -comodule on $|0\rangle$.

More precisely: the bar construction of the vacuum Verma is

$$\overline{B}_{\mathcal{A}}(\mathcal{M}(0)_k) = \bigoplus_{n \geq 0} (\overline{\mathcal{A}})^{\otimes n} \otimes_{\mathcal{A}} \mathcal{M}(0)_k$$

with the bar differential. At the vacuum (highest weight 0), the tensor product $(\overline{\mathcal{A}})^{\otimes n} \otimes_{\mathcal{A}} \mathcal{M}(0)$ selects the weight-0 component of the bar complex, which generates the cofree comodule of highest weight 0 over $\overline{B}(\widehat{\mathfrak{sl}}_{2,k})$. On the finite-type graded-dual lane, the linear dual identification $\overline{B}(\widehat{\mathfrak{sl}}_{2,k})^\vee \cong \widehat{\mathfrak{sl}}_{2,-k-4}$ (Theorem G.7.1) translates this cofree comodule into the complete $\widehat{\mathfrak{sl}}_{2,-k-4}$ -module $\mathcal{M}(0)_{-k-4}$, giving (15.14) on the graded-dual side. Both this rewriting and the equivalence Φ itself depend on the proved finite-type quadratic lane.

Step 3: Verification at grade 1. At conformal weight $h = 1$, the vacuum Verma $\mathcal{M}(0)_k$ has basis $\{J_{-1}^a |0\rangle\}_{a=1}^3 = \{e_{-1}, f_{-1}, h_{-1}\} \cdot |0\rangle$. The module bar differential maps this to the degree-0 piece:

$$\begin{aligned} d_{\text{bar}}^{\text{mod}}(e_{-1}|0\rangle) &= e \cdot |0\rangle = 0 & (\text{augmentation: } e \text{ annihilates vacuum}) \\ d_{\text{bar}}^{\text{mod}}(f_{-1}|0\rangle) &= f \cdot |0\rangle = 0 \\ d_{\text{bar}}^{\text{mod}}(h_{-1}|0\rangle) &= h \cdot |0\rangle = 0 \end{aligned}$$

(All positive-mode generators annihilate the vacuum; the zero modes e_0, f_0, h_0 act by the finite-dimensional representation structure, giving 0 on the $\mathfrak{sl}_2$ vacuum vector.)

Under Φ , the corresponding elements at the dual level are $e_{-1}|0\rangle_{-k-4}, f_{-1}|0\rangle_{-k-4}, h_{-1}|0\rangle_{-k-4}$, generating the same 3-dimensional space at grade 1. The differential structure agrees because the structure constants f_c^{ab} are level-independent. $\square$

PROPOSITION 15.6.17 (*Shapovalov form under Koszul duality*;). The Shapovalov form on $\mathcal{M}(0)_k$ transforms under module Koszul duality as follows. Write $\det S_n(k)$ for the Shapovalov determinant at grade n . Then:

$$\det S_n(-k-4) = (-1)^{s_n} \det S_n(k)$$

where $s_n = \sum_{\substack{r,s \geq 1 \\ rs \leq n}} P(n-rs)$ counts the total multiplicity of Shapovalov factors at grade n , and $P(m)$ is the number of partitions of m .

In particular:

- (i) $\mathcal{M}(0)_k$ has a singular vector at grade n (i.e., $\det S_n(k) = 0$) if and only if $\mathcal{M}(0)_{-k-4}$ has a singular vector at the same grade.
- (ii) The singular vector condition for $\widehat{\mathfrak{sl}}_2$ at grade 1 is $(k+2) = 0$ (i.e., $k = -2$ is critical). Under duality: $(-k-4)+2 = -(k+2) = 0$, so the dual module is also singular at the critical level $k = -2$, consistent with the self-duality $(-2)^! = -(-2) - 4 = -2$ at critical level.

Proof. The Kac determinant formula for $\widehat{\mathfrak{sl}}_2$ at highest weight 0 gives (Kac [238], Theorem 11.2):

$$\det S_n(k) = C_n \prod_{\substack{r,s \geq 1 \\ rs \leq n}} (k+2-r/s)^{P(n-rs)}$$

where $C_n > 0$ is a positive constant depending only on the normalization. Under $k \mapsto -k-4$:

$$k+2-r/s \mapsto (-k-4)+2-r/s = -(k+2)-r/s = -(k+2+r/s)$$

Therefore each factor transforms as $(k+2-r/s) \mapsto -(k+2+r/s)$, and the full determinant picks up a sign $(-1)^{s_n}$ from the product of these sign changes.

The zero locus is preserved: $\det S_n(k) = 0$ at $k = r/s-2$, and $\det S_n(-k-4) = 0$ at $-k-4 = r'/s'-2$, i.e., $k = -r'/s'-2$. The zeros are *not* the same (they are $k = r/s-2$ vs. $k = -r/s-2$), but they come in *complementary pairs*: singular vectors in the module at level k correspond to singular vectors in the dual module at level $-k-4$ via the Feigin–Frenkel involution. The exception is the critical level $k = -2$, which is a fixed point of $k \mapsto -k-4$ and admits singular vectors that are self-dual. $\square$

PROPOSITION 15.6.18 (*Non-vacuum Verma modules under the module bar functor on the finite-type E_1 lane*;). For $\widehat{\mathfrak{sl}}_2$ at generic level $k \neq -2$ and arbitrary highest weight $\lambda \in \mathbb{C}$, on the finite-type graded-dual quadratic genus-0 E_1 lane of Theorem 11.6.2, the module bar functor Φ of Definition 15.1.9 sends

$$\Phi(\mathcal{M}(\lambda)_k) \simeq \mathcal{M}(\lambda)_{-k-4}, \quad (15.15)$$

where the right-hand side is read in $\text{Mod}_{\widehat{\mathfrak{sl}}_{2,-k-4}}^{\text{compl}}$ via the graded-dual identification $\overline{B}(\widehat{\mathfrak{sl}}_{2,k})^\vee \cong \widehat{\mathfrak{sl}}_{2,-k-4}$. The Kac–Kazhdan determinant at grade n transforms as:

$$\det S_n(\lambda, -k-4) = C_n \prod_{\substack{r,s \geq 1 \\ rs \leq n}} ((\lambda+1) - s - r(k+2))^{P(n-rs)} \quad (15.16)$$

where $P(m)$ is the partition number. The zero locus at the dual level is:

$$\lambda = s - 1 + r(k+2), \quad r, s \geq 1, \quad rs \leq n,$$

while the zero locus at the original level is $\lambda = s - 1 - r(k+2)$.

Proof. The module bar resolution $B^{\text{mod}}(\mathcal{M}(\lambda)_k)$ is constructed from the algebra bar complex $B(\widehat{\mathfrak{sl}}_{2k})$ by tensoring with the module $\mathcal{M}(\lambda)_k$ and equipping with the bar differential $d_{\text{bar}}^{\text{mod}}$ incorporating both the algebra and module structures (Definition 15.3.2). The key input is that the grade- n bar module chain group

$$B_n^{\text{mod}}(\mathcal{M}(\lambda)_k) = (s^{-1}\overline{\mathcal{A}})^{\otimes n} \otimes \mathcal{M}(\lambda)_k$$

has chain-group dimensions independent of k (the PBW basis of the universal enveloping algebra is level-independent), and the bar differential acts on the level k structure via the OPE coefficients, which enter linearly in k through the double-pole term $\kappa(e, f) = k$.

The functor Φ replaces k by $-k - 4$ throughout the OPE data (Feigin–Frenkel involution, Theorem G.4.1). Since λ parametrizes the $\mathfrak{sl}_2$ -action (zero-mode eigenvalue $h_0 v_\lambda = \lambda v_\lambda$), it is invariant under the level shift, giving (15.15).

For the Shapovalov identity, the Kac–Kazhdan formula ([238], Theorem 11.2) gives

$$\det S_n(\lambda, k) = C_n \prod_{\substack{r, s \geq 1 \\ rs \leq n}} ((\lambda + 1) - s + r(k + 2))^{P(n-rs)}.$$

Each factor $F_{r,s}(\lambda, k) := (\lambda + 1) - s + r(k + 2)$ transforms under $k \mapsto -k - 4$ as

$$F_{r,s}(\lambda, -k-4) = (\lambda + 1) - s + r(-k - 2) = (\lambda + 1) - s - r(k + 2),$$

which is *not* proportional to $F_{r,s}(\lambda, k)$ for $\lambda \neq 0$, in contrast to the vacuum case, where the factors are simply negated. This yields (15.16).

The zero loci follow immediately: $F_{r,s}(\lambda, k) = 0$ gives $\lambda = s - 1 - r(k + 2)$, and $F_{r,s}(\lambda, -k-4) = 0$ gives $\lambda = s - 1 + r(k + 2)$. $\square$

COROLLARY 15.6.19 (*Singular vector locus symmetry*;). Define the grade- n singular vector locus $\Sigma_n \subset \mathbb{C}^2$ by

$$\Sigma_n = \{(\lambda, k) : \det S_n(\lambda, k) = 0\} = \bigcup_{\substack{r, s \geq 1 \\ rs \leq n}} \{\lambda = s - 1 - r(k + 2)\}.$$

The Feigin–Frenkel involution $\iota: (\lambda, k) \mapsto (\lambda, -k - 4)$ acts on the irreducible components: it sends the component $\{\lambda = s - 1 - r(k + 2)\}$ to $\{\lambda = s - 1 + r(k + 2)\}$, reversing the sign of the k -dependent term.

In particular:

- (i) At grade 1, $\mathcal{M}(\lambda)_k$ has a singular vector when $\lambda = -k - 2$, and $\Phi(\mathcal{M}(\lambda)_k) = \mathcal{M}(\lambda)_{-k-4}$ has a singular vector when $\lambda = k + 2$. These coincide only at the critical level $k = -2$, the unique fixed point of ι .
- (ii) At grade 2, three components contribute:

$$\det S_2(\lambda, k) \sim (\lambda + k + 2)(\lambda + k + 1)(\lambda + 2k + 4),$$

with dual determinant

$$\det S_2(\lambda, -k-4) \sim -(\lambda - k - 2)(\lambda - k - 3)(\lambda - 2k - 4).$$

- (iii) The integrable weight $\lambda = \Lambda_1 = 1$ at $k = 1$ maps to: $\Phi(L(\Lambda_1)_1) \simeq L(\Lambda_1)_{-5}$, sending the level-1 integrable module to an admissible module at level -5 .

Proof. Items (i) and (ii) are direct substitutions in Proposition 15.6.18, verified by explicit computation: $\det S_2(1, 3) = 6 \cdot 5 \cdot 11 = 330$ while $\det S_2(1, -7) = (-4)(-5)(-9) = -180$. Item (iii): $L(\Lambda_1)_1$ is the unique irreducible quotient of $\mathcal{M}(1)_1$ (the 2-dimensional level-1 representation). Since Φ acts on the bar spectral sequence by replacing $k \mapsto -k - 4$ in the OPE data, it preserves the filtration that computes the irreducible quotient, giving $\Phi(L(\Lambda_1)_1) \simeq L(\Lambda_1)_{-5}$. $\square$

15.6.6 VIRASORO VERMA MODULES UNDER KOSZUL DUALITY

The Virasoro algebra Vir_c is the DS reduction $\mathcal{W}^k(\mathfrak{sl}_2)$ with $c = 1 - 6(k+1)^2/(k+2)$. Its Feigin–Frenkel same-family partner is Vir_{26-c} (Example 8.1.21), corresponding to the dual level $k' = -k - 4$ via the Feigin–Frenkel involution. In this section, Vir_{26-c} is the proved M/S-level shadow partner governing module transport, genus complementarity, and semi-infinite calculations; the stronger H-level infinite-generator realization is delegated to the exact W_∞ MC₄ package of filtered H-level targets, residue identities, and finite detection on $\mathcal{I}_N$, whose first live higher-spin stages are already reduced on the theorem surface to the stage-3 fifteen-coefficient packet and the stage-4 six-coefficient packet organized as three local OPE blocks.

PROPOSITION 15.6.20 (*Virasoro Verma module under the same-family involution;*). For $c \neq 0, 26$ (generic central charge), the module bar functor Φ of Definition 15.1.9 sends the Virasoro Verma module of conformal weight h to a cofree $\bar{B}(\text{Vir}_c)$ -comodule that, after the same-family $c \mapsto 26 - c$ rewrite of Remark 15.2.30, identifies with the Verma module at the dual central charge:

$$\Phi(\mathcal{M}(h, c)) \simeq \mathcal{M}(h, 26 - c)$$

where $\mathcal{M}(h, c) = \text{Ind}_{L_0, L_{n>0}}^{\text{Vir}_c} \mathbb{C}_h$ is the Verma module of conformal weight h and central charge c , and the right-hand side is read after the same-family rewrite. This is the proved M/S-level shadow identification under $c \mapsto 26 - c$; it does not construct the stronger H-level infinite-generator W_∞ -type dual object.

Proof. The proof parallels that of Proposition 15.6.16 for $\widehat{\mathfrak{sl}}_2$, with the Virasoro modes L_n replacing the affine generators J_n^a .

Step 1: Functoriality. The module bar construction $\bar{B}_{\text{Vir}_c}(\mathcal{M}(h, c))$ produces a comodule over $\bar{B}(\text{Vir}_c)$. By the Virasoro model-level quasi-isomorphism underlying the complementarity involution, $\bar{B}(\text{Vir}_c)$ is identified with the coalgebra model attached to the same-family partner Vir_{26-c} (Remark 15.2.30). Therefore the result is a Vir_{26-c} -comodule.

Step 2: Verma modules are free. The Verma module $\mathcal{M}(h, c)$ is free over the subalgebra generated by $\{L_{-n}\}_{n \geq 1}$: $\mathcal{M}(h, c) = \mathbb{C}[L_{-1}, L_{-2}, \dots] \cdot v_h$. The module bar construction sends free modules to cofree comodules. At the dual central charge, the cofree comodule on a weight- h vector is $\mathcal{M}(h, 26 - c)$.

Step 3: Conformal weight is preserved. The conformal weight h parametrizes the L_0 -eigenvalue of the highest weight vector and is independent of the central charge. The bar differential involves OPE residues of the form $L_{(n)}$, which shift L_0 -eigenvalues by the mode number, preserving the grading structure. Therefore Φ maps the weight- h sector at central charge c to the weight- h sector at central charge $26 - c$. $\square$

PROPOSITION 15.6.21 (*Virasoro Kac determinant under Koszul duality;*). The Virasoro Kac determinant at level N of the Verma module $\mathcal{M}(h, c)$ transforms under $c \mapsto 26 - c$ as follows. Write $c = 1 - 6(p - q)^2/(pq)$ for the parametrization by (p, q) . Then the Koszul dual central charge $26 - c = 25 + 6(p - q)^2/(pq)$ corresponds to the *shadow parametrization* $(p', q') = (p, -q)$ (formal sign flip).

The degenerate representations at central charge c form the Kac table $\{h_{r,s}(c) : r, s \geq 1\}$ where

$$h_{r,s}(c) = \frac{(pr - qs)^2 - (p - q)^2}{4pq}.$$

Under Koszul duality, the Kac table transforms as:

$$h_{r,s}(c) \mapsto h_{r,s}(26-c) = \frac{(p+q)^2 - (pr+qs)^2}{4pq}$$

This is the formal substitution $q \mapsto -q$ in the Kac formula, so the numerator and denominator change sign together. In particular:

- (i) The degenerate weight at $(r, s) = (1, 1)$ is $h_{1,1}(c) = 0$ (vacuum) and $h_{1,1}(26-c) = \frac{(p+q)^2 - (p+q)^2}{4pq} = 0$. The vacuum module is degenerate at *both* central charges.
- (ii) At $c = 1/2$ (Ising model, $(p, q) = (4, 3)$): the dual is $c' = 25.5$, and the Kac tables are complementary. The Ising degenerate weights $h = 0, 1/16, 1/2$ map to $h = 0, -17/16, -3/2$ at $c' = 25.5$. The negative dual weights reflect the non-unitarity of the $c > 25$ regime.
- (iii) At $c = 1$ (free boson, $(p, q) = (1, 1)$): the dual is $c' = 25$, and all degenerate weights $h_{r,s}(1) = (r-s)^2/4$ map to $h_{r,s}(25) = 1 - (r+s)^2/4$.

Proof. The Virasoro Kac determinant at level N is (Kac [238], Feigin–Fuchs [162]):

$$\det S_N(h, c) = C_N \prod_{\substack{r,s \geq 1 \\ rs \leq N}} (h - h_{r,s}(c))^{P(N-rs)}$$

where $P(m)$ is the partition function and $C_N > 0$. The zero locus is the union of curves $h = h_{r,s}(c)$ in the (h, c) -plane.

Under $c \mapsto 26 - c$, the parametrization $c = 1 - 6(p-q)^2/(pq)$ becomes

$$26 - c = 25 + \frac{6(p-q)^2}{pq} = 1 - \frac{6(p-(-q))^2}{p(-q)}.$$

So the transformed central charge is encoded by the formal replacement $q \mapsto -q$.

Apply this substitution to $h_{r,s}(c) = ((pr - qs)^2 - (p - q)^2)/(4pq)$. The numerator becomes $(pr + qs)^2 - (p + q)^2$, while the denominator becomes $4p(-q) = -4pq$. Therefore

$$h_{r,s}(26-c) = \frac{(p+q)^2 - (pr+qs)^2}{4pq}.$$

The zero loci $\{h = h_{r,s}(c)\}$ and $\{h = h_{r,s}(26-c)\}$ are complementary: singular vectors in $\mathcal{M}(h, c)$ correspond to distinct singular vectors in $\mathcal{M}(h, 26-c)$.

For (i): $h_{1,1} = 0$ is preserved since $((p+q)^2 - (p+q)^2)/(4pq) = 0$ as well.

For (ii): Ising $(p, q) = (4, 3)$: $h_{1,2}(c) = 1/16$ maps to $h_{1,2}(25.5) = ((4+3)^2 - (4+6)^2)/(48) = (49 - 100)/48 = -51/48 = -17/16$. The negative dual weight reflects the non-unitarity of $c' = 25.5 > 25$. The degenerate weights at $c' = 25.5$ are $h_{r,s}(25.5) \leq 0$ for all $r, s \geq 1$, which are disjoint from the positive Ising values. $\square$

Remark 15.6.22 (Virasoro module Koszul duality and minimal models). For the (p, q) minimal model, the same-family partner $c' = 26 - c_{p,q} > 25$ has no minimal model structure, the Virasoro analog of the KM phenomenon (Remark 15.1.27). Complementarity (Theorem 13.15.14) applies at generic c where Koszulness holds (Theorem 11.1.21): $\mathcal{Q}_g(\text{Vir}_c) + \mathcal{Q}_g(\text{Vir}_{26-c}) = H^*(\mathcal{M}_g, Z(\text{Vir}_c))$. MC4 is proved (Theorem 8.1.27); the residual H-level identification is example-specific (Remark 15.2.30).

15.7 DEVIATIONS FROM HOMOLOGICAL TRIVIALITY

15.7.1 WHEN HOMOLOGY IS NON-TRIVIAL

THEOREM 15.7.1 (*Character with homological corrections*;). If $H^k(\mathcal{P}_\bullet) \neq 0$ for some $k > 0$, the Euler characteristic of the complex still gives:

$$\mathrm{ch}(\mathcal{M}) = \sum_n (-1)^n \mathrm{ch}(\mathcal{P}_n) = \sum_{k \geq 0} (-1)^k \mathrm{ch}(H^k(\mathcal{P}_\bullet))$$

The first equality is the definition of the Euler characteristic of the complex; the second follows from the fact that χ is additive on exact sequences. However, the individual cohomology groups H^k for $k > 0$ contribute non-trivially, and extracting $\mathrm{ch}(\mathcal{M}) = \mathrm{ch}(H^0)$ from this alternating sum requires understanding the higher cohomology.

Proof. The failure of acyclicity means the alternating sum does not telescope completely.

Using spectral sequences, write:

$$E_1^{p,q} = H^q(\mathcal{P}_p) \Rightarrow H_{\mathrm{total}}^{p+q}$$

At E_2 :

$$E_2^{p,q} = H_{\mathrm{horizontal}}^p(H^q(\mathcal{P}_*))$$

By the standard spectral sequence Euler characteristic argument, $\chi(E_r) = \chi(E_{r+1})$ for all r (homology preserves Euler characteristic), so:

$$\chi_{\mathrm{total}} = \chi(E_\infty) = \chi(E_2) = \chi(E_1).$$

When the spectral sequence does not degenerate at E_2 , higher differentials provide cancellations. Each page encodes finer structural information: E_2 captures extensions between modules, E_3 captures Massey products, and E_r in general encodes higher coherences. $\square$

EXAMPLE 15.7.2 (*Logarithmic modules*). For a non-semisimple category of modules (e.g., at admissible levels), indecomposable modules may admit non-split extensions $0 \rightarrow \mathcal{L} \rightarrow \mathcal{M} \rightarrow \mathcal{L}' \rightarrow 0$ with $\mathcal{L} \not\cong \mathcal{L}'$. The bar resolution of such a module $\mathcal{M}$ satisfies $H^1 \neq 0$, where H^1 encodes the extension data (the “logarithmic partner”). The character of $\mathcal{M}$ then acquires contributions from H^1 :

$$\mathrm{ch}(\mathcal{M}) = \mathrm{ch}(\mathcal{L}') + \mathrm{ch}(\mathcal{L}) = \mathrm{ch}(\mathcal{L}') + \mathrm{ch}(H^1(\mathcal{P}_\bullet))$$

(as opposed to the semisimple case where $\mathrm{ch}(\mathcal{M}) = \mathrm{ch}(\mathcal{L}')$ alone). In physics, these are the *logarithmic conformal field theories*, where correlation functions develop logarithmic singularities.

15.7.2 TRACKING THE TRANSITION

THEOREM 15.7.3 (*Deformation of acyclicity*;). Let $(\mathcal{P}_\bullet, d_t)$ be a flat family of bounded cochain complexes over a smooth connected base S , with $\mathcal{P}_\bullet(t_0)$ acyclic at some $t_0 \in S$. Then:

1. The Euler characteristic $\chi(\mathcal{P}_\bullet(t)) = 0$ for all $t \in S$.
2. On the smooth locus $S^\circ \subset S$ (complement of the discriminant where homology dimensions jump), the homology sheaves $\mathcal{H}^k = R^k \pi_* \mathcal{P}_\bullet$ carry the Gauss–Manin connection ∇^{GM} , and the graded character $\mathrm{ch}(t) = \sum_k (-1)^k \mathrm{ch}(H^k(t))$ is a flat section: $\nabla^{GM} \mathrm{ch} = 0$.

3. At a point $t_1 \in S \setminus S^\circ$ where homology appears, the individual $H^k(t)$ jump (upper-semicontinuously in dimension), but $\chi = 0$ is preserved: each new H^k is balanced by a compensating H^{k+1} .

Proof. (1) *Constancy of Euler characteristic.* For a flat family of bounded complexes, the Euler characteristic is locally constant on S (Grothendieck, EGA III; see also Hartshorne [216], III.12). Since $\chi(\mathcal{P}_\bullet(t_0)) = 0$ (acyclicity implies all $H^k = 0$, so $\chi = 0$) and S is connected, $\chi(t) = 0$ for all t .

(2) *Gauss–Manin connection.* On the smooth locus S° where $\dim H^k(t)$ is constant, the Katz–Oda construction ([254]) provides the Gauss–Manin connection ∇^{GM} on each $\mathcal{H}^k|_{S^\circ}$: the connecting homomorphism in the long exact sequence of the de Rham complex of the family. Flatness $(\nabla^{GM})^2 = 0$ follows from the integrability of the de Rham differential. The alternating character ch is flat because ∇^{GM} acts on each $\mathcal{H}^k$ and the Euler characteristic is additive.

(3) *Wall-crossing.* At a discriminant point t_1 , the nearby cycles functor $\psi_{t_1}(\mathcal{H}^k)$ (Deligne, SGA 7) relates the generic fiber to the special fiber. The exact triangle $\psi \rightarrow i^* \rightarrow \phi \xrightarrow{+1}$ (where ϕ is the vanishing cycles functor) gives: $\dim H^k(t_1) - \dim H^k(t_{\text{gen}}) = \dim \phi_{t_1}(\mathcal{H}^k) - \dim \phi_{t_1}(\mathcal{H}^{k-1})$. Summing over k with alternating signs, the vanishing cycle contributions cancel (the Euler characteristic of the vanishing cycles complex is zero, since it is the mapping cone of a quasi-isomorphism on the generic fiber), confirming $\chi(t_1) = \chi(t_{\text{gen}}) = 0$. $\square$

Remark 15.7.4 (Context). In the chiral algebra setting, S is the character variety or level space, $\mathcal{P}_\bullet(t)$ is the bar-cobar resolution at level parameter t , and the transition from acyclic (generic level) to non-acyclic (critical/admissible levels) corresponds to the appearance of non-trivial chiral homology. The Gauss–Manin connection on the smooth locus is the Beilinson–Drinfeld connection on the chiral homology sheaf ([40]), and the wall-crossing at discriminant points reflects the non-semisimplicity of the representation category at admissible levels.

15.8 CALCULATIONS

15.8.1 FREE BOSON

Calculation 15.8.1 (Boson vacuum module;). For free boson $\mathcal{B}$:

Resolution:

$$\cdots \rightarrow \mathcal{B}^{\otimes n} \otimes \Omega^n(\overline{C}_n) \rightarrow \cdots \rightarrow \mathcal{B} \rightarrow \mathbb{C}$$

Character of $\mathcal{B}^{\otimes n}$:

$$\text{ch}(\mathcal{B}^{\otimes n}) = \prod_{i=1}^n \prod_{m>0} (1 - q^m)^{-1} = q^{n/24} \eta(q)^{-n}$$

Configuration space contribution:

$$\chi(\overline{C}_n, \Omega^k) = (-1)^k \binom{n-1}{k}$$

Acyclicity of the bar-cobar resolution gives:

$$1 = \text{ch}(\text{vac}) = \sum_{n \geq 0} (-1)^n \text{ch}(\mathcal{P}_n).$$

This is the free boson denominator identity.

15.8.2 FREE FERMION

Calculation 15.8.2 (Fermion vacuum;). For the free fermion $\mathcal{F}$, the Koszul dual is the β - γ system $\mathcal{B}^{\beta\gamma}$ (Theorem 7.0.29). The Koszul resolution of the vacuum module $\omega_X \in \text{Mod}_{\mathcal{F}}$ has n -th term

$$\mathcal{Q}_n = \mathcal{F} \otimes (\mathcal{B}^{\beta\gamma})_n \otimes \omega_X,$$

where $(\mathcal{B}^{\beta\gamma})_n$ denotes the degree- n component of the Koszul dual. Since $\mathcal{F}$ is a free-field algebra (generated by ψ, ψ^* with OPE $\psi(z)\psi^*(w) \sim 1/(z-w)$) and hence Koszul by the Lie $\leftrightarrow$ Com mechanism (the fermionic OPE is quadratic), the bar-cobar resolution is acyclic (Theorem 8.6.1). The alternating character sum gives:

$$1 = \text{ch}(\text{vac}_{\mathcal{F}}) = \sum_{n \geq 0} (-1)^n \text{ch}(\mathcal{Q}_n).$$

This is the fermionic denominator identity: the exterior algebra character $\prod_{m \geq 0} (1 + q^m)$ of $\mathcal{F}$ and the symmetric algebra character $\prod_{m \geq 0} (1 - q^m)^{-1}$ of $\mathcal{B}^{\beta\gamma}$ satisfy the Hilbert series relation $h_{\mathcal{F}}(t) \cdot h_{\mathcal{B}^{\beta\gamma}}(-t) = 1$.

15.8.3 $\mathcal{W}$ -ALGEBRAS

Calculation 15.8.3 (W -algebra at critical level;). For $W^{-h^\vee}(\mathfrak{g})$ at critical level $k = -h^\vee$:

Setup. By the Drinfeld–Sokolov reduction ([161]; see Part II), $W^{-h^\vee}(\mathfrak{g}) = H^0(\mathcal{Q}_{\text{DS}}, V^{-h^\vee}(\mathfrak{g}))$ where $\mathcal{Q}_{\text{DS}} = \sum_{\alpha \in \Delta_+} \oint S_{\alpha}^{\text{BRST}}$ involves fermionic ghosts c_{α}, b_{α} for each positive root $\alpha > 0$. At critical level, the bar complex of $\widehat{\mathfrak{g}}_{-h^\vee}$ satisfies $d^2 = 0$ (Proposition 7.1.11(i)), so the bar-cobar resolution is acyclic (Theorem 8.6.1).

Resolution. The vacuum module resolution takes the form:

$$\cdots \rightarrow V^{-h^\vee}(\mathfrak{g}) \otimes \wedge^n \mathfrak{n}_+ \xrightarrow{\mathcal{Q}_{\text{DS}}} \cdots \rightarrow V^{-h^\vee}(\mathfrak{g}) \otimes \mathfrak{n}_+ \xrightarrow{\mathcal{Q}_{\text{DS}}} V^{-h^\vee}(\mathfrak{g}) \rightarrow W^{-h^\vee}(\mathfrak{g}) \rightarrow 0$$

where $\mathfrak{n}_+ = \bigoplus_{\alpha > 0} \mathfrak{g}_{\alpha}$ is the nilpotent subalgebra and the differentials are given by the BRST operator $\mathcal{Q}_{\text{DS}}$. This resolution is acyclic by the Koszul property: the DS reduction at critical level is exact because at critical level $m_1^2 = 0$ (Proposition 7.1.11(i)), so the screening charges commute.

Character computation. Acyclicity of the resolution gives:

$$\begin{aligned} \text{ch}(W^{-h^\vee}(\mathfrak{g})) &= \sum_{n \geq 0} (-1)^n \text{ch}(V^{-h^\vee}(\mathfrak{g}) \otimes \wedge^n \mathfrak{n}_+) \\ &= \text{ch}(V^{-h^\vee}(\mathfrak{g})) \cdot \prod_{\alpha > 0} (1 - e^{-\alpha}) \end{aligned}$$

The second equality uses $\sum_n (-1)^n \text{ch}(\wedge^n \mathfrak{n}_+) = \prod_{\alpha > 0} (1 - e^{-\alpha})$, which is the standard exterior algebra Euler characteristic.

Denominator identity. Caution at critical level. At critical level $k = -h^\vee$, the W -algebra $W^{-h^\vee}(\mathfrak{g})$ has a large center $\mathfrak{z}(\widehat{\mathfrak{g}})$ (the Feigin–Frenkel center [160]), isomorphic to $\text{Fun}(\text{Op}_{\tilde{G}}(D))$, so $\text{ch}(W^{-h^\vee}(\mathfrak{g})) \neq 1$. At generic level, $W_k(\mathfrak{g})$ has a unique vacuum and the normalization $\text{ch}(W_k) = 1$ yields:

$$1 = \text{ch}(V_k(\mathfrak{g})) \cdot \prod_{\alpha > 0} (1 - e^{-\alpha})$$

expressing the vacuum character of $V_k(\mathfrak{g})$ as the inverse Weyl denominator (using only the finite roots; the full affine denominator involves additional factors $(1 - q^n e^{-\alpha})$).

15.9 LOCALIZATION AND D-MODULES

15.9.1 BEILINSON–BERNSTEIN LOCALIZATION

THEOREM 15.9.1 (*Beilinson–Bernstein [39];*). Let $\mathfrak{g}$ be a semisimple Lie algebra, G/B the flag variety, and $\lambda \in \mathfrak{h}^*$ a dominant regular weight. The *twisted sheaf of differential operators* $\mathcal{D}_\lambda$ on G/B satisfies:

- (i) The global sections functor $\Gamma : \text{Mod}(\mathcal{D}_\lambda) \rightarrow \text{Mod}(U(\mathfrak{g})_\chi)$ is an equivalence of abelian categories, where $U(\mathfrak{g})_\chi$ denotes modules with generalized infinitesimal character $\chi = \chi_{\lambda+\rho}$.
- (ii) The inverse is the localization functor $\Delta_\lambda : M \mapsto \mathcal{D}_\lambda \otimes_{U(\mathfrak{g})} M$.
- (iii) Both functors are exact and preserve the derived categories: $D^b(\text{Mod}(\mathcal{D}_\lambda)) \simeq D^b(\text{Mod}(U(\mathfrak{g})_\chi))$.

Proof. This is [39, Theorem 1.1]. The key ingredients are: (a) the global sections of $\mathcal{D}_\lambda$ are $U(\mathfrak{g})/\ker \chi_{\lambda+\rho}$ (by the Beilinson–Bernstein isomorphism); (b) the higher cohomology $H^i(G/B, \mathcal{D}_\lambda \otimes \mathcal{F}) = 0$ for $i > 0$ and λ dominant (Borel–Weil–Bott vanishing); (c) faithful flatness of $\mathcal{D}_\lambda$ over $U(\mathfrak{g})_\chi$. $\square$

THEOREM 15.9.2 (*Chiral localization [172];*). The Beilinson–Bernstein equivalence admits a chiral (loop group) analogue: for non-critical level $k \neq -h^\vee$, there is an equivalence

$$\Gamma^{\text{ch}} : \text{Mod}(\widehat{\mathcal{D}}_k)_{G/B} \xrightarrow{\sim} \text{Mod}(\widehat{\mathfrak{g}}_k)_\chi$$

where $\widehat{\mathcal{D}}_k$ is the chiral differential operator algebra on G/B at level k , and χ denotes modules with fixed central character (determined by the Feigin–Frenkel center at critical level, or by the Sugawara operator at generic level).

Proof. This is the Frenkel–Gaitsgory localization theorem [172, Theorem 1]. The proof uses the Wakimoto module construction (Theorem E.7.1) to produce $\widehat{\mathcal{D}}_k$ -modules from $\widehat{\mathfrak{g}}_k$ -modules, and the Drinfeld–Sokolov reduction to establish the equivalence. At critical level $k = -h^\vee$, the functor Γ^{ch} acquires a derived correction: Γ^{ch} becomes a derived equivalence involving the ind-completion of the category. $\square$

PROPOSITION 15.9.3 (*Bar complex as localization;*). The module bar complex $\bar{B}^{\text{ch}}(\widehat{\mathfrak{g}}_k, M)$ for an integrable module $M \in \mathcal{O}_k^{\text{int}}$ computes the localization of M to G/B :

$$H^i(\bar{B}^{\text{ch}}(\widehat{\mathfrak{g}}_k, M)) \cong H^i(G/B, \Delta_k(M))$$

where $\Delta_k(M) = \widehat{\mathcal{D}}_k \otimes_{\widehat{\mathfrak{g}}_k} M$ is the localized $\widehat{\mathcal{D}}_k$ -module. In particular, for dominant generic level: $H^i = 0$ for $i > 0$ and $H^0 = \Gamma(G/B, \Delta_k(M)) \cong M$.

Proof. By Theorem 15.9.2, the localized module $\Delta_k(M)$ is a $\widehat{\mathcal{D}}_k$ -module on G/B . The bar complex $\bar{B}^{\text{ch}}(\widehat{\mathfrak{g}}_k, M)$ is constructed on configuration spaces $\bar{C}_{n+1}(X)$; the forgetful map $\pi : \bar{C}_{n+1}(X) \rightarrow X^{n+1}$ pushes the bar complex down to X^{n+1} .

The Wakimoto realization identifies $\widehat{\mathfrak{g}}_k$ with sections of $\widehat{\mathcal{D}}_k$ over the big cell $N_- \subset G/B$: the $\beta\gamma$ generators are coordinates on N_- , and the Heisenberg generators are Cartan sections. Under this identification, the bar complex differential $d_{\text{bar}} = \sum_{i < j} \text{Res}_{D_{ij}}$ corresponds to the Cousin resolution of $\Delta_k(M)$ on G/B (residues at Schubert cell boundaries).

For M integrable at generic level, the Borel–Weil–Bott vanishing $H^i(G/B, \Delta_k(M)) = 0$ for $i > 0$ translates to the acyclicity of the bar resolution, which is the Koszul property (Theorem 8.6.1). $\square$

Remark 15.9.4 (Koszul duality and Langlands duality on the flag variety). The level shift $k \leftrightarrow -k - 2h^\vee$ acts on D-modules on G/B via the Feigin–Frenkel involution, exchanging G/B with the Langlands dual $G^\vee/B^\vee$ at the level of opers: $\mathrm{Op}_{G^\vee}(X) \xrightarrow{\mathrm{FF}} Z(\widehat{\mathfrak{g}}_{-h^\vee})$. The bar-cobar adjunction mediates: $\bar{B}(\Delta_k(M)) \simeq \Delta_{k'}(M^\dagger)$. This is the D-module incarnation of Theorem G.7.1.

15.9.2 AFFINE HECKE ALGEBRA

Definition 15.9.5 (Affine Hecke algebra). The *affine Hecke algebra* $H_q(\mathcal{W})$ associated to the affine Weyl group $\mathcal{W}$ of $\mathfrak{g}$ is the associative algebra over $\mathbb{C}(q)$ with generators T_{s_i} (s_i simple reflections) and X^λ ($\lambda \in P$ weight lattice), subject to:

- (i) *Hecke relation:* $(T_{s_i} - q)(T_{s_i} + q^{-1}) = 0$.
- (ii) *Braid relations:* $T_{s_i} T_{s_j} T_{s_i} \cdots = T_{s_j} T_{s_i} T_{s_j} \cdots$ (m_{ij} factors on each side).
- (iii) *Bernstein relation:* $T_{s_i} X^\lambda - X^{s_i(\lambda)} T_{s_i} = (q - q^{-1}) \frac{X^\lambda - X^{s_i(\lambda)}}{1 - X^{-\alpha_i}}$.

At $q = 1$, this recovers the group algebra $\mathbb{C}[\mathcal{W}]$.

PROPOSITION 15.9.6 (*Affine Hecke algebra and Koszul duality* [41];). The affine Hecke algebra H_q admits a Koszul duality theory:

- (i) H_q is a Koszul algebra (Beilinson–Ginzburg–Soergel [41]); the Ext algebra $\mathrm{Ext}_{H_q}^*(\mathbb{C}, \mathbb{C})$ is generated in degree 1.
- (ii) The Koszul dual $H_q^\dagger$ is the *periodic Hecke module* (Soergel bimodule algebra), which computes the Kazhdan–Lusztig polynomials via the combinatorial formula

$$P_{x,y}(q) = \sum_i \dim \mathrm{Ext}_{H_q}^i(L_x, L_y) q^{i/2}.$$

- (iii) Under the Kazhdan–Lusztig equivalence $\mathcal{O}_k^{\mathrm{int}} \simeq C(U_q(\mathfrak{g}))$ with $q = e^{\pi i/(k+h^\vee)}$, the affine Hecke algebra acts as the endomorphism algebra of a projective generator.
- (iv) (Koszul–Langlands) The inversion $q \mapsto q^{-1}$ on H_q (corresponding to $k \mapsto -k - 2h^\vee$) is an anti-involution exchanging left and right modules; this is the Hecke-algebraic avatar of the chiral Koszul duality of Theorem G.7.1.

Proof. For (i): see [41, Theorem 3.11.1]. For (ii): the Kazhdan–Lusztig polynomials arise as graded multiplicities in the Koszul resolution; see [380, Theorem 1.1]. For (iii): the projective generator is $P = \bigoplus_{\lambda \in P_+^k} P(\lambda)$ where $P(\lambda)$ is the projective cover of $L(\lambda)$ in $\mathcal{O}_k$; its endomorphism algebra is H_q by Soergel’s Struktursatz [380]. For (iv): the anti-involution $T_{s_i} \mapsto T_{s_i}^{-1}$ sends $q \mapsto q^{-1}$ and exchanges the bar involution on H_q (which governs the self-dual basis = KL basis). Under the KL equivalence, this corresponds to the Feigin–Frenkel level inversion $k \mapsto -k - 2h^\vee$ on $\widehat{\mathfrak{g}}_k$ -modules. $\square$

Remark 15.9.7 (Bar complex and KL polynomials). The bar resolution of $L(\lambda)$ in $\mathcal{O}_k$ has n -th term $\bigoplus_{\ell(w)=n} \mathcal{M}(w \cdot \lambda)^{P_{e,w}(q)}$, where $P_{e,w}(q) = \sum_i \dim \mathrm{IH}^{2i}(\overline{BwB}/B) q^i$ is the intersection cohomology of the Schubert variety (KL conjecture, proved by Beilinson–Bernstein [39] and Brylinski–Kashiwara [74]).

15.9.3 ASSOCIATED VARIETY AND SINGULAR SUPPORT

PROPOSITION 15.9.8 (*Bar complex and singular support*;). For an integrable $\widehat{\mathfrak{g}}_k$ -module M , the singular support of the localized D-module $\Delta_k(M)$ on G/B is related to the bar complex by:

$$\mathrm{SS}(\Delta_k(M)) = \overline{\mathbf{O}}_M \cap T^*(G/B)$$

where $\mathbf{O}_M \subset \mathfrak{g}^*$ is the nilpotent orbit associated to M via the Arakawa associated variety construction (Definition 15.2.33).

Proof. The localized D-module $\Delta_k(M)$ is holonomic when M has finite-dimensional associated variety (which holds for integrable modules by the Arakawa–Moreau theorem [13]). The singular support is the characteristic variety $\mathrm{Ch}(\Delta_k(M)) \subset T^*(G/B)$, which is a Lagrangian subvariety.

The Springer resolution $\mu : T^*(G/B) \rightarrow \mathcal{N}$ (where $\mathcal{N} \subset \mathfrak{g}^*$ is the nilpotent cone) maps $\mathrm{SS}(\Delta_k(M))$ to $\overline{\mathbf{O}}_M$. The fiber $\mu^{-1}(\mathbf{O}_M) \cap \mathrm{SS}(\Delta_k(M))$ is a union of conormal bundles to Schubert cells, and the components correspond to the terms of the BGG resolution. $\square$

Remark 15.9.9 (*Conjectural dual-level singular-support transport*). If the type-A orbit-duality principle (Conjecture 15.2.36) holds, then one expects level shifting and module Koszul duality to transport singular support by Barbasch–Vogan duality. The present manuscript does not prove that dual-level transport statement, so it is kept separate from Proposition 15.9.8.

Remark 15.9.10 (*Microlocal viewpoint*). Via Riemann–Hilbert, D-modules on G/B with singular support in $\overline{\mathbf{O}} \cap T^*(G/B)$ correspond to constructible sheaves microsupported in the same Lagrangian. The bar complex resolves the corresponding perverse sheaf: terms $\bar{B}_n^{\mathrm{ch}}(M)$ on $\bar{C}_{n+1}(X)$ form the Cousin complex. Both the geometric bar complex and BB localization compute the same cohomology (Proposition 15.9.3), the former via configuration spaces on any curve X , the latter on the flag variety.

15.10 DRINFELD–SOKOLOV REDUCTION AND MODULE KOSZUL DUALITY

THEOREM 15.10.1 (*DS reduction intertwines with Koszul duality*;). Let $\mathfrak{g}$ be a simple Lie algebra and $k \neq -h^\vee$ a non-critical level. The DS reduction functor $H_{\mathrm{DS}}^0 : \mathrm{Mod}(\widehat{\mathfrak{g}}_k) \rightarrow \mathrm{Mod}(\mathcal{W}^k(\mathfrak{g}))$ is compatible with Koszul duality in the following sense. There is a commutative diagram of functors:

$$\begin{array}{ccc} \mathrm{Mod}(\widehat{\mathfrak{g}}_k) & \xrightarrow{H_{\mathrm{DS}}^0} & \mathrm{Mod}(\mathcal{W}^k(\mathfrak{g})) \\ \bar{B} \downarrow & & \downarrow \bar{B}_W \\ \mathrm{CoMod}(\widehat{\mathfrak{g}}_k^{\dagger,c}) & \xrightarrow{H_{\mathrm{DS}^\dagger}^0} & \mathrm{CoMod}(\mathcal{W}^k(\mathfrak{g})^{\dagger,c}) \end{array} \quad (15.17)$$

where $\bar{B}$ and $\bar{B}_W$ are the bar constructions for the respective algebras, and $H_{\mathrm{DS}^\dagger}^0$ is the DS reduction applied to the Koszul dual coalgebras.

In particular, for a highest weight $\widehat{\mathfrak{g}}_k$ -module M with $\mathcal{W}$ -algebra reduction $M^W = H_{\mathrm{DS}}^0(M)$:

$$\bar{B}_W(M^W) \simeq H_{\mathrm{DS}}^0(\bar{B}(M)) \quad (15.18)$$

as complexes of $\mathcal{W}^k(\mathfrak{g})^{\dagger,c}$ -comodules.

Proof. The DS reduction is a BRST cohomology: $H_{\text{DS}}^0(M) = H^0(M \otimes F_\chi, Q_{\text{DS}})$. The bar complex of M is the complex $\bar{B}_n(M) = \Gamma(\bar{C}_{n+1}(X), j_* j^*(\mathcal{A}^{\boxtimes n} \boxtimes M) \otimes \Omega_{\log}^n)$ with differential d_{bar} .

Step 1: commutativity of Q_{DS} and d_{bar} . The BRST differential Q_{DS} acts *fiberwise*: at each configuration of insertion points $z_1, \dots, z_{n+1} \in X$, it acts on the chiral algebra fiber $\mathcal{A}_{z_i} \otimes F_{\chi, z_i}$ by the standard BRST formula. The bar differential d_{bar} acts on the *configuration space* data: it is the Poincaré residue along the boundary divisors $D_{ij} = \{z_i = z_j\}$, extracting OPE poles. Since Q_{DS} is a derivation of the vertex algebra structure (it preserves OPE poles and commutes with n -th products by the BRST definition), the two differentials commute: $[Q_{\text{DS}}, d_{\text{bar}}] = 0$.

Step 2: double complex. The commutativity of (15.17) follows from the double complex $\text{Tot}(\bar{B}_n(M) \otimes F_\chi, d_{\text{bar}}, Q_{\text{DS}})$, which computes both sides. Taking bar first, then DS, gives $H_{\text{DS}}^0(\bar{B}(M))$; taking DS first, then bar, gives $\bar{B}_W(M^W)$.

Step 3: spectral sequence. Filter the total complex by *bar degree* n . The E_0 differential is Q_{DS} (which preserves bar degree), so $E_1^{n,q} = H_{\text{DS}}^q(\bar{B}_n(M) \otimes F_\chi)$. By the DS vanishing theorem (Arakawa [12]; at generic level the vanishing also follows from irreducibility of Verma modules, cf. Proposition G.11.36(i)): $H_{\text{DS}}^q(\bar{B}_n(M) \otimes F_\chi) = 0$ for $q \neq 0$. Here the extension from M to $\bar{B}_n(M)$ uses closure of the relevant module category under the tensor products appearing in the bar construction (Proposition G.11.36(ii)). Therefore $E_1^{n,q} = 0$ for $q \neq 0$, the spectral sequence degenerates at E_1 , and the surviving row $E_1^{n,0} = H_{\text{DS}}^0(\bar{B}_n(M))$ computes the total cohomology. The identification $H_{\text{DS}}^0(\bar{B}(M)) \simeq \bar{B}_W(M^W)$ follows. $\square$

Remark 15.10.2 (Geometric content of DS–bar commutativity). Through the Slodowy-slice localization principle (Remark H.2.7), Theorem 15.10.1 says: *computing bar, then Hamiltonian-reducing to the Slodowy slice $J_\infty(S_f)$, gives the same result as Hamiltonian-reducing first, then computing bar on the reduced algebra.* The spectral-sequence argument (Step 3) is the algebraic incarnation of a geometric fact: at generic level, the $\mathfrak{n}_+$ -action on configuration spaces is *free* on the relevant stratum (OPE-pole transversality ensures the moment-map fiber is smooth), so higher BRST cohomology vanishes and H_{DS}^0 suffices. At admissible or critical levels, the freeness can fail (the moment-map fiber acquires singularities) and commutativity requires the full derived DS functor $\mathbf{R}DS$.

At the associated-variety level, the commutativity upgrades Arakawa’s intersection theorem (Theorem H.2.6) from support to chain level: the bar complex models $\bar{B}(M) \otimes_{\mathbb{C}[J_\infty(\mathfrak{g}^*)]}^L \mathbb{C}[J_\infty(S_f)] \simeq \bar{B}_W(M^W)$. This chain-level base-change identity upgrades Arakawa’s cohomology-level result; a full proof requires verifying the derived tensor product commutes with the bar construction, which we expect to follow from the master commutative square (Theorem H.26.31).

COROLLARY 15.10.3 (Characters under DS reduction;). For a simple highest weight module $\mathcal{L}(\lambda) \in \mathcal{O}_k(\widehat{\mathfrak{g}})$ at generic level (i.e., $H_{\text{DS}}^i(\mathcal{L}(\lambda)) = 0$ for $i \neq 0$), the character of the DS reduction $\mathcal{L}^W(\lambda) = H_{\text{DS}}^0(\mathcal{L}(\lambda))$ is given by the alternating Euler characteristic of the ghost system:

$$\text{ch}(\mathcal{L}^W(\lambda)) = \text{ch}(\mathcal{L}(\lambda)) \cdot \prod_{\alpha \in \Delta_+} (1 - e^{-\alpha})^{-1}.$$

Here the factor $\prod_{\alpha \in \Delta_+} (1 - e^{-\alpha})^{-1} = \chi(\wedge^\bullet \mathfrak{n}_+^*)^{-1}$ is the inverse of the graded Euler characteristic of the ghost complex; the identity holds in the formal character ring $\mathbb{Z}[[e^{-\alpha_1}, \dots, e^{-\alpha_r}]]$, where each $e^{-\alpha}$ is nilpotent after restriction to a given weight space.

Proof. By Theorem 15.10.1, the bar complex of $\mathcal{L}^W(\lambda)$ is the DS reduction of the bar complex of $\mathcal{L}(\lambda)$.

Taking alternating Euler characteristics:

$$\mathrm{ch}(\mathcal{L}^W(\lambda)) = \sum_{n \geq 0} (-1)^n \mathrm{ch}(\bar{B}_n^W(\mathcal{L}^W)) = \sum_{n \geq 0} (-1)^n \mathrm{ch}(H_{\mathrm{DS}}^0(\bar{B}_n(\mathcal{L})))$$

Using the exactness of H_{DS}^0 on highest weight modules and the ghost Euler characteristic $\chi(\bigwedge^\bullet \mathfrak{n}_+^*) = \prod_{\alpha > 0} (1 - e^{-\alpha})$, the right side equals $\mathrm{ch}(\mathcal{L}(\lambda)) / \prod_{\alpha > 0} (1 - e^{-\alpha})$. $\square$

COROLLARY 15.10.4 (*$\mathcal{W}$ -algebra bar at dual level via DS and Verdier intertwining*;). For a simple Lie algebra $\mathfrak{g}$ and non-critical level $k \neq -h^\vee$:

$$H_{\mathrm{DS}}^0(\bar{B}^{\mathrm{ch}}(\widehat{\mathfrak{g}}_k)) \simeq \bar{B}_W^{\mathrm{ch}}(\mathcal{W}^k(\mathfrak{g})), \quad (15.19)$$

and composing with the Verdier intertwining (Corollary 7.1.13):

$$H_{\mathrm{DS}}^0(\mathbb{D}_{\mathrm{Ran}} \bar{B}^{\mathrm{ch}}(\widehat{\mathfrak{g}}_k)) \simeq \bar{B}_W^{\mathrm{ch}}(\mathcal{W}^{k'}(\mathfrak{g})), \quad k' = -k - 2h^\vee. \quad (15.20)$$

Proof. Equation (15.19) is the algebra-level case of Theorem 15.10.1 (take $M = \widehat{\mathfrak{g}}_k$ as a module over itself). For (15.20): Corollary 7.1.13 provides the algebra-level Verdier intertwining $\mathbb{D}_{\mathrm{Ran}} \bar{B}^{\mathrm{ch}}(\widehat{\mathfrak{g}}_k) \simeq \bar{B}^{\mathrm{ch}}(\widehat{\mathfrak{g}}_{k'})$ (this is the Koszul-dual identification, distinct from bar-cobar inversion $\Omega^{\mathrm{ch}}(\bar{B}^{\mathrm{ch}}(\widehat{\mathfrak{g}}_k)) \simeq \widehat{\mathfrak{g}}_k$, which recovers the original algebra by Theorem B). Applying H_{DS}^0 to both sides and using (15.19) for $\widehat{\mathfrak{g}}_{k'}$ gives $\bar{B}_W^{\mathrm{ch}}(\mathcal{W}^{k'}(\mathfrak{g}))$. $\square$

Conjecture 15.10.5 (*DS-derived chiral center commutation*;). Let $\mathfrak{g}$ be a simple Lie algebra and $k \notin \mathbb{Q}_{\leq 0}$ a generic level. Principal Drinfeld–Sokolov reduction commutes with the derived chiral center:

$$CH^*(H_{\mathrm{DS}}^0(V_k(\mathfrak{g}))) \simeq H_{\mathrm{DS}}^0(CH^*(V_k(\mathfrak{g}))) \quad (15.21)$$

as Gerstenhaber algebras, where both sides carry the cup product and degree-(-1) Lie bracket of Theorem 15.5.4.

Remark 15.10.6 (*Proof sketch and exact gap for Conjecture 15.10.5*). Write $A = V_k(\mathfrak{g})$ and $W = H_{\mathrm{DS}}^0(A) = \mathcal{W}^k(\mathfrak{g})$. On the generic principal lane, a proof should proceed as follows.

- (i) The chiral Hochschild complex is computed from the bar resolution: for each bar degree p , the cochain term $C_{\mathrm{ch}}^p(A, A)$ is the internal-hom object from the p -th bar term $\bar{B}_p(A)$ to A , with Hochschild differential assembled from the bar differential and the left-right A -action. The same description computes $C_{\mathrm{ch}}^\bullet(W, W)$.
- (ii) Principal DS reduction commutes with the bar construction (Theorem 15.10.1), and on the generic principal lane the classical functor already computes the derived one by filtration formality (Proposition H.26.46). Hence for every bar degree p one has

$$\bar{B}_p(W) \simeq H_{\mathrm{DS}}^0(\bar{B}_p(A)).$$

- (iii) The BRST differential acts fiberwise on both the source and the target of the cochain term $C_{\mathrm{ch}}^p(A, A)$. Since Q_{DS} is a derivation of the chiral product and commutes with the bar differential exactly as in Step 1 of the proof of Theorem 15.10.1, it commutes with the Hochschild differential. The same derivation property implies compatibility with brace insertion, hence with the cup product and Gerstenhaber bracket of Theorem 15.5.4.

(iv) Filter the resulting double complex by bar degree. Its E_1 -page is

$$E_1^{p,q} = H_{\text{DS}}^q(C_{\text{ch}}^p(A, A)).$$

If one proves the degreewise comparison map

$$H_{\text{DS}}^0(C_{\text{ch}}^p(A, A)) \longrightarrow C_{\text{ch}}^p(W, W)$$

is a quasi-isomorphism and that $H_{\text{DS}}^q(C_{\text{ch}}^p(A, A)) = 0$ for $q > 0$, then the spectral sequence collapses at E_1 and yields

$$H_{\text{DS}}^0(C_{\text{ch}}^\bullet(A, A)) \simeq C_{\text{ch}}^\bullet(W, W),$$

hence (15.21) as an isomorphism of Gerstenhaber algebras.

Thus the conjecture is reduced to a single precise missing input: generic-level DS exactness on the internal-hom terms computing the derived center, equivalently on the bar resolution of the diagonal bimodule. Theorem 15.10.1 proves the coalgebra-side commutation; the unresolved point is exactly the vanishing and comparison statement in (iv).

15.II GENUS-GRADED MODULE CATEGORIES

The full bar complex $\bar{B}^{\text{full}}(\mathcal{A}) = \bigoplus_{g \geq 0} \bar{B}^{(g)}(\mathcal{A})$ is genus-graded (Theorem K.7.1).

Definition 15.II.1 (Genus-graded module). Let $\mathcal{A}$ be a Koszul chiral algebra. A *genus-graded $\mathcal{A}$ -module* is a collection $\{M^{(g)}\}_{g \geq 0}$ where $M^{(g)}$ is a module over the genus- g bar complex $\bar{B}^{(g)}(\mathcal{A})$, equipped with:

(i) *Factorization maps:* For each partition $g = g_1 + g_2$, a chain map

$$\Delta_M : M^{(g)} \rightarrow M^{(g_1)} \otimes_{\mathcal{A}} M^{(g_2)} \quad (15.22)$$

compatible with the algebra factorization (Theorem K.7.1(ii)).

(ii) *Self-sewing maps:* A chain map

$$\sigma_M : M^{(g)} \rightarrow M^{(g-1)} \quad (15.23)$$

compatible with the algebra self-sewing (Theorem K.7.1(iii)).

(iii) *Coherence:* The factorization and self-sewing maps satisfy associativity and commutativity up to homotopies provided by the A_∞ module operations.

The curvature $m_0^{(g)} = \kappa(\mathcal{A}) \cdot \lambda_g$ mixes the genus components: $d_{M^{(g)}}^2 = m_0^{(g)} \cdot \text{id}$, so the genus-graded module is a curved complex over the formal genus parameter $\hbar$.

THEOREM 15.II.2 (Module tower from bar complex with insertions;). For a Koszul chiral algebra $\mathcal{A}$ and an $\mathcal{A}$ -module M , the bar complex with module insertion $\bar{B}_n^{(g)}(\mathcal{A}; M) := \bar{B}_n^{(g)}(\mathcal{A}; M, \mathcal{A}, \dots, \mathcal{A})$ (with M inserted at the first marked point) forms a genus-graded $\mathcal{A}$ -module in the sense of Definition 15.II.1.

Proof. The bar complex with module insertion $\bar{B}_n^{(g)}(\mathcal{A}; M)$ is defined via configuration space integrals on the logarithmic FM compactification (Theorem 8.2.10). The nilpotency $d^2 = 0$ is proved there.

The factorization map (15.22) is constructed as follows. The separating boundary divisor $D_{\text{sep}} \subset \overline{\mathcal{M}}_{g,n}$ with the module insertion on the genus- g_1 component produces a residue map $\text{Res}_{D_{\text{sep}}} : \bar{B}_n^{(g)}(\mathcal{A}; M) \rightarrow$

$\bar{B}_{|I|+1}^{(g_1)}(\mathcal{A}; M) \otimes \bar{B}_{|J|+1}^{(g_2)}(\mathcal{A})$. The module insertion stays on one component; the other component carries only algebra insertions. That this is a chain map follows from the compatibility of the Feynman transform differential with boundary strata (Getzler–Kapranov [199]).

The self-sewing map (15.23) is constructed from the nonseparating boundary divisor, analogously to the algebra case (Theorem K.7.1(iii)).

Coherence follows from the A_∞ module structure on $\bar{B}_n^{(g)}(\mathcal{A}; M)$, which provides the required homotopies between different orderings of degeneration. $\square$

PROPOSITION 15.11.3 (*Koszul duality of genus-graded modules*;). For a Koszul pair $(\mathcal{A}, \mathcal{A}^!)$ and a Koszul $\mathcal{A}$ -module M with Koszul dual module $M^! = \Phi(M)$ (Theorem 11.6.2), the genus-graded module structures are related by:

$$\bar{B}_n^{(g)}(\mathcal{A}; M) \simeq \mathrm{RHom}_{\mathcal{A}^!}(\bar{B}_n^{(g)}(\mathcal{A}^!; M^!), \omega_{\overline{\mathcal{M}}_{g,n}})[- \dim_{\mathbb{C}} \mathcal{M}_{g,n}] \quad (15.24)$$

In particular, the factorization maps dualize: Δ_M for $\mathcal{A}$ is Verdier dual to $\Delta_{M^!}$ for $\mathcal{A}^!$.

Proof. Combine Theorem 11.6.2 (the module bar functor $\Phi: \mathrm{Mod}_{\mathcal{A}}^{\mathrm{compl}} \rightarrow \mathrm{CoMod}_{\bar{B}(\mathcal{A})}^{\mathrm{conil}}$ of Definition 15.1.9, which becomes a complete $\mathcal{A}$ -module/complete $\mathcal{A}^!$ -module comparison only after the finite-type graded-dual identification $\bar{B}(\mathcal{A})^\vee \cong \mathcal{A}^!$ is justified) with Corollary K.7.1 (Verdier duality of the chain-level modular functor). The module insertion at a marked point transforms covariantly under the bar functor Φ , while the algebra insertions at other marked points transform via the algebra-level Verdier intertwining $\mathbb{D}_{\mathrm{Ran}} \bar{B}(\mathcal{A}) \simeq \mathcal{A}_\infty^!$ (Theorem 11.1.84). The Verdier duality on $\overline{\mathcal{M}}_{g,n}$ interchanges the factorization maps by the naturality argument of Corollary K.7.1. The right-hand side of (15.24) is therefore literally the module bar complex on the dual side; only on finite-type graded-dual lanes is $\bar{B}_n^{(g)}(\mathcal{A}^!; M^!)$ further rewritten as a complete $\mathcal{A}^!$ -module. $\square$

Remark 15.11.4 (*Curvature as obstruction to strict genus-grading*). When $\kappa(\mathcal{A}) \neq 0$, the curvature $m_0^{(g)} = \kappa \cdot \lambda_g$ mixes genus components: individual $M^{(g)}$ are curved ($d^2 = m_0^{(g)} \cdot \mathrm{id}$) and only $M^{\mathrm{total}} = \bigoplus_g \hbar^{2g-2} M^{(g)}$ has $d^2 = 0$. At critical level $\kappa = 0$, the genus-grading becomes strict and classical module theory is recovered as the $g = 0$ summand.

Example 15.11.5 (*KM Verma modules: explicit genus-1 computation*). We compute the genus-1 layer of $\mathcal{M}(0)_k$ for $\widehat{\mathfrak{sl}}_2$ at level k .

Genus-0 piece. $M^{(0)} = \bar{B}^{(0)}(\mathcal{A}; \mathcal{M}(0))$ is the bar complex of the Verma module on genus-0 curves, whose cohomology is the Verma–BGG resolution (Theorem O.9.5). The chain group at degree n and grade h has dimension

$$\dim M_n^{(0)}(h) = (\text{bar chain dim at degree } n) \cdot [q^h] \prod_{m \geq 1} (1 - q^m)^{-3},$$

the product reflecting three $\widehat{\mathfrak{sl}}_2$ current generators. The first Verma module dimensions are:

$$\dim \mathcal{M}(0)_h = 1, 3, 9, 22, 51, 108, 221, 429, 810, \dots \quad (h = 0, 1, 2, \dots).$$

Genus-1 curvature. The genus-1 module bar differential satisfies $d_{M^{(1)}}^2 = m_0^{(1)} \cdot \mathrm{id}$ with curvature (Theorem K.7.1):

$$m_0^{(1)}(\mathcal{M}(0)_k) = \kappa(\widehat{\mathfrak{sl}}_{2k}) \cdot \lambda_1 = \frac{3(k+2)}{4} \cdot \frac{1}{24} = \frac{k+2}{32}. \quad (15.25)$$

At $k = 1$, this gives $m_0^{(1)} = 3/32$; at $k = -2$ (critical level), the curvature vanishes.

The genus-1 correction to the module partition function is:

$$Z_1(\mathcal{M}(0)_k) = \frac{k(k+4)}{48(k+2)} \cdot \prod_{m \geq 1} (1 - q^m)^{-3} = \frac{k(k+4)}{48(k+2)} \cdot (1 + 3q + 9q^2 + 22q^3 + \cdots).$$

Module complementarity. The dual module $\Phi(\mathcal{M}(0)_k) = \mathcal{M}(0)_{-k-4}$ (Proposition 15.6.16) has genus-1 correction:

$$Z_1(\mathcal{M}(0)_{-k-4}) = \frac{(-k-4)(-k)}{48(-k-2)} = -\frac{k(k+4)}{48(k+2)} = -Z_1(\mathcal{M}(0)_k).$$

Thus $Z_1(\mathcal{M}(0)_k) + Z_1(\mathcal{M}(0)_{-k-4}) = 0$: the genus-1 corrections of a module and its Koszul dual are complementary, instantiating Theorem 13.15.14 at the module level.

Independence of highest weight. For a non-vacuum Verma module $\mathcal{M}(\lambda)_k$ (Proposition 15.6.18), the curvature (15.25) is unchanged: $m_0^{(1)}$ depends on the algebra $\widehat{\mathfrak{sl}}_{2k}$ but not on the module highest weight λ . Only the genus-0 graded dimension changes (via the h_0 -eigenvalue), so the full genus-1 correction is:

$$Z_1(\mathcal{M}(\lambda)_k) = \frac{k(k+4)}{48(k+2)} \cdot \text{ch}^{(0)}(\mathcal{M}(\lambda))$$

with the complementarity $Z_1(\mathcal{M}(\lambda)_k) + Z_1(\mathcal{M}(\lambda)_{-k-4}) = 0$ holding for all λ .

Factorization. The factorization map $\Delta_M : M^{(g)}(\lambda) \rightarrow M^{(g_1)}(\lambda) \otimes M^{(g_2)}(0)$ (with vacuum module at the second factor) recovers the genus tower restriction maps of Theorem K.7.1.

15.II.1 EXT GROUPS VIA THE BAR RESOLUTION

The bar resolution of a module M over a chiral algebra $\mathcal{A}$ is the complex $B_n(\mathcal{A}) \otimes_{\mathcal{A}} M \xrightarrow{d_{\text{bar}}^{\text{mod}}} B_{n-1}(\mathcal{A}) \otimes_{\mathcal{A}} M \rightarrow \cdots \rightarrow M \rightarrow 0$ (Definition 15.3.2).

PROPOSITION 15.II.6 (*Ext via bar resolution*;). For a Koszul chiral algebra $\mathcal{A}$ and modules $M, N \in \text{Mod}(\mathcal{A})$:

$$\text{Ext}_{\mathcal{A}}^n(M, N) \simeq H^n(\text{Hom}_{\mathcal{A}}(B_{\bullet}(\mathcal{A}) \otimes_{\mathcal{A}} M, N)). \quad (15.26)$$

For Verma modules $\mathcal{M}(\lambda)_k$ at generic level k : $\text{Ext}^n(\mathcal{M}(\lambda), \mathcal{M}(\mu)) = 0$ for all $n \geq 1$ and all λ, μ .

Proof. Formula (15.26) holds because $B_{\bullet}(\mathcal{A}) \otimes_{\mathcal{A}} M$ is a projective resolution of M in the module category (the bar terms are free modules by the PBW property of the bar complex, Theorem 11.1.84).

The vanishing for Verma modules follows from their freeness: $\mathcal{M}(\lambda)_k = \text{Ind}_{\hat{\mathfrak{b}}_+}^{\hat{\mathfrak{g}}} \mathbb{C}_{\lambda, k}$ is the free $U(\hat{\mathfrak{n}}_-)$ -module on a highest weight vector. At generic k , the bar differential $d_{\text{bar}}^{\text{mod}} : B_1 \otimes_{\mathcal{A}} M \rightarrow M$ is surjective onto the augmentation ideal, so $H^1 = 0$; higher Ext groups vanish similarly. $\square$

Example 15.II.7 (Non-trivial Ext¹ at special level;). At $\widehat{\mathfrak{sl}}_2$ with $k = 1$ and $\lambda = -k - 2 = -3$:

- (i) The grade-1 Shapovalov determinant $\det S_1(-3, 1) \sim (-3 + 1 + 2) = 0$ vanishes, so $\mathcal{M}(-3)_1$ has a singular vector v_{sing} at grade 1. The irreducible quotient $L(-3)_1 = \mathcal{M}(-3)_1 / \langle v_{\text{sing}} \rangle$ has

$$\dim \text{Ext}_{\widehat{\mathfrak{sl}}_2}^1(L(-3)_1, \mathbb{C}) = 1,$$

the extension class being the singular vector class $[v_{\text{sing}}] \in H^1(B_{\bullet}(\mathcal{A}) \otimes_{\mathcal{A}} L(-3))$.

- (ii) Under Koszul duality $k \mapsto -k - 4 = -5$: $\det S_1(-3, -5) \sim (-3 - 5 + 2) = -6 \neq 0$, so $\mathcal{M}(-3)_{-5}$ has no grade-1 singular vector. The dual module $L(-3)_{-5} = \mathcal{M}(-3)_{-5}$ is irreducible, and $\text{Ext}^1(L(-3)_{-5}, \mathbb{C}) = 0$ at grade 1.

The asymmetry $\dim \text{Ext}^1 = 1$ at level $k = 1$ versus $\dim \text{Ext}^1 = 0$ at the dual level $k = -5$ reflects the complementary placement of singular vectors (Corollary 15.6.19): the Koszul duality functor Φ maps the non-trivial extension at level k to a trivial one at level $-k - 4$.

Example 15.11.8 (Ext at admissible fractional level;). At the admissible level $k = -\frac{1}{2}$ ($p = 3, q = 2, k + 2 = \frac{3}{2}$), the Kac–Kazhdan factor at grade 1 for $\mathcal{M}(\lambda)$ with $(r, s) = (1, 1)$ is $\lambda + 1 - 1 + \frac{3}{2} = \lambda + \frac{3}{2}$. This vanishes at $\lambda = -\frac{3}{2}$, producing a singular vector $v_{\text{sing}} \in \mathcal{M}(-\frac{3}{2})_{-1/2}$ at grade 1.

- (i) The simple quotient $L(-\frac{3}{2})_{-1/2}$ satisfies

$$\dim \text{Ext}_{\widehat{\mathfrak{sl}}_2}^1(L(-\frac{3}{2})_{-1/2}, \mathbb{C}) = 1,$$

computed via the bar resolution: the grade-1 module bar differential $d_{\text{bar}}^{\text{mod}}: B_1 \otimes L(-\frac{3}{2}) \rightarrow L(-\frac{3}{2})$ has a one-dimensional cokernel detected by $[v_{\text{sing}}]$.

- (ii) Under Feigin–Frenkel duality $k \mapsto -k - 4 = -\frac{7}{2}$ (with $k' + 2 = -\frac{3}{2}$): the factor at grade 1 becomes $-\frac{3}{2} + 1 - 1 + (-\frac{3}{2}) = -3 \neq 0$, so $\mathcal{M}(-\frac{3}{2})_{-7/2}$ has no grade-1 singular vector and $\text{Ext}^1(L(-\frac{3}{2})_{-7/2}, \mathbb{C}) = 0$.
- (iii) The singular vector at grade 1 generates a submodule $\mathcal{M}(-\frac{7}{2})_{-1/2} \hookrightarrow \mathcal{M}(-\frac{3}{2})_{-1/2}$, yielding the BGG resolution

$$0 \rightarrow \mathcal{M}(-\frac{7}{2})_{-1/2} \rightarrow \mathcal{M}(-\frac{3}{2})_{-1/2} \rightarrow L(-\frac{3}{2})_{-1/2} \rightarrow 0.$$

This is read off the E_2 page of the bar spectral sequence (Theorem 8.6.16) applied to $B_{\bullet}(\widehat{\mathfrak{sl}}_2) \otimes L(-\frac{3}{2})$: the two non-zero columns at positions $(0, *)$ and $(1, *)$ encode $\mathcal{M}(-\frac{3}{2})$ and $\mathcal{M}(-\frac{7}{2})$ respectively. Collapse at E_2 gives the character

$$\text{ch } L(-\frac{3}{2})_{-1/2} = \frac{q^{-1/8}(1-q)}{\prod_{n \geq 1} (1-q^n)},$$

where $h(-\frac{3}{2}) = (-\frac{3}{2})(\frac{1}{2})/(4 \cdot \frac{3}{2}) = -\frac{1}{8}$ and the grade-1 submodule has $h(-\frac{7}{2}) = -\frac{1}{8} + 1 = \frac{7}{8}$.

Remark 15.11.9 (Admissible characters via bar spectral sequence). On the worked benchmark surface of Example 15.11.8, the bar spectral sequence for $B_{\bullet}(\widehat{\mathfrak{sl}}_2) \otimes L(-\frac{3}{2})_{-1/2}$ recovers the two-term BGG resolution and the corresponding admissible character at $k = -1/2$. At the dual level $k' = -k - 4$, Corollary 15.6.19 describes the complementary singular-vector pattern. What is not proved here is a general theorem that the bar spectral sequence determines all admissible $\widehat{\mathfrak{sl}}_2$ characters at arbitrary fractional level.

15.11.2 FUSION PRODUCT PRESERVATION UNDER BAR-COBAR

THEOREM 15.11.10 (Fusion product compatibility on the module bar surface;). Assume $\mathcal{A}$ lies on a module-theoretic lane where Proposition 15.1.10 applies and that the fusion products under consideration are defined on the complete module category. Then the module bar functor

$$\Phi: \text{Mod}_{\mathcal{A}}^{\text{compl}} \longrightarrow \text{CoMod}_{\widehat{B}(\mathcal{A})}^{\text{conil}}$$

is compatible with fusion products by a natural transformation

$$\Phi(M_1 \boxtimes_{\mathcal{A}} M_2) \longrightarrow \Phi(M_1) \square_{\overline{B}(\mathcal{A})} \Phi(M_2) \quad (15.27)$$

which is a quasi-isomorphism when M_1 and M_2 are Koszul modules and the Künneth/Tor-independence hypotheses from Theorem 15.1.12 hold. On finite-type graded-dual lanes, one may further rewrite the cotensor target after dualization on the graded-dual algebra side.

For Kac–Moody algebras $\widehat{\mathfrak{g}}_k$ at integrable level:

- (i) The fusion product $\boxtimes_k$ on $\mathcal{O}_k^{\text{int}}(\widehat{\mathfrak{g}})$ is sent to the tensor product on the semisimplified tilting quotient $\mathcal{C}(U_q(\mathfrak{g}))$, preserving the braiding up to a sign determined by the level shift.
- (ii) For Heisenberg Fock modules $F_\lambda \boxtimes_\kappa F_\mu \cong F_{\lambda+\mu}$, the braiding phase $e^{2\pi i \lambda \mu / k}$ is sent to $e^{-2\pi i \lambda \mu / k}$ under $\kappa \mapsto -\kappa$.
- (iii) The bar coalgebra coproduct

$$\Delta: \overline{B}(\mathcal{A}, M_1 \boxtimes M_2) \rightarrow \overline{B}(\mathcal{A}, M_1) \otimes \overline{B}(\mathcal{A}, M_2)$$

is the chain-level realization of the fusion product, induced by the separating degeneration map of Theorem K.7.1(ii).

Proof. The general compatibility statement is the content of Theorem 15.1.12; the remaining affine and Heisenberg clauses are the special surfaces where that bar-comodule statement is identified more concretely. Concretely:

Main statement (15.27). Theorem 15.1.12, equation (15.1), constructs the natural transformation

$$\mu_{M_1, M_2}: \Phi(M_1 \boxtimes_{\mathcal{A}} M_2) \rightarrow \Phi(M_1) \square_{\overline{B}(\mathcal{A})} \Phi(M_2)$$

via the Alexander–Whitney factorization on configuration spaces (Step 1 of that proof), and proves it is a quasi-isomorphism when M_1, M_2 are Koszul modules (Step 2, using the Künneth theorem and diagonal concentration).

Part (i): braiding reversal. On the affine Drinfeld–Kohno surface, the composite equivalence reverses the braiding ($\sigma^! = \sigma^{-1}$) by Theorem O.13.5: Verdier duality on $\overline{\mathcal{C}}_2(\mathbb{P}^1)$ inverts the KZ monodromy, and the Kohno–Drinfeld theorem identifies that monodromy with the quantum group R -matrix. This identifies the affine specialization of the bar-comodule comparison with the $\boxtimes_k \leftrightarrow \otimes_q$ correspondence.

Part (ii): Heisenberg phase inversion. For the Heisenberg algebra, the braiding on Fock modules F_λ is the scalar $e^{2\pi i \lambda \mu / k}$. By Remark 15.1.8, orientation reversal sends $e^{2\pi i \lambda \mu / k} \mapsto e^{-2\pi i \lambda \mu / k}$ under $\kappa \mapsto -\kappa$.

Part (iii): chain-level coproduct. Step 1 of Theorem 15.1.12 identifies the Alexander–Whitney map with the factorization along separating divisors of $\overline{\mathcal{M}}_{g,n}$: the summand where p points cluster near the first marked point and q near the second yields $\overline{B}_p(M_1) \otimes \overline{B}_q(M_2)$. This is precisely the separating degeneration map Δ_{sep} of Theorem K.7.1(ii). $\square$

Remark 15.11.11 (Non-semisimple lift). At chain level, the KL functor Φ factors through a non-semisimple category before semisimplification to $\mathcal{C}(U_q(\mathfrak{g}))$. A chain-level lift of Theorem 15.11.10(i) to this non-semisimple intermediate (the full tilting category before the quotient) would strengthen the result but is not needed for the present applications and is deferred.

Remark 15.11.12 (Proof structure). The monoidality of Φ was the hardest part of the Kazhdan–Lusztig programme [257]. The configuration space proof via the bar complex resolves this: residue maps along separating divisors of $\overline{\mathcal{M}}_{g,n}$ are compatible with the fusion product’s associativity and commutativity constraints (Theorem 15.1.12, Steps 1–2). The stronger affine/Yangian braiding reversal is established separately on the derived Drinfeld–Kohno surfaces.

15.11.3 VERIFICATION: HEISENBERG FUSION IN THE BAR COMPLEX

We verify Theorem 15.11.10 for the Heisenberg algebra $\mathcal{H}_k$ acting on Fock modules F_λ, F_μ .

PROPOSITION 15.11.13 (*Heisenberg fusion splitting*;). Let $\mathcal{H}_k$ be the Heisenberg chiral algebra at level $\kappa \neq 0$, and let F_λ, F_μ be Fock modules. Then

$$\Phi(F_\lambda \boxtimes_\kappa F_\mu) \cong \Phi(F_\lambda) \otimes \Phi(F_\mu) \quad (15.28)$$

as comodules over the Koszul dual coalgebra $\overline{B}(\mathcal{H}_k)$.

Proof. The Heisenberg OPE is $a(z)a(w) \sim \kappa/(z-w)^2$: there is a double pole but *no simple pole*. By the pole decomposition (Proposition 6.1.24), the bar differential on any module decomposes as $d = d_{\text{bracket}} + d_{\text{curvature}}$, where d_{bracket} arises from simple-pole residues and $d_{\text{curvature}}$ from double-pole residues. For $\mathcal{H}_k$, the simple-pole residue vanishes identically, so $d_{\text{bracket}} = 0$.

Consider the bar complex of the fusion product $\overline{B}(\mathcal{H}_k, F_\lambda \boxtimes F_\mu)$. The underlying graded space is $\overline{B}(\mathcal{H}_k) \otimes (F_\lambda \otimes F_\mu)$. The differential decomposes as $d = d_\lambda + d_\mu + d_{\text{cross}}$, where d_λ (resp. d_μ) acts on the F_λ (resp. F_μ) factor through the double-pole curvature, and d_{cross} encodes interactions between the two module factors via the configuration space of points distributed between the two components.

We have $d_{\text{cross}} = 0$: the cross-term arises from residues of the OPE between generators acting on F_λ and generators acting on F_μ . In the genus-0 fusion (pants decomposition of $\overline{\mathcal{M}}_{0,4}$), these cross-terms are governed by simple-pole residues along the separating divisor. Since the Heisenberg OPE has no simple pole, all such residues vanish. The vanishing of d_{cross} gives the Künneth splitting

$$\overline{B}(\mathcal{H}_k, F_\lambda \boxtimes F_\mu) \cong \overline{B}(\mathcal{H}_k, F_\lambda) \otimes \overline{B}(\mathcal{H}_k, F_\mu)$$

as chain complexes, which descends to the isomorphism (15.28) after applying Φ . The phase inversion $\kappa \mapsto -\kappa$ on the dual side (Proposition 15.1.7) is automatic: $d_{\text{curvature}}$ is linear in κ , and the Koszul dual acts at level $-\kappa$. $\square$

Remark 15.11.14. The Heisenberg case is exceptional: $d_{\text{cross}} = 0$ because the OPE is purely double-pole. For non-abelian $\widehat{\mathfrak{g}}_k$, $d_{\text{cross}} \neq 0$ and the bar complex of the fusion product does not split; monoidality requires the separating-divisor analysis of Theorem K.7.1.

15.12 KOSZUL DUALITY AND UNIVERSAL CHIRAL DEFECTS

Poincaré duality for manifolds pairs cochains with chains; quantum Poincaré duality for chiral algebras pairs the algebra with its Koszul dual. The bar-cobar engine of the preceding chapters manufactures this pairing automatically: the universal chiral defect $\mathcal{D}(\mathcal{A}) = \mathbb{D}_{\text{Ran}} \bar{B}^{\text{ch}}(\mathcal{A})$ is the Verdier dual of the bar coalgebra, carrying the homotopy Koszul dual $\mathcal{A}^!$ as its algebra structure. This section traces the pairing across genera and into the holographic regime, where the boundary algebra and the bulk algebra are conjecturally related by genus-graded Koszul duality.

Strictness as shadow: the genus-0 statement $\mathcal{D}(\mathcal{A}) \simeq \mathcal{A}^!$ is the shadow of a genus-graded tower in which each level carries a curved correction. The universal MC class $\Theta_{\mathcal{A}}$ mediates the Lagrangian polarization of these corrections across all genera. *Modularity at chain level:* at the scalar projection, the complementarity sum is family-dependent (Theorem C). For Kac–Moody and free-field pairs, $\kappa(\mathcal{A}) + \kappa(\mathcal{A}^!) = 0$. For Virasoro (self-dual at $c = 13$), the Koszul partner is $\text{Vir}_c^! = \text{Vir}_{26-c}$ and the sum $\kappa(\text{Vir}_c) + \kappa(\text{Vir}_{26-c}) = 13$. For $\mathcal{W}$ -algebras, $\kappa(\mathcal{A}) + \kappa(\mathcal{A}^!) = \rho \cdot K$, where ρ is the anomaly ratio and K the Killing-form normalization. The full chain-level complementarity lives in the modular convolution algebra. *Examples as proving grounds:* the $bc/\beta\gamma$ Koszul pair, the Heisenberg/ $\mathcal{W}$ -algebra pairs, and the M2-brane/Yangian pair each illustrate the mechanism in a different regime (quadratic, curved, filtered). The $\text{AdS}_3/\text{CFT}_2$ example (boundary = $W_{1+\infty}$, bulk = KS gravity) tests the conjecture at the physics boundary. *Close the loop:* the Verdier dual $\mathcal{D}(\mathcal{A}) = \mathbb{D}_{\text{Ran}} \bar{B}^{\text{ch}}(\mathcal{A}) \simeq \mathcal{A}^!$ on the Koszul locus provides the dual algebra, while bar-cobar inversion (Theorem B) gives $\Omega(\bar{B}^{\text{ch}}(\mathcal{A})) \simeq \mathcal{A}$, recovering the original algebra. These are distinct functors applied to the same input.

15.12.1 HOLOGRAPHIC PRINCIPLE: GENUS-GRADED KOSZUL DUALITY

Remark 15.12.1 (Costello–Li holographic conjecture across genera). For N D-branes, the genus-graded boundary operator algebra (at $N \rightarrow \infty$) and the twisted supergravity bulk algebra are conjecturally related by genus-graded Koszul duality [433, 110].

Remark 15.12.2 (Genus-graded Koszul duality). The universal MC class $\Theta_{\mathcal{A}}$ (Theorem 13.21.80) mediates genus-graded Koszul duality: the Verdier involution exchanges the eigenspace contributions of $\Theta_{\mathcal{A}}$ and $\Theta_{\mathcal{A}^!}$, producing the Lagrangian polarization of the quantum corrections across the genus tower. At the scalar level, the complementarity sum is family-dependent (Theorem C): $\kappa(\mathcal{A}) + \kappa(\mathcal{A}^!) = 0$ for Kac–Moody and free-field pairs; for Virasoro (self-dual at $c = 13$), $\kappa(\text{Vir}_c) + \kappa(\text{Vir}_{26-c}) = 13$; and for $\mathcal{W}$ -algebras, $\kappa(\mathcal{A}) + \kappa(\mathcal{A}^!) = \rho \cdot K$ where ρ is the anomaly ratio and K is the Killing form normalization.

15.12.2 UNIVERSAL CHIRAL DEFECTS AND BAR-COBAR DUALITY

Definition 15.12.3 (Universal chiral defect). For a chiral algebra $\mathcal{A}$, the *universal chiral defect* $\mathcal{D}(\mathcal{A})$ is the chiral algebra satisfying:

1. *Universality:* Any defect coupling to $\mathcal{A}$ factors through $\mathcal{D}(\mathcal{A})$
2. *Koszul property:* $\mathcal{D}(\mathcal{A})$ is (quasi-)Koszul dual to $\mathcal{A}$
3. *Geometric realization:* $\mathcal{D}(\mathcal{A}) \cong \mathbb{D}_{\text{Ran}} \bar{B}(\mathcal{A})$ (Verdier dual of bar, *not* cobar of bar; see Theorem 15.12.4)

THEOREM 15.12.4 (*Universal defect = Koszul dual* [299, 350];). The universal chiral defect $\mathcal{D}(\mathcal{A})$ is characterized as the Koszul dual:

$$\mathcal{D}(\mathcal{A}) = \mathcal{A}^! := \mathrm{RHom}_{\mathcal{A}\text{-mod}}(\mathbb{C}, \mathbb{C})$$

where the RHom is computed in the derived category of $\mathcal{A}$ -modules.

On the Koszul locus, the strict Koszul dual $\mathcal{A}^!$ is computed by the linear dual of bar cohomology:

$$\mathcal{A}^! \simeq H^*(\bar{B}(\mathcal{A}))^\vee,$$

with algebra structure from the cup product on bar cohomology. In general (off the Koszul locus), the homotopy Koszul dual $\mathcal{A}_\infty^! = \mathbb{D}_{\mathrm{Ran}} \bar{B}(\mathcal{A})$ is obtained via Verdier duality and carries a homotopy algebra structure. The compatibility $H^*(\mathcal{A}_\infty^!) \simeq \mathcal{A}^!$ on the Koszul locus is the content of Theorem A (Convention 6.0.2), not a tautology *Caution*: the cobar construction $\Omega(\bar{B}(\mathcal{A}))$ recovers $\mathcal{A}$ itself (bar-cobar inversion, Theorem B), *not* $\mathcal{A}^!$. The Koszul dual is obtained via Verdier duality, not cobar.

15.12.3 THE M₂ BRANE EXAMPLE: QUANTUM YANGIAN AS KOSZUL DUAL

Example 15.12.5 (*M₂ branes at A_{N-1} singularity*). For K M₂ branes at an A_{N-1} singularity [97]: the boundary algebra is $\mathcal{A}_{\mathrm{M}_2} = \text{Yangian}(\mathfrak{gl}_N)$ (twisted ABJM at $K \rightarrow \infty$), and the bulk algebra is $\mathcal{A}_{\mathrm{bulk}} = U_{h,c}(\mathrm{Diff}(\mathbb{C}) \otimes \mathfrak{gl}_N)$. These are conjecturally related by curved Koszul duality with deformation parameter c .

THEOREM 15.12.6 (*Curved Koszul duality (algebraic form)* [350, 213];). Let $\mathcal{A}$ be a complete filtered chiral algebra satisfying the finite-type filtered-to-curved hypotheses used in Theorem 8.1.15 and the convergence hypotheses of Theorem 8.4.1. Then:

1. $\mathcal{A}$ admits a curved A_∞ model with curvature m_0 and

$$m_1^2(x) = m_2(m_0, x) - m_2(x, m_0) = [m_0, x];$$

2. the completed bar construction produces a curved coalgebra $\hat{\bar{B}}(\mathcal{A})$, and Verdier duality yields the curved homotopy Koszul dual $\mathcal{A}_{\mathrm{curv}}^! = \mathbb{D}_{\mathrm{Ran}}(\hat{\bar{B}}(\mathcal{A}))$;
3. the completed bar-cobar adjunction gives the corresponding derived equivalence in the curved setting (the cobar recovers $\mathcal{A}$ itself, not the dual).

15.12.4 THE AD₃/CFT₂ EXAMPLE: TWISTED SUPERGRAVITY

Example 15.12.7 (*AdS₃ × S³ × T⁴ holography*). For type IIB on AdS₃ × S³ × T⁴ [102]: boundary = $\mathrm{Sym}^N(T^4)$ (at $N \rightarrow \infty$, single-trace algebra $W_{1+\infty}$ at $c = 6N$), bulk = Kodaira–Spencer gravity. Conjectural Koszul template:

$$W_{1+\infty} \text{ at } c = 6N \quad \xleftrightarrow{\text{conj. Koszul template}} \quad \text{KS gravity on AdS}_3$$

Conjecture 15.12.8 (*Gravitational backreaction and deformation*;). The gravitational backreaction deforms the Koszul duality by:

1. Shifting generators by $\mathcal{O}(1/N)$ corrections
2. Modifying the differential: $d \rightarrow d + \delta d$ where $\delta d \sim g_s$

3. Curving the A_∞ structure with $m_0 = \frac{1}{N} \text{Tr}(T^2)$

The deformed pairing becomes:

$$\langle \mathcal{A}, \mathcal{B} \rangle_{\text{deformed}} = \langle \mathcal{A}, \mathcal{B} \rangle_0 + \sum_{n=1}^{\infty} \frac{1}{N^n} \langle \mathcal{A}, \mathcal{B} \rangle_n$$

where $\langle \cdot, \cdot \rangle_n$ includes n -loop gravitational corrections.

A precise formulation requires specifying the $1/N$ expansion of the differential and generators in terms of Witten diagrams on AdS_3 . The conjecture originates from the twisted $\text{AdS}_3/\text{CFT}_2$ correspondence [102] (Example 15.12.7); a rigorous derivation within the bar-cobar formalism remains open (contributing to Conjecture K.7.1).

THEOREM 15.12.9 (*Universal defect construction [299];*). For any chiral algebra $\mathcal{A}$, the universal defect $\mathcal{D}(\mathcal{A})$ is constructed as:

$$\mathcal{D}(\mathcal{A}) = \bigoplus_{n=0}^{\infty} \text{Ext}_{\mathcal{A}}^n(\mathbb{C}, \mathbb{C})$$

with multiplication given by Yoneda product. This satisfies:

1. *Functoriality*: $\mathcal{A} \rightarrow \mathcal{B}$ induces $\mathcal{D}(\mathcal{B}) \rightarrow \mathcal{D}(\mathcal{A})$
2. *Universality*: Any defect factors through $\mathcal{D}(\mathcal{A})$
3. *Duality*: $\mathcal{D}(\mathcal{D}(\mathcal{A})) \simeq \mathcal{A}$ (under mild conditions)

15.12.5 EXAMPLES AND COMPUTATIONS

15.12.5.1 Example: free fermion and its Koszul dual

Example 15.12.10 (*bc ghost system $\leftrightarrow$ $\beta\gamma$ system*). The bc - $\beta\gamma$ Koszul duality is treated in §E.3.2 (Theorem E.3.2); we record only the result needed here. The bc ghost system (two fermionic generators b, c with OPE $b(z)c(w) \sim (z-w)^{-1}$) is Koszul dual to the bosonic $\beta\gamma$ system:

$$bc \text{ ghosts} \xleftrightarrow{\text{Koszul}} \beta\gamma \text{ system}.$$

The duality exchanges the exterior (fermionic) relation algebra with the symmetric (bosonic) one, generalising the classical $\Lambda(V) \leftrightarrow \text{Sym}(V^*)$ Koszul duality.

15.12.5.2 Example: Heisenberg and $\mathcal{W}$ -algebras

Example 15.12.11 (*Affine Kac–Moody: Koszul duality vs Feigin–Frenkel involution*). *Caution*: the Feigin–Frenkel involution $k \mapsto -k - 2h^\vee$ and the chiral Koszul duality $\widehat{\mathfrak{g}}_k \mapsto (\widehat{\mathfrak{g}}_k)^\dagger$ are *distinct* operations. The Feigin–Frenkel involution replaces the level within the *same* family of affine algebras; chiral Koszul duality produces $(\widehat{\mathfrak{g}}_k)^\dagger = H^*(\widehat{B}(\widehat{\mathfrak{g}}_k))^\vee$, a different algebra whose modular characteristic satisfies $\kappa((\widehat{\mathfrak{g}}_k)^\dagger) = -\kappa(\widehat{\mathfrak{g}}_k)$ (Theorem C). The two operations produce algebras with the *same* κ -value but different OPE structures.

For the Heisenberg algebra $\mathcal{H}_k$, the Koszul dual is $\mathcal{H}_k^\dagger \simeq \text{Sym}^{\text{ch}}(V^*)$ with curvature $-k \cdot \omega_X$ (Part II). This is *not* the same as $\mathcal{H}_{-k}$: the dual $\mathcal{H}_k^\dagger$ is generated by V^* with its own OPE structure, while $\mathcal{H}_{-k}$ is

generated by V with level $-k$. The bar complex $\bar{B}(\mathcal{H}_k)$ is the Chevalley–Eilenberg complex $\text{CE}(\hat{\mathfrak{h}}_k)$; this is the bar construction, not the Koszul dual itself.

The curvature element $m_0 = \kappa \cdot \omega_X$ satisfies $m_1^2 = [m_0, -]$ on the A_∞ structure; the bar differential itself always satisfies $d_B^2 = 0$ (cf. Part II).

15.12.5.3 Yangian from M2 branes

Calculation 15.12.12 (Yangian structure constants [135];). For M2 branes, the Yangian generators $\{E_{ij}^{(r)}\}$ satisfy:

In the Drinfeld “new” presentation, the Yangian $Y_h(\mathfrak{gl}_N)$ has generators $\{T_{ij}^{(r)}\}_{1 \leq i, j \leq N, r \geq 0}$ with $T_{ij}^{(0)} = \delta_{ij}$ and the *RTT relation*:

$$[T_{ij}^{(r+1)}, T_{kl}^{(s)}] - [T_{ij}^{(r)}, T_{kl}^{(s+1)}] = \hbar \left(T_{kj}^{(r)} T_{il}^{(s)} - T_{kj}^{(s)} T_{il}^{(r)} \right)$$

Setting $E_{ij}^{(r)} = T_{ij}^{(r+1)}$ for the shifted generators, the first few relations are:

$$\begin{aligned} [E_{ij}^{(0)}, E_{jk}^{(0)}] &= E_{ik}^{(0)} \quad (\mathfrak{gl}_N \text{ at level } 0) \\ [E_{ij}^{(0)}, E_{jk}^{(1)}] &= E_{ik}^{(1)} \quad (\mathfrak{gl}_N\text{-equivariance}) \\ [E_{ij}^{(1)}, E_{jk}^{(1)}] - [E_{ij}^{(0)}, E_{jk}^{(2)}] &= \hbar \left(E_{jj}^{(0)} E_{ik}^{(1)} - E_{jj}^{(1)} E_{ik}^{(0)} \right) \quad (\text{quantum correction}) \end{aligned}$$

15.12.5.4 Bar complex computation for $\mathcal{W}_3$ algebra

Example 15.12.13 ($\mathcal{W}_3$ bar complex). For $\mathcal{W}_3$ (the $\mathfrak{sl}_3$ principal W-algebra):

Generators. T (spin 2), W (spin 3).

Bar complex. The bar complex is bigraded by bar degree n and conformal weight h . At the level of generators (ignoring descendants):

$$\begin{aligned} \dim \bar{B}^0 &= 1 \quad (\text{vacuum}) \\ \dim \bar{B}^1 &= 2 \quad (\text{generators: } T, W) \end{aligned}$$

Higher bar degrees involve the $\mathcal{W}_3$ OPE relations. For a *single-generator* operad, the dimensions would follow the Catalan sequence 1, 1, 2, 5, 14, $\dots$; for a two-generator algebra like $\mathcal{W}_3$, the dimensions of $\bar{B}_{\leq h}^n$ (truncated to conformal weight $\leq h$) depend on the specific $\mathcal{W}_3$ OPE relations and require case-by-case computation.

15.12.5.5 Critical level phenomena

Definition 15.12.14 (Critical level). The critical level is $k = -h^\vee$ where $h^\vee$ is the dual Coxeter number. At this level:

- The Sugawara construction fails (denominator vanishes)
- The center becomes large (Feigin–Frenkel center)
- The center identifies with ${}^L\mathfrak{g}$ -opers (geometric Langlands)

THEOREM 15.12.15 (*Feigin–Frenkel center* [160, 40];). At critical level, the center of $\widehat{\mathfrak{g}}_{-h^\vee}$ is:

$$Z(\widehat{\mathfrak{g}}_{-h^\vee}) \cong \text{Fun}(\text{Op}_{L\mathfrak{g}}(D^\times))$$

functions on the space of $L\mathfrak{g}$ -opers on the punctured formal disk $D^\times$. The global version on a curve X follows from Beilinson–Drinfeld’s chiral algebra formalism [40].

Remark 15.12.16 (*Opers and connections*). An oper is a special kind of connection:

$$\nabla = \partial + p_{-1} + \text{regular terms}$$

where p_{-1} is a principal nilpotent element. Opers are related to solutions of the KZ equations through the theory of conformal blocks.

15.12.5.6 Chiral coalgebra structure for $\beta\gamma$

PROPOSITION 15.12.17 ($\beta\gamma$ bar complex coalgebra;). The bar complex $\bar{B}^{\text{ch}}(\beta\gamma)$ has chiral coalgebra structure:

1. *Comultiplication*: Elements decompose as:

$$\Delta(\beta_{i_1} \cdots \beta_{i_p} \gamma_{j_1} \cdots \gamma_{j_q} \partial^k) = \sum_{\substack{I_\beta \sqcup I'_\beta = \{i_1, \dots, i_p\} \\ I_\gamma \sqcup I'_\gamma = \{j_1, \dots, j_q\}}} \beta_{I_\beta} \gamma_{I'_\beta} \partial^{k_1} \otimes \beta_{I'_\gamma} \gamma_{I_\gamma} \partial^{k_2}$$

respecting normal ordering: β ’s to the left of γ ’s.

2. *Growth*: The bar complex is bigraded by bar degree n and conformal weight h . At each conformal weight, $\bar{B}_h^n$ is finite-dimensional with generating function

$$\sum_{n,h} \dim(\bar{B}_h^n) q^h t^n = \prod_{m \geq 0} \frac{1}{(1 - q^{m+\lambda} t)(1 - q^{m+1-\lambda} t)}$$

reflecting the two families of generators $\beta_{-m-\lambda}$ and $\gamma_{-m-1+\lambda}$ in the augmentation ideal. Without a conformal weight bound, $\dim(\bar{B}^n) = \infty$ for each $n \geq 1$.

3. *Coassociativity*: Follows from the factorization property of the FM operad. The boundary divisors $D_S \subset \bar{C}_n(X)$ parametrizing collision of a subset S of points induce maps

$$\bar{C}_n(X) \supset D_S \cong \bar{C}_{|S|}(X) \times \bar{C}_{n-|S|+1}(X)$$

and these compose associatively by the operad axioms.

Proof. Part (3) is a special case of Theorem 11.1.84: the bar complex of *any* augmented chiral algebra carries a factorization coalgebra structure, and coassociativity is the operad axiom for the boundary strata of $\bar{C}_n(X)$. Part (1) is the explicit formula for the *factorization coproduct* on $\bar{B}^{\text{ch}}(\beta\gamma)$: the chiral bracket of the $\beta\gamma$ system is bilinear in modes, so when two groups of points separate, a normally-ordered monomial $\beta_{i_1} \cdots \beta_{i_p} \gamma_{j_1} \cdots \gamma_{j_q}$ decomposes by distributing its mode indices between the two groups. This is the Wick-type decomposition inherited from the free-field OPE; the normal-ordering convention is preserved because the factorization coproduct respects the weight grading. Part (2) is a character computation: the

augmentation ideal $\overline{\beta\gamma}$ has generators of conformal weights $m + \lambda$ (β modes) and $m + 1 - \lambda$ (γ modes) for $m \geq 0$, so the bar complex at bar degree n and weight h counts n -fold tensor products of these generators with total weight h , giving the stated plethystic product. The infinite-dimensionality of $\bar{B}^n$ at unfixed weight is standard for any chiral algebra with infinitely many modes; the positive-energy axiom ensures finite-dimensionality at each weight. $\square$

Remark 15.12.18 (Physical interpretation). The coalgebra structure arises from correlation functions on punctured curves.

Step 1: Propagator Expansion. The $\beta\gamma$ propagator:

$$\langle \beta(z)\gamma(w) \rangle = \frac{1}{z - w}$$

defines a distribution on $C_2(X) = X \times X \setminus \Delta$.

Step 2: Feynman Graphs. Higher correlations factor through tree graphs:

$$\langle \beta(z_1)\gamma(z_2)\beta(z_3)\gamma(z_4) \rangle = \sum_{\text{pairings}} \prod_{\text{edges}} \frac{1}{z_i - z_j}$$

Step 3: Compactification. The Fulton–MacPherson compactification $\bar{C}_n(X)$ regularizes these distributions, with the coalgebra structure encoding how correlators factorize when points collide.

15.12.6 THE PRISM PRINCIPLE IN ACTION

Example 15.12.19 (Structure coefficients via residues). For generators ϕ_i with OPE $\phi_i(z)\phi_j(w) = \sum_k C_{ij}^k \phi_k(w)/(z - w)^{h_i+h_j-h_k} + \dots$, the bar complex extracts $\text{Res}_{D_{ij}}[\phi_i \otimes \phi_j \otimes \eta_{ij}] = \sum_k C_{ij}^k \phi_k$.

15.12.7 THE AYALA–FRANCIS PERSPECTIVE

THEOREM 15.12.20 (*Factorization homology and the bar complex [168, 303];*). For a chiral algebra $\mathcal{A}$ on X , the Ayala–Francis factorization homology and the geometric bar complex are related by Koszul duality:

$$\int_X \mathcal{A} \simeq \mathcal{A} \otimes_{\text{Disk}(X)}^{\mathbb{L}} \text{pt} \quad (\text{chains}), \quad \bar{B}^{\text{ch}}(\mathcal{A}) \simeq \text{RHom}_{\mathcal{A}\text{-mod}}(k, k) \quad (\text{cochains})$$

These are *dual* constructions: factorization homology computes the derived tensor product (the *homological* side), while the derived Hom (the *cohomological* side) is computed via the bar complex. They are related by $\mathbb{E}_2$ -Koszul duality as developed by Francis [168], building on Lurie’s operadic bar-cobar framework [303, §5.2].

Proof. By Francis [168], both constructions are derived functors of the forgetful functor from $\mathcal{A}$ -modules to chain complexes, evaluated on the trivial module k . The factorization homology $\int_X \mathcal{A} \simeq \mathcal{A} \otimes_{\text{Disk}(X)}^{\mathbb{L}} \text{pt}$ is the derived tensor product (left adjoint, homological), while the bar complex $\bar{B}^{\text{ch}}(\mathcal{A}) \simeq \text{RHom}_{\mathcal{A}\text{-mod}}(k, k)$ is the derived Hom (right adjoint, cohomological). These are related by $\mathbb{E}_2$ -Koszul duality: the $\mathbb{E}_2$ -operad is Koszul self-dual up to shift [168, Theorem 5.2], which induces the duality between the two functors. $\square$

15.12.8 THE PRISM PRINCIPLE: OPERADIC IDENTIFICATION

The geometric bar-cobar duality of chiral algebras is an instance of *operadic Koszul duality* in the sense of Ginzburg–Kapranov [203] and Getzler [201].

15.12.8.1 The chiral operad

Definition 15.12.21 (Chiral operad). The *chiral operad* $\mathcal{P}_{\text{ch}}$ is the topological operad with:

$$\mathcal{P}_{\text{ch}}(n) = \Omega_{\log}^*(\overline{C}_{n+1}(X)), \quad n \geq 1,$$

the complex of logarithmic differential forms on the Fulton–MacPherson compactification of $n + 1$ points on the curve X . The operad composition maps:

$$\circ_i : \mathcal{P}_{\text{ch}}(m) \otimes \mathcal{P}_{\text{ch}}(n) \rightarrow \mathcal{P}_{\text{ch}}(m + n - 1)$$

are induced by the gluing maps $\overline{C}_{m+1}(X) \times \overline{C}_{n+1}(X) \rightarrow \overline{C}_{m+n}(X)$ that identify the i -th point of the first configuration with the distinguished point of the second.

The symmetric group $\mathfrak{S}_n$ acts by permuting the non-distinguished points, and the unit is the identity form in $\Omega^0(\overline{C}_2(X)) = \mathbb{C}$.

PROPOSITION 15.12.22 (Genus-zero identification;). At genus 0 (i.e., $X = \mathbb{P}^1$), the chiral operad is quasi-isomorphic to the hypercommutative operad:

$$\mathcal{P}_{\text{ch}}|_{g=0} \simeq \text{HyCom}.$$

Explicitly, $\overline{C}_{n+1}(\mathbb{P}^1) \cong \overline{\mathcal{M}}_{0,n+2}$ (the Deligne–Mumford compactification of the moduli space of rational curves with $n + 2$ marked points), and the cohomology operad $\{H^*(\overline{\mathcal{M}}_{0,n+2})\}_{n \geq 1}$ is the hypercommutative operad HyCom of Getzler [201].

Proof. The identification $\overline{C}_{n+1}(\mathbb{P}^1) \cong \overline{\mathcal{M}}_{0,n+2}$ is classical: the Fulton–MacPherson compactification of $n + 1$ points on $\mathbb{P}^1$ with one point fixed at ∞ is isomorphic to the Deligne–Mumford moduli space of stable rational curves with $n + 2$ punctures [186]. Under this identification, the operad composition maps of $\mathcal{P}_{\text{ch}}$ correspond to the clutching maps

$$\overline{\mathcal{M}}_{0,m+1} \times \overline{\mathcal{M}}_{0,n+1} \rightarrow \overline{\mathcal{M}}_{0,m+n}$$

that glue two rational curves at marked points. The cohomology operad of $\{\overline{\mathcal{M}}_{0,n+2}\}$ is the hypercommutative operad by Getzler’s theorem [201, Theorem 1.5]: the fundamental classes of the boundary strata satisfy exactly the relations defining HyCom.

The quasi-isomorphism follows because $\overline{\mathcal{M}}_{0,n+2}$ is a smooth projective variety with pure Hodge structure, hence formal as a dga by Deligne–Griffiths–Morgan–Sullivan [125]. Thus $\Omega^*(\overline{\mathcal{M}}_{0,n+2})$ is quasi-isomorphic to $H^*(\overline{\mathcal{M}}_{0,n+2})$ as an operad. $\square$

15.12.8.2 Operadic Koszul duality and the prism

THEOREM 15.12.23 (Prism principle: operadic identification;). [Regime: quadratic at genus 0; curved-central at genus $g \geq 1$ (Convention 1.10.2).]

The geometric bar-cobar duality of chiral algebras (Definition 6.1.15, Definition 7.0.10) is an instance of operadic Koszul duality. Precisely:

- (i) *Genus 0*: The chiral operad $\mathcal{P}_{\text{ch}}|_{g=0} \simeq \text{HyCom}$ is Koszul, with Koszul dual cooperad:

$$\mathcal{P}_{\text{ch}}^i|_{g=0} \simeq \text{Grav}^c,$$

the gravity cooperad. Here $\text{Grav}(n) = H_{n-2}(\mathcal{M}_{0,n+2})$ is the gravity operad of Getzler [201] (note: the *open* moduli space $\mathcal{M}_{0,n+2}$, not the compactification $\overline{\mathcal{M}}_{0,n+2}$), and Grav^c is its cooperad incarnation.

- (ii) *Bar as operadic bar*: For a chiral algebra $\mathcal{A}$ that is an algebra over $\mathcal{P}_{\text{ch}}$, the geometric bar complex is the operadic bar construction:

$$\bar{B}^{\text{ch}}(\mathcal{A}) \simeq B_{\mathcal{P}_{\text{ch}}}(\mathcal{A}) := \mathcal{P}_{\text{ch}}^i \circ_{\mathcal{P}_{\text{ch}}} \mathcal{A}.$$

The bar differential $d_{\text{bar}} = d_{\text{int}} + d_{\text{res}} + d_{\text{config}}$ corresponds to the standard operadic bar differential: d_{res} is the twisting cochain component and d_{config} is the cooperad cocomposition component.

- (iii) *Cobar as operadic cobar*: Dually, the geometric cobar complex is the operadic cobar construction:

$$\Omega^{\text{ch}}(C) \simeq \Omega_{\mathcal{P}_{\text{ch}}}^i(C) := \mathcal{P}_{\text{ch}} \circ_{\mathcal{P}_{\text{ch}}^i} C.$$

Under Verdier duality (Definition 7.0.10), the gravity cooperad Grav^c controlling the bar maps to the hypercommutative operad HyCom controlling the cobar.

- (iv) *Bar-cobar resolution*: For a Koszul chiral algebra $\mathcal{A}$ (Definition 11.1.15), the augmentation map $\varepsilon: \Omega^{\text{ch}}(\bar{B}^{\text{ch}}(\mathcal{A})) \rightarrow \mathcal{A}$ (Proposition 7.0.38) is a quasi-isomorphism. This is an instance of the general operadic bar-cobar resolution for Koszul operads [299, Theorem 11.3.3].

Proof. Part (i): HyCom–Grav Koszul duality. This is Getzler’s theorem [201, Theorem 2.3]. The hypercommutative operad HyCom is defined by the presentation: generators are the fundamental classes $[\overline{\mathcal{M}}_{0,n+2}] \in H^{2(n-1)}(\overline{\mathcal{M}}_{0,n+2})$ with the WDVV (associativity) relations arising from boundary divisors. The Koszul dual cooperad has components $\text{Grav}^c(n) = H_{n-2}(\mathcal{M}_{0,n+2})^\vee$, which identifies with the gravity cooperad (the linear dual of Getzler’s gravity operad $\text{Grav}(n) = H_{n-2}(\mathcal{M}_{0,n+2})$, defined using the *open* moduli space). The Koszulity of HyCom is established in [201, Theorem 2.3] via the purity of the Hodge structure on $H^*(\overline{\mathcal{M}}_{0,n})$.

Part (ii): Identification of the bar complex. The geometric bar complex (Definition 6.1.15) at genus 0 is:

$$\bar{B}_n^{\text{ch}}(\mathcal{A}) = \Gamma(\bar{C}_{n+1}(\mathbb{P}^1), j_* j^* \mathcal{A}^{\boxtimes(n+1)} \otimes \Omega_{\log}^n).$$

The logarithmic forms $\Omega_{\log}^*(\bar{C}_{n+1}(\mathbb{P}^1))$ compute the cohomology of the *open* moduli space $\mathcal{M}_{0,n+2}$ by the logarithmic comparison theorem (Deligne), providing the propagators for the bar differential. The bar complex is controlled by the cohomology operad of $\overline{\mathcal{M}}_{0,n+2}$, i.e., HyCom .

The standard operadic bar construction $B_{\text{HyCom}}(\mathcal{A}) = \text{Grav}^c \circ_{\text{HyCom}} \mathcal{A}$ is a two-sided composition product. Concretely, its n -th component is:

$$B_{\text{HyCom}}(\mathcal{A})_n = \bigoplus_{\text{trees } T} \bigotimes_{v \in V(T)} \text{Grav}^c(|v|) \otimes_{\mathfrak{S}_{|v|}} \mathcal{A}^{\otimes |v|}$$

summed over planar trees T with n leaves. The three components of the bar differential correspond to:

- d_{res} : the twisting cochain $\kappa: \text{Grav}^c \rightarrow \text{HyCom}$ (Ginzburg–Kapranov [203, §2.1]), which maps the gravity cooperad to the hypercommutative operad. Geometrically, this is the residue map: extracting the leading OPE coefficient at a collision divisor.
- d_{config} : the cooperad cocomposition $\Delta: \text{Grav}^c \rightarrow \text{Grav}^c \circ \text{Grav}^c$, which geometrically corresponds to the de Rham differential on configuration forms and the boundary stratification of $\overline{\mathcal{M}}_{0,n}$.
- d_{int} : the internal differential of $\mathcal{A}$.

Part (iii): Cobar via Verdier duality. By the intrinsic cobar definition (Definition 7.0.10), Ω^{ch} is the Verdier dual of the bar. Since Verdier duality on $\overline{\mathcal{M}}_{0,n+2}$ exchanges Grav^c and HyCom (this is the geometric content of Koszul duality: the Koszul dual operad is the Poincaré dual of the Koszul dual cooperad), the operadic cobar construction $\Omega_{\text{Grav}^c}(C) = \text{HyCom} \circ_{\text{Grav}^c} C$ agrees with the geometric cobar $\Omega^{\text{ch}}(C)$.

Part (iv): Bar-cobar resolution. For a Koszul operad $\mathcal{P}$, the canonical map $\Omega(B_{\mathcal{P}}(\mathcal{A})) \rightarrow \mathcal{A}$ is a quasi-isomorphism for any $\mathcal{P}$ -algebra $\mathcal{A}$ (this is the fundamental theorem of operadic Koszul duality [299, Theorem 11.3.3]). Since HyCom is Koszul by Part (i), and the geometric bar-cobar agree with the operadic bar-cobar by Parts (ii)–(iii), the result follows. $\square$

Definition 15.12.24 (Modular operad). A modular operad (Getzler–Kapranov [199, §5]) in a symmetric monoidal category $\mathcal{V}$ consists of:

- (i) A collection of objects $\{\mathcal{M}(g, n)\}_{2g-2+n>0}$ in $\mathcal{V}$, each equipped with a Σ_n -action (the stability condition $2g - 2 + n > 0$ excludes $(g, n) = (0, 0), (0, 1), (0, 2)$).
- (ii) *Separating gluing maps*: for each partition $\{1, \dots, n\} = S_1 \sqcup S_2$ and $g = g_1 + g_2$,

$$\xi_{S_1, S_2}: \mathcal{M}(g_1, |S_1| + 1) \otimes \mathcal{M}(g_2, |S_2| + 1) \longrightarrow \mathcal{M}(g, n),$$

corresponding to gluing two curves at marked points.

- (iii) *Non-separating gluing maps*: for each pair of distinguished marked points,

$$\xi_{\text{ns}}: \mathcal{M}(g, n + 2) \longrightarrow \mathcal{M}(g + 1, n),$$

corresponding to self-gluing (identifying two marked points on the same curve).

These maps satisfy:

- *Equivariance*: compatibility with the Σ_n -actions;
- *Associativity*: iterated gluings are independent of the order in which they are performed;
- *Commutativity*: separating gluing is symmetric in the two factors.

The canonical example is the collection of Deligne–Mumford moduli spaces $\{\overline{\mathcal{M}}_{g,n}\}_{2g-2+n>0}$ with clutching maps at the boundary strata.

Definition 15.12.25 (Feynman transform). Let Mod be a modular operad and $\mathcal{A}$ an algebra over Mod . The Feynman transform $\text{FT}_{\text{Mod}}(\mathcal{A})$ [199, Definition 4.1] is the chain complex

$$\text{FT}_{\text{Mod}}(\mathcal{A}) = \bigoplus_{\substack{g,n \\ 2g-2+n>0}} \bigoplus_{\Gamma \in \mathcal{G}_{g,n}} \bigotimes_{v \in V(\Gamma)} \mathcal{A}(\text{val}(v)) \otimes \bigotimes_{e \in E(\Gamma)} \det(e),$$

summed over *stable graphs* Γ of type (g, n) (connected graphs with genus decoration g_v at each vertex v satisfying $\sum_v g_v + b_1(\Gamma) = g$ and $\sum_v \text{val}(v) = n + 2|E(\Gamma)|$, where b_1 is the first Betti number and $\text{val}(v)$ counts half-edges at v). The differential is the signed sum over edge contractions:

$$d_{\text{FT}} = \sum_{\substack{e \in E(\Gamma) \\ e \text{ internal}}} (-1)^{\epsilon(e, \Gamma)} \xi_e^*,$$

where ξ_e^* contracts the edge e of Γ (merging its two endpoint vertices and applying the modular operad composition at the contracted marking pair), and $\epsilon(e, \Gamma) = \sum_{e' < e} 1$ is the position of e in the chosen total ordering of edges. More precisely, each edge e connecting vertices v_1, v_2 at half-edge labels i_1, i_2 contributes

$$\xi_e^*: \mathcal{A}(\text{val}(v_1)) \otimes \mathcal{A}(\text{val}(v_2)) \xrightarrow{\xi_{i_1 i_2}} \mathcal{A}(\text{val}(v_1) + \text{val}(v_2) - 2),$$

using the separating gluing map of the modular operad. For a self-loop at vertex v connecting half-edges i_1, i_2 , the contribution is the non-separating gluing $\xi_{\text{ns}}: \mathcal{A}(\text{val}(v)) \rightarrow \mathcal{A}(\text{val}(v) - 2)$. The identity $d_{\text{FT}}^2 = 0$ follows because each codimension-2 face (edge pair $\{e, e'\}$) appears in exactly two codimension-1 faces with opposite signs $(-1)^{\epsilon(e, \Gamma)} \cdot (-1)^{\epsilon(e', \Gamma/e)} + (-1)^{\epsilon(e', \Gamma)} \cdot (-1)^{\epsilon(e, \Gamma/e')} = 0$, the standard boundary-of-boundary cancellation.

THEOREM 15.12.26 (*Prism principle: higher-genus extension*;). The operadic identification extends to all genera via the modular operad structure on $\{\overline{\mathcal{M}}_{g,n}\}$ (Definition 15.12.24). Precisely:

- (i) The collection $\text{Mod} = \{\overline{\mathcal{M}}_{g,n}\}_{2g-2+n>0}$ forms a modular operad in the sense of Getzler–Kapranov [199], with composition maps given by clutching at marked points.
- (ii) The full genus-graded bar complex $\bar{B}^{\text{full}}(\mathcal{A}) = \bigoplus_{g \geq 0} \bar{B}^{(g)}(\mathcal{A})$ is the *Feynman transform* of $\mathcal{A}$ with respect to the modular operad Mod :

$$\bar{B}^{\text{full}}(\mathcal{A}) \simeq \text{FT}_{\text{Mod}}(\mathcal{A}).$$

- (iii) The nilpotence $d_{\text{bar}}^2 = 0$ at all genera (Theorem 8.2.10) is a consequence of the modular operad boundary relation $\partial^2 = 0$ on the stratification of $\overline{\mathcal{M}}_{g,n}$, combined with the centrality of the curvature μ_0 .

Proof. *Part (i)* is the foundational result of Getzler–Kapranov [199, §5]: the boundary stratification of $\overline{\mathcal{M}}_{g,n}$ gives gluing maps

$$\xi_{g_1, g_2}: \overline{\mathcal{M}}_{g_1, n_1+1} \times \overline{\mathcal{M}}_{g_2, n_2+1} \rightarrow \overline{\mathcal{M}}_{g_1+g_2, n_1+n_2} \quad (\text{separating})$$

and self-gluing maps $\xi_g: \overline{\mathcal{M}}_{g, n+2} \rightarrow \overline{\mathcal{M}}_{g+1, n}$ (non-separating). These satisfy the axioms of a modular operad.

Part (ii). The Feynman transform (Definition 15.12.25) applied to the modular operad $\text{Mod} = \{\overline{\mathcal{M}}_{g,n}\}$ yields a sum controlled by the boundary strata of $\overline{\mathcal{M}}_{g,n}$, which are indexed by stable graphs. The genus- g bar complex $\bar{B}^{(g)}(\mathcal{A})$ integrates $\mathcal{A}^{\boxtimes n}$ against logarithmic forms on $\overline{\mathcal{M}}_{g,n}$, which is precisely what the Feynman transform produces: each stable graph Γ contributes an integral over the corresponding boundary stratum, with the logarithmic propagator η_{ij} along each edge.

Part (iii). The Feynman transform differential squares to zero by the modular operad axioms: the modular operad boundary relation states that the composition $\partial \circ \partial$ on the stratification of $\overline{\mathcal{M}}_{g,n}$ vanishes

(each codimension-2 stratum is reached from exactly two codimension-1 strata with opposite orientations). This is exactly the mechanism proved in Theorem 8.2.10: the Arnold relations at genus 0, the centrality of the curvature μ_0 for cross-genus terms, and the modular operad boundary relation for pure higher-genus terms combine to give $d_{\text{bar}}^2 = 0$. $\square$

COROLLARY 15.12.27 (*Genus-0 reduction to the operadic bar construction*;). The genus-0 truncation of the Feynman transform recovers the operadic bar construction:

$$\text{FT}_{\text{Mod}}(\mathcal{A})|_{g=0} \simeq \overline{B}_{\text{op}}(\mathcal{A}).$$

Proof. At genus 0, the only stable graphs are trees ($b_1(\Gamma) = 0$, each vertex has $g(v) = 0$, stability $2g(v) - 2 + \text{val}(v) > 0$ forces $\text{val}(v) \geq 3$). Trees with n leaves and internal vertices of valence ≥ 3 are precisely the objects indexing the operadic bar construction. The edge determinant $\det(E(\Gamma))$ provides the correct suspension signs. The Feynman-transform differential restricted to trees contracts one internal edge, the operadic bar differential. No loop graphs, no genus labels, no $\hbar$ -weighting. $\square$

COROLLARY 15.12.28 (*The loop expansion is the genus expansion*;). Assign to each stable graph Γ the weight $\hbar^{g(\Gamma)}$, where $g(\Gamma) = b_1(\Gamma) + \sum_v g(v)$ is the total genus. Then the Feynman transform decomposes as

$$\text{FT}_{\text{Mod}}(\mathcal{A}) = \sum_{g \geq 0} \hbar^g \text{FT}_{\text{Mod}}(\mathcal{A})|_{\text{genus } g},$$

and $g(\Gamma)$ equals the number of independent loops in Γ plus the sum of the genus decorations at its vertices. At $\hbar = 0$ (genus 0), only trees survive (Corollary 15.12.27). The $\hbar$ -expansion is the genus expansion: each power of $\hbar$ counts one unit of topological complexity added to the underlying surface, whether by forming a loop in the graph ($b_1 \rightarrow b_1 + 1$) or by increasing a vertex genus ($g(v) \rightarrow g(v) + 1$).

Proof. The genus grading on stable graphs is additive under edge contraction and vertex splitting, hence compatible with the Feynman-transform differential. The identification $g(\Gamma) = b_1(\Gamma) + \sum_v g(v)$ is the definition of total genus for a stable graph (Definition 5.1.6). $\square$

Example 15.12.29 (*The Heisenberg genus expansion from graph counting*). For the Heisenberg algebra $\mathcal{H}_k$, every transferred operation $\Phi_v^{\mathcal{A}}$ at a vertex of valence ≥ 3 vanishes (the OPE is abelian). The only stable graphs that contribute to $\Theta_{\mathcal{H}_k}$ are therefore graphs with all vertices bivalent. Stability $2g(v) - 2 + \text{val}(v) > 0$ with $\text{val}(v) = 2$ forces $g(v) \geq 1$. The contributing graphs at genus g with no external legs are all connected graphs on bivalent genus-1 vertices. The edge-vertex relation $2|E| = \sum \text{val}(v) = 2|V|$ gives $|E| = |V|$, so every connected component is a single cycle. Connectedness forces a single cycle of length $|V|$. Its genus is $g(\Gamma) = b_1 + \sum g(v) = 1 + (g - 1) = g$. At each edge, the contraction inserts the metric $k = \langle \alpha, \alpha \rangle$, and at each vertex the genus-1 operation contributes a factor from the self-trace. The symmetry factor is $|\text{Aut}(\Gamma)| = 2g$ (rotations and reflections of a g -gon). The resulting coefficient is

$$F_g(\mathcal{H}_k) = \frac{k^g}{2g} \cdot \text{tr}(\underbrace{\Delta \circ \cdots \circ \Delta}_g) = k \cdot \frac{2^{2g-1} - 1}{2^{2g-1}} \cdot \frac{|B_{2g}|}{(2g)!},$$

where B_{2g} is the Bernoulli number, via the Faber–Pandharipande λ_g formula [153]. The genus expansion $\sum_{g \geq 1} F_g x^{2g} = k(\hat{A}(ix) - 1)$ recovers the $\hat{A}$ -genus from graph counting.

Definition 15.12.30 (Modular graph coefficient algebra). The modular graph coefficient algebra is the completed dg Lie algebra

$$\mathcal{G}^{\text{mod}} := \text{FT}_{\text{Mod}}(\{R\Gamma(\overline{\mathcal{M}}_{g,n}, \mathbb{Q})\}_{2g-2+n>0}),$$

the Feynman transform of the modular operad $\text{Mod} = \{\overline{\mathcal{M}}_{g,n}\}$ (Definition 15.12.24) applied to the rational cohomology of the moduli spaces themselves. The Lie bracket is induced by edge-gluing of stable graphs; the differential is induced by boundary stratification. Each stable graph Γ contributes the integral over the corresponding modular stratum, weighted by the automorphism factor $|\text{Aut}(\Gamma)|^{-1}$.

Role. The universal Maurer–Cartan class (Theorem K.7.1) lives in $\text{MC}(\text{Def}_{\text{cyc}}(\mathcal{A}) \widehat{\otimes} \mathcal{G}^{\text{mod}})$: the cyclic deformation complex of $\mathcal{A}$ tensored with the modular graph coefficient algebra. This is the correct target for the full non-scalar genus tower. (Part of the MC2 theorem package; Theorem 13.21.17.)

Example 15.12.31 (Heisenberg specialization). For the Heisenberg algebra $\mathcal{H}_k$ at level k , Theorem 15.12.26 gives: the genus- g bar complex $\bar{B}^{(g)}(\mathcal{H}_k)$ is the Feynman transform of $\mathcal{H}_k$ with respect to the modular operad $\{\overline{\mathcal{M}}_{g,n}\}$. Because $\mathcal{H}_k$ has a single generator with quadratic OPE, each stable graph Γ of type (g, n) contributes a one-dimensional integral $k^{|E(\Gamma)|}$ (one power of k per propagator edge), producing the genus- g obstruction $\text{obs}_g = k \cdot \lambda_g \in H^1(\overline{\mathcal{M}}_g, \mathbb{E}^\vee)$ computed in §2.11.

COROLLARY 15.12.32 (*The prism principle*;). The geometric bar complex acts as a mathematical prism decomposing a chiral algebra $\mathcal{A}$ into its *operadic spectrum*:

- (i) *Genus-0 spectrum:* The bar complex extracts the Grav^c -coalgebra structure on $\bar{B}^{\text{ch}}(\mathcal{A})$; the “colors” are indexed by the gravity cooperad, with OPE structure constants appearing as residues at boundary divisors of $\overline{\mathcal{M}}_{0,n}$.
- (ii) *Higher-genus harmonics:* At genus $g \geq 1$, the Feynman transform adds “higher harmonics” controlled by the cohomology of $\overline{\mathcal{M}}_{g,n}$: central extensions at genus 1, Siegel modular corrections at genus 2, and so forth.
- (iii) *Reconstruction:* The cobar construction Ω^{ch} acts as the inverse prism, reconstructing $\mathcal{A}$ from its operadic spectrum. For Koszul chiral algebras, this reconstruction is exact: $\Omega^{\text{ch}}(\bar{B}^{\text{ch}}(\mathcal{A})) \xrightarrow{\sim} \mathcal{A}$.

Proof. Part (i) is the content of Theorem 15.12.23(ii): the bar complex is the operadic bar for the Koszul operad HyCom , so it produces a Grav^c -coalgebra. The residue map d_{res} extracts OPE coefficients, which are the components of the twisting cochain $\kappa: \text{Grav}^c \rightarrow \text{HyCom}$.

Part (ii) follows from Theorem 15.12.26(ii): the Feynman transform includes contributions from all genera.

Part (iii) combines Theorem 15.12.23(iv) with Corollary 7.0.37. □

Example 15.12.33 (Heisenberg specialization). For $\mathcal{H}_k$, Corollary 15.12.32 specializes as follows. The genus-0 spectrum is the Grav^c -coalgebra encoding the single OPE pole $J(z)J(w) \sim k/(z-w)^2$. The higher-genus harmonics produce the free energy $F_g(\mathcal{H}_k) = k \cdot \frac{2^{2g-1}-1}{2^{2g-1}} \cdot \frac{|B_{2g}|}{(2g)!}$ (where B_{2g} are Bernoulli numbers), recovering the genus expansion of §2.11. Reconstruction via the cobar is exact: $\Omega^{\text{ch}}(\bar{B}^{\text{ch}}(\mathcal{H}_k)) \xrightarrow{\sim} \mathcal{H}_k$, since $\mathcal{H}_k$ is Koszul (§2.12).

COROLLARY 15.12.34 (*Feynman transform involution* [199];). Let Mod be a modular operad and $\mathcal{A}$ an algebra over Mod . Then there is a natural weak equivalence

$$\text{FT} \circ \text{FT}(\mathcal{A}) \xrightarrow{\sim} \mathcal{A}.$$

In particular, the Feynman transform is a homotopy involution on the category of modular operad algebras.

Proof. This is [199, Theorem 5.4]. Getzler–Kapranov construct a natural chain map $\mathrm{FT}(\mathrm{FT}(\mathcal{A})) \rightarrow \mathcal{A}$ and prove it is a quasi-isomorphism by a spectral sequence argument on the genus filtration: at genus 0, the double Feynman transform reduces to the operadic bar-cobar resolution $\Omega(\overline{B}(\mathcal{P})) \xrightarrow{\sim} \mathcal{P}$ (which is a quasi-isomorphism for any operad), and the higher-genus contributions are acyclic by the contractibility of the modular envelope of the bar-cobar resolution. $\square$

Remark 15.12.35 (Relation to bar-cobar inversion). Corollary 15.12.34 is the *all-genera* generalization of our Main Theorem B (Theorem 13.18.4): at genus 0, $\mathrm{FT} \circ \mathrm{FT} \simeq \mathrm{Id}$ specializes to $\Omega \circ \overline{B} \simeq \mathrm{Id}$. The full modular operad statement guarantees that the genus- g bar complex $\overline{B}^{(g)}(\mathcal{A})$ retains complete information about $\mathcal{A}$: no data is lost in the passage to any fixed genus. Combined with Theorem 15.12.26(ii), this shows that the geometric bar complex is a *faithful* encoding of the chiral algebra at all genera.

15.12.9 THE MODULAR CONVOLUTION ALGEBRA

The Feynman transform $\mathrm{FT}_{\mathrm{Mod}}(\mathcal{A})$ carries a modular cooperad coalgebra structure. Its coderivation complex is the deformation-theoretic dual: a dg Lie algebra whose MC elements encode the algebraic structures that the Feynman transform classifies. This dg Lie algebra is a *strict model* of the underlying modular L_∞ convolution algebra (Definition 13.22.1); the MC moduli coincide, but the full L_∞ structure is needed for transfer, formality, and gauge equivalence. We define the strict model and show that its genus-0 shadow is the tree-level chiral convolution.

Definition 15.12.36 (Modular convolution dg Lie algebra). Let $\mathcal{A}$ be a cyclic chiral algebra on a smooth projective curve X with non-degenerate invariant form. The *modular convolution dg Lie algebra* is

$$\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}} := \mathrm{CoDer}(\mathrm{FT}_{\mathrm{Mod}}(\mathcal{A}))[1] \cong \prod_{\substack{g,n \\ 2g-2+n>0}} \mathrm{Hom}_{\Sigma_n}(C_*(\overline{\mathcal{M}}_{g,n}), \mathrm{End}_{\mathcal{A}}(n)),$$

completed with respect to the genus grading. The full dg Lie structure (differential and bracket) is developed in Definition 13.22.1.

THEOREM 15.12.37 (dg Lie structure;). The dg Lie structure on $\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}}$ has differential $D = d_{\mathrm{int}} + [\tau, -] + d_{\mathrm{sew}} + d_{\mathrm{pf}} + \hbar\Delta$ (internal, kernel twist, separating edge, planted-forest correction, non-separating clutching) and Lie bracket $[\alpha, \beta] = \sum_{\mathrm{sep. clutchings}} \alpha \circ_i \beta - (-1)^{|\alpha||\beta|} \beta \circ_j \alpha$. $D^2 = 0$ follows from $\partial^2 = 0$ on $\overline{\mathcal{M}}_{g,n}$; Jacobi follows from associativity of the modular operad composition.

Proof. This is the modular operad convolution of Getzler–Kapranov [199, §4–5], applied to $\mathrm{Mod} = \{\overline{\mathcal{M}}_{g,n}\}$ and the cyclic algebra $\mathcal{A}$. The differential D transports the boundary operator ∂ on $C_*(\overline{\mathcal{M}}_{g,n})$ through the Hom functor, so $\partial^2 = 0$ gives $D^2 = 0$. The Jacobi identity follows from the associativity of iterated clutchings. $\square$

Definition 15.12.38 (Chiral convolution dg Lie algebra). The *chiral convolution dg Lie algebra* is the tree-level coderivation complex:

$$\mathfrak{g}_{\mathcal{A}}^{\mathrm{ch}} := \mathrm{CoDer}(\overline{B}^{\mathrm{ch}}(\mathcal{A}))[1],$$

where $\overline{B}^{\mathrm{ch}}(\mathcal{A}) = \overline{B}^{(0)}(\mathcal{A})$ is the genus-0 bar coalgebra.

THEOREM 15.12.39 (Genus completion;). The genus filtration on $\mathrm{FT}_{\mathrm{Mod}}(\mathcal{A})$ induces a complete descending filtration on $\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}}$ satisfying:

- (i) $\mathrm{gr}_F^g \mathrm{FT}_{\mathrm{Mod}}(\mathcal{A}) \cong \bar{B}^{(g)}(\mathcal{A})$: the genus- g bar complex is the genus- g graded piece. At genus 0, only trees survive: $\bar{B}^{(0)} = \bar{B}_{\mathrm{op}}$ (Corollary 15.12.27).
- (ii) $\mathrm{gr}_F^0 \mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}} \cong \mathfrak{g}_{\mathcal{A}}^{\mathrm{ch}}$: the chiral convolution is the genus-0 shadow.
- (iii) $\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}} = \varprojlim_g \mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}}/F^g$: the modular convolution is the genus completion of the chiral convolution.

The non-separating clutching $\Delta: F^g \rightarrow F^{g+1}$ raises genus by one and is the sole primitive that creates genuine modular obstructions.

Proof. The differential decomposes as $D = D_0 + D_1$ where D_0 preserves genus and $D_1 = \hbar\Delta$ raises it by one. The associated graded at genus g picks out stable graphs of total genus exactly g . A coderivation of the Feynman transform restricts, via F^0/F^1 , to a coderivation of the genus-0 bar coalgebra; the kernel is $F^1 \mathrm{CoDer}$, so $\mathrm{gr}_F^0 \mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}} = \mathfrak{g}_{\mathcal{A}}^{\mathrm{ch}}$. Completeness follows from finiteness of stable graphs at each genus. $\square$

The Lie bracket on $\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}}$ is a correspondence product in the sense of Chriss–Ginzburg: for α at (g_1, n_1) and β at (g_2, n_2) , the bracket $[\alpha, \beta]$ composes through the separating clutching correspondence $\overline{\mathcal{M}}_{g_1, n_1+1} \times \overline{\mathcal{M}}_{g_2, n_2+1} \xleftarrow{p} Z \xrightarrow{\xi} \overline{\mathcal{M}}_{g, n}$ via $[\alpha, \beta] = \xi_* \circ p^*(\alpha \boxtimes \beta)$. As the Steinberg self-intersection presents the Hecke algebra, the modular clutching correspondence presents the modular convolution. The Jacobi identity is the associativity of the correspondence.

PROPOSITION 15.12.40 (*The algebra structure as MC element;*). The assignment $\mathcal{A} \mapsto \Theta_{\mathcal{A}} \in \mathrm{MC}(\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}})$ is a functor from cyclic chiral algebras to MC moduli of the modular convolution algebra. The algebra structure on $\mathcal{A}$ is $\Theta_{\mathcal{A}}$: the bar complex is the twisting of $\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}}$ by $\Theta_{\mathcal{A}}$; the genus tower is the filtration of $\Theta_{\mathcal{A}}$ by graph loop order; the modular invariants $\kappa, \mathfrak{C}, \mathfrak{Q}$ are projections of this single element. The genus-0 projection $\Theta_{\mathcal{A}} \mapsto \pi$ recovers the universal twisting morphism of Proposition 3.1.21; the positive-genus corrections are the modular deformation data.

Proof. The MC equation $D\Theta + \frac{1}{2}[\Theta, \Theta] = 0$ is the genus-expanded nilpotence $D_{\mathcal{A}}^2 = 0$ (Theorem 15.12.26(iii)). Functoriality holds because the transferred operations ℓ_n^{tr} and the propagator $P_{\mathcal{A}}$ are natural. The genus filtration of $\Theta_{\mathcal{A}}$ is the graph-loop-order filtration; projection to degree r gives the degree- r shadow. $\square$

Remark 15.12.41 (*Factorisation homology*). In the Beilinson–Drinfeld framework, $\mathfrak{g}_{\mathcal{A}}^{\mathrm{ch}}$ is $\int_{\mathrm{Ran}(X)} \mathrm{End}_{\mathcal{A}}$ and $\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}}$ is $\int_{\mathrm{Mod}} \mathrm{End}_{\mathcal{A}}$. The MC element $\Theta_{\mathcal{A}}$ is a section of the factorisation algebra over the moduli tower; its factorisation along clutching maps is the factorisation property. The ribbon-graph variant $\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod} E_1} = \mathrm{CoDer}(F\mathrm{Ass}(\mathcal{A}))[1]$ is the ordered convolution algebra, and its genus expansion is the algebraic ’t Hooft $1/N$ expansion: planar ribbon graphs dominate at large N .

15.12.10 LOGARITHMIC FORMS

PROPOSITION 15.12.42 (*Forced by conformal invariance [45];*). The appearance of logarithmic forms $\eta_{ij} = d \log(z_i - z_j)$ is not a choice but forced by:

1. *Translation and scale invariance*: Under $z \mapsto az + b$, $\eta_{ij} \mapsto \eta_{ij}$
2. *Single-valuedness*: Around collision divisors, forms must have logarithmic singularities
3. *Residue theorem*: Only logarithmic forms give well-defined residues

Convention 15.12.43 (Signs from trees). For the bar differential on decorated trees, we use the following sign convention:

1. Label edges by depth-first traversal starting from the root
2. For contracting edge e connecting vertices with operations p_1, p_2 of degrees $|p_1|, |p_2|$:
3. The sign is $(-1)^{\epsilon(e)}$ where:

$$\epsilon(e) = \sum_{e' < e} |p_{s(e')}| + |p_1| + 1$$

where $s(e')$ is the source vertex of edge e' and the sum is over edges preceding e in the ordering.

4. The extra $+1$ comes from the suspension in the bar construction.

To verify $d^2 = 0$ for this sign convention, consider a tree with three vertices and two edges e_1, e_2 . The two ways to contract both edges give:

- Contract e_1 then e_2 : sign is $(-1)^{\epsilon(e_1)} \cdot (-1)^{\epsilon'(e_2)}$
- Contract e_2 then e_1 : sign is $(-1)^{\epsilon(e_2)} \cdot (-1)^{\epsilon'(e_1)}$

where ϵ' accounts for the change in edge labeling after the first contraction. A detailed calculation shows these contributions cancel:

$$(-1)^{\epsilon(e_1) + \epsilon'(e_2)} + (-1)^{\epsilon(e_2) + \epsilon'(e_1)} = 0$$

This generalizes to all trees by induction on the number of edges.

This ensures $d^2 = 0$ by a careful analysis of double contractions.

LEMMA 15.12.44 (*Sign consistency for bar differential [299];*). The sign convention above ensures that for any pair of edges e_1, e_2 in a tree, the signs arising from contracting e_1 then e_2 versus contracting e_2 then e_1 differ by exactly (-1) , ensuring $d^2 = 0$.

Proof. This is a standard result in operad theory; see Loday–Vallette [299], Proposition 6.3.2. The key mechanism: label the edges $1, \dots, E$. Contracting edge i produces a tree with $E - 1$ edges, relabeled $1, \dots, E - 1$. If $i < j$, then contracting i first shifts edge j to position $j - 1$. The sign for contracting edge at position k in a tree T is $\epsilon(k, T) = k - 1 + \sum_{\ell < k} |v_\ell|$ where $|v_\ell|$ is the degree of the operation at the vertex below edge ℓ . One checks:

$$\epsilon(i, T) + \epsilon(j - 1, T/e_i) = \epsilon(j, T) + \epsilon(i, T/e_j) + 1$$

so that contracting in opposite order introduces a sign of $(-1)^1 = -1$, giving $d^2 = 0$. $\square$

The dual cobar construction is as follows.

Definition 15.12.45 (*Cobar construction*). Dually, for a coaugmented cooperad C with coaugmentation $\eta : \mathbb{I} \rightarrow C$, the cobar construction $\Omega(C)$ is the free operad on the desuspension $s^{-1}\bar{C}$ (where $\bar{C} = \text{coker}(\eta)$) with differential induced by the cooperad comultiplication.

THEOREM 15.12.46 (*Bar-cobar adjunction [299];*). There is an adjunction:

$$\bar{B} : \text{Operads} \rightleftarrows \text{Cooperads}^{\text{op}} : \Omega$$

If P is Koszul (Definition 3.7.3), then the unit and counit are quasi-isomorphisms, establishing an equivalence of homotopy categories.

15.12.11 PARTITION COMPLEXES AND THE COMMUTATIVE OPERAD

For the commutative operad Com , the bar construction admits an explicit combinatorial model via partition lattices:

Definition 15.12.47 (Partition lattice). The partition lattice Π_n is the poset of all partitions of $\{1, 2, \dots, n\}$, ordered by refinement: $\pi \leq \sigma$ if every block of π is contained in some block of σ . The proper part $\bar{\Pi}_n = \Pi_n \setminus \{\hat{0}, \hat{1}\}$ excludes the minimum (discrete partition) and maximum (trivial partition).

THEOREM 15.12.48 (*Partition complex structure;*). The bar complex $\bar{B}(\text{Com})(n)$ is quasi-isomorphic to the reduced chain complex $\tilde{C}_*(\bar{\Pi}_n)$ of the proper part of the partition lattice Π_n . More precisely:

$$\bar{B}(\text{Com})(n) \simeq s^{n-1} \tilde{C}_*(\bar{\Pi}_n) \otimes \text{sgn}_n$$

where sgn_n is the sign representation of S_n .

Proof. Elements of $\text{Com}^{\circ k}(n)$ (the k -fold composition) correspond to ways of iteratively partitioning n elements through k levels. The simplicial structure is:

- Face maps compose adjacent levels of partitioning (coarsening)
- Degeneracy maps repeat a level (refinement followed by immediate coarsening)

After normalization (removing degeneracies), we obtain chains on $\bar{\Pi}_n$. The dimension shift and sign representation arise from the suspension in the bar construction and the need for S_n -equivariance.

The poset $\bar{\Pi}_n$ has the homology of a wedge of $(n-1)!$ spheres of dimension $n-3$, with the S_n -action on the top homology given by the Lie representation tensored with the sign. This follows from the classical results of Björner–Wachs [52] and Stanley [381], who computed:

$$\tilde{H}_{n-3}(\bar{\Pi}_n) \cong \text{Lie}(n) \otimes \text{sgn}_n \text{ as } S_n\text{-representations}$$

and $\tilde{H}_k(\bar{\Pi}_n) = 0$ for $k \neq n-3$. □

Remark 15.12.49 (Simplicial model). The simplicial bar for Com literally consists of chains of refinements $\pi_0 \leq \pi_1 \leq \dots \leq \pi_k$ in Π_n . This is the nerve of the poset Π_n , and the identification with the cooperad structure follows from taking normalized chains.

15.12.12 HOLOGRAPHIC INTERPRETATION

Conjecture 15.12.50 (Holographic Koszul duality;).

For appropriate chiral algebra pairs $(\mathcal{A}_{\text{bdy}}, \mathcal{A}_{\text{bulk}})$, we expect the following dictionary: boundary observables and bulk amplitudes are related by the square below.

$$\begin{array}{ccc} \text{Boundary CFT } \mathcal{A}_{\text{bdy}} & \xrightarrow{Z_{\text{der}}} & \text{Bulk } Z_{\text{der}}(\mathcal{A}_{\text{bdy}}) \simeq C_{\text{ch}}^\bullet(\mathcal{A}_{\text{bdy}}) \\ \downarrow \text{correlators} & & \downarrow \text{amplitudes} \\ \text{Boundary observables} & \xrightarrow{\text{AdS/CFT}} & \text{Bulk amplitudes} \end{array}$$

Specifically:

1. The *derived center* $Z_{\text{der}}(\mathcal{A}_{\text{bdy}}) \simeq C_{\text{ch}}^{\bullet}(\mathcal{A}_{\text{bdy}}, \mathcal{A}_{\text{bdy}})$ should furnish the bulk observable algebra (the boundary-to-bulk map is the center map, not the bar construction; the bar construction classifies twisting data/MC elements, which encode coupling constants rather than bulk operators)
2. Residues at collision divisors should model bulk interactions (via the brace operations on Hochschild cochains)
3. The cobar construction should recover the boundary package from suitable bulk data (via the bar-cobar adjunction as a representability theorem for deformations)
4. The bar-cobar adjunction is conjecturally interpreted as the algebraic shadow of holographic duality: bar classifies couplings, center acts as bulk

Example. For $\mathcal{A}_{\text{bdy}} = \mathcal{W}_{\infty}[\lambda]$ at $c = N$:

- Bulk theory candidate: Vasiliev higher-spin gravity in AdS_3
- Derived center: should organize the same higher-spin interaction data as $\text{hs}[\lambda] \otimes C^{\bullet}(\text{AdS}_3)$ (the bar complex provides the coalgebraic input, but the bulk observable algebra is the center, not the bar complex itself)
- Cobar complex: should recover the boundary $\mathcal{W}_{\infty}$ package from suitable bulk input
- The parameter λ controls both boundary $\mathcal{W}$ -algebra structure constants and bulk higher-spin coupling constants

Remark 15.12.51 (Physical evidence and scope). This conjecture is supported by matching of partition functions, three-point functions, and conformal blocks between boundary $\mathcal{W}$ -algebras and bulk Vasiliev theory [189]. It is labeled because the holographic identification of the bar construction with bulk field content, and of the cobar construction with boundary reconstruction, requires physical input from the $\text{AdS}_3/\text{CFT}_2$ correspondence that lies outside the algebraic framework of this monograph. The mathematical content is the structural parallel between the bar-cobar adjunction and the holographic dictionary.

Remark 15.12.52 (Scope). Conjecture 15.12.50 is tagged because the claimed dictionary between the bar-cobar adjunction and the AdS/CFT correspondence requires physics input at two levels: (i) the identification of bar complex generators with bulk higher-spin fields relies on the Gaberdiel–Gopakumar duality, which is itself a physics conjecture supported by numerical evidence (partition function matching, three-point function agreement) but without a mathematical proof; (ii) the cobar reconstruction of boundary correlators from bulk Witten diagrams presupposes the $\text{AdS}_3/\text{CFT}_2$ correspondence, which is not a theorem. Within the algebraic framework of this monograph, one can prove that the bar-cobar adjunction has the same formal structure as the holographic dictionary, but the identification of the two requires external physical input that we do not attempt to supply. In the logical order, the theorematic input here is the completed M-level bar-cobar package and its finite-stage coefficient identities; any filtered H-level higher-spin bulk target is upstream MC₄, and the holographic comparison itself is downstream MC₅.

Homotopy template (Convention 1.10.1): Type VII (physics-dictionary). The conjecture treats the bar-cobar adjunction as the algebraic shadow of the holographic dictionary, mapping boundary correlators to bulk Witten-diagram data only after additional physics input. (Contributing to Conjecture K.7.1.)

Chapter 16

Quantum corrections to Arnold relations

The MC element $\Theta_{\mathcal{A}}$ satisfies $D\Theta_{\mathcal{A}} + \frac{1}{2}[\Theta_{\mathcal{A}}, \Theta_{\mathcal{A}}] = 0$; the genus- g components of this equation are the quantum corrections to the genus-0 bar differential. At genus 0, the Arnold relation ensures $d^2 = 0$; at genus $g \geq 1$, it deforms by coherent higher homotopies whose leading term is the modular curvature $\kappa(\mathcal{A})$.

Definition 16.0.1 (Quantum corrections). In this monograph, *quantum corrections* are the genus- $g \geq 1$ components of the modular bar differential that vanish on genus-0 configuration spaces. Precisely: the total differential $D = \sum_{g \geq 0} \hbar^g D^{(g)}$ splits by loop genus; the genus-0 part $D^{(0)}$ is the chiral bar differential on configuration spaces of X , governed by the Arnold relation for the logarithmic forms $\eta_{ij} = d \log(z_i - z_j)$ on $\text{FM}_n(X)$ (this is *not* the classical bar differential over a point, which retains no configuration-space geometry), and the higher-genus parts $D^{(g)}$ for $g \geq 1$ are the quantum corrections. The parameter $\hbar$ is a formal loop-counting variable with $|\hbar| = 0$; it tracks the genus grading and has no physical content beyond bookkeeping.

When strict Arnold relations fail at genus $g \geq 1$, they fail by coherent higher homotopies: quantum corrections are new higher operations in the homotopy algebra, not errors.

Four principles govern the structure. *Strictness as shadow.* The genus-0 identity $\eta_{12} \wedge \eta_{23} + \eta_{23} \wedge \eta_{31} + \eta_{31} \wedge \eta_{12} = 0$ is the shadow of a chain-level identity in $\text{Conv}_{\infty}(\bar{B}^{\text{ch}}(\mathcal{A}), \mathcal{A})$. When the curve acquires non-trivial periods, that identity deforms by an Eisenstein correction whose leading term is $\kappa(\mathcal{A})$. *Modularity at chain level.* The correction is a Maurer–Cartan deformation of the differential in the modular convolution algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$, dictated by the Feynman transform of the modular operad and recorded in the shadow obstruction tower of Chapter 13.21. *Examples.* Each standard family behaves differently: Heisenberg terminates at degree 2 (pure curvature), affine algebras at degree 3 (cubic shadow), $\beta\gamma$ at degree 4 (quartic contact), while Virasoro and $\mathcal{W}_N$ produce infinite towers forced by non-vanishing quintic obstructions. *Closing the loop.* Every quantum correction computed here reappears as input to Theorem C (complementarity, Chapter 13) and Theorem D (modular characteristic, Chapter K.7.1), confirming that the corrections assemble into a universal, additive, duality-constrained invariant.

Strict genus-0 nilpotence breaks once the propagator remembers the periods of the curve. Curvature terms, Eisenstein regularizations, and their assembly into a curved A_{∞} package constitute the explicit correction mechanism behind the higher-genus theory. The Heisenberg computation of Chapter 2 is the frame case; the genus-1 identity already exhibits the universal pattern.

16.1 BRAID GROUPS AND ARNOLD RELATIONS

16.1.1 ARNOLD RELATIONS AND THE BRAID GROUP

Arnold's relations among differential forms on configuration spaces arise from the topology of the braid group. Consider three strands in a braid, labeled 1, 2, and 3. Their projections onto a plane trace out paths $z_1(t)$, $z_2(t)$, and $z_3(t)$. The fundamental group of the configuration space of three distinct points in the plane is the braid group B_3 .

16.1.1.1 The braid derivation of Arnold relations

Start with a specific braid where strand 1 circles around strand 2, while strand 3 remains fixed. The winding number of this motion is captured by the integral:

$$\oint \frac{dz_1 - dz_2}{z_1 - z_2} = 2\pi i$$

If we compose three such braids (where 1 circles 2, then 2 circles 3, then 3 circles 1) we return to the identity braid. This topological fact translates to an algebraic relation.

To see this explicitly, consider the logarithmic 1-forms:

$$\begin{aligned}\eta_{12} &= d \log(z_1 - z_2) = \frac{dz_1 - dz_2}{z_1 - z_2} \\ \eta_{23} &= d \log(z_2 - z_3) = \frac{dz_2 - dz_3}{z_2 - z_3} \\ \eta_{31} &= d \log(z_3 - z_1) = \frac{dz_3 - dz_1}{z_3 - z_1}\end{aligned}$$

The braid group relation forces a dependence among these forms, visible via the *partial fraction identity*: clearing denominators in

$$\frac{1}{(z_1 - z_2)(z_2 - z_3)} + \frac{1}{(z_2 - z_3)(z_3 - z_1)} + \frac{1}{(z_3 - z_1)(z_1 - z_2)} = 0$$

gives the numerator $(z_3 - z_1) + (z_1 - z_2) + (z_2 - z_3) = 0$.

Computing the wedge product $\eta_{ij} \wedge \eta_{jk}$ and using the form-level analogue of this identity yields:

$$\eta_{12} \wedge \eta_{23} + \eta_{23} \wedge \eta_{31} + \eta_{31} \wedge \eta_{12} = 0$$

This is Arnold's relation: it encodes the fact that the three braiding operations compose to the identity.

16.1.2 THE MEANING OF INTEGRABILITY

These relations are the integrability conditions for the geometric bar complex: $d^2 = 0$ is flatness of the Knizhnik–Zamolodchikov connection on the local system of conformal blocks [40, Section 3.4].

Consider the bar complex:

$$\bar{B}^{\text{geom}}(\mathcal{A}) = \bigoplus_n \Gamma(\bar{C}_n(X), \mathcal{A}^{\boxtimes n} \otimes \Omega_{\log}^*)$$

with differential $d = d_{\text{internal}} + d_{\text{residue}} + d_{\text{deRham}}$. The condition $d^2 = 0$ says that the differential defines a flat connection on an infinite-dimensional bundle.

16.1.2.1 The Maurer–Cartan perspective

More precisely, we can view d as a connection on the graded vector bundle:

$$\mathcal{E} = \bigoplus_{n,k} \mathcal{A}^{\boxtimes n} \otimes \Omega_{\log}^k$$

The flatness condition $d^2 = 0$ is equivalent to the Maurer–Cartan equation:

$$d\omega + \frac{1}{2}[\omega, \omega] = 0$$

where $\omega = \sum_{i < j} t_{ij} \eta_{ij}$ is the residue-valued logarithmic coefficient in the geometric bar differential, with $t_{ij} \in \text{End}(\mathcal{A}^{\otimes n})$ acting on the i -th and j -th tensor factors via the chiral bracket and $\eta_{ij} = d \log(z_i - z_j)$ the Arnold form. The Arnold relations are precisely the conditions ensuring this equation holds.

16.1.2.2 Concrete computation

We verify this for $n = 3$. The differential acts on $a_1 \otimes a_2 \otimes a_3 \otimes \eta_{12}$ as:

$$d(a_1 \otimes a_2 \otimes a_3 \otimes \eta_{12}) = a_1 \otimes a_2 \otimes a_3 \otimes d\eta_{12} + \text{residue terms}$$

For $d^2 = 0$, we need:

$$d(d\eta_{12}) = 0$$

But $d\eta_{12} = d(d \log(z_1 - z_2)) = 0$ automatically. The non-trivial constraint comes from mixed terms:

$$d_{\text{residue}}(d_{\text{deRham}}(\dots)) + d_{\text{deRham}}(d_{\text{residue}}(\dots)) = 0$$

This is satisfied if and only if the Arnold relations hold.

16.2 GENUS ONE: THETA FUNCTIONS AND CENTRAL EXTENSIONS**16.2.1 THE GENUS ONE QUANTUM CORRECTION**

On the torus $E_\tau = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ with modular parameter $\tau \in \mathbb{H}$, the logarithmic forms must respect the double periodicity.

16.2.1.1 The Weierstrass construction

We need a function with a simple zero at the origin and the correct periodicity. Weierstrass constructed the sigma function:

$$\sigma(z|\tau) = z \prod_{(m,n) \neq (0,0)} \left(1 - \frac{z}{m + n\tau}\right) \exp\left(\frac{z}{m + n\tau} + \frac{z^2}{2(m + n\tau)^2}\right)$$

This infinite product converges due to the exponential factors. The logarithmic derivative gives the Weierstrass zeta function:

$$\zeta(z|\tau) = \frac{d}{dz} \log \sigma(z|\tau) = \frac{1}{z} + \sum_{(m,n) \neq (0,0)} \left(\frac{1}{z - m - n\tau} + \frac{1}{m + n\tau} + \frac{z}{(m + n\tau)^2} \right)$$

16.2.1.2 The quasi-periodicity and its consequences

The zeta function is not doubly periodic but quasi-periodic:

$$\begin{aligned}\zeta(z+1|\tau) &= \zeta(z|\tau) + 2\eta_1 \\ \zeta(z+\tau|\tau) &= \zeta(z|\tau) + 2\eta_\tau\end{aligned}$$

where the quasi-periods satisfy the *Legendre relation*:

$$\tau\eta_1 - \eta_\tau = \pi i$$

(from $\oint_{\partial\mathcal{F}} \zeta(z) dz = 2\pi i$ and the quasi-periodicity $\zeta(z+\omega) = \zeta(z) + 2\eta_\omega$)

The quantum correction arises from this quasi-periodicity:

16.2.1.3 Computing the quantum correction

The logarithmic forms on the torus are:

$$\eta_{ij}^{(1)} = d \log \sigma(z_i - z_j|\tau) = \zeta(z_i - z_j|\tau)(dz_i - dz_j)$$

Now compute the Arnold combination:

$$\mathcal{A}_3^{(1)} = \eta_{12}^{(1)} \wedge \eta_{23}^{(1)} + \eta_{23}^{(1)} \wedge \eta_{31}^{(1)} + \eta_{31}^{(1)} \wedge \eta_{12}^{(1)}$$

We derive the defect from first principles via the Eisenstein-regularised Laurent expansion of ζ .

Step 1: Form-factor reduction. Write $u = z_{12}$, $v = z_{23}$, $w = z_{31} = -(u + v)$ and $\alpha = dz_1 - dz_2$, $\beta = dz_2 - dz_3$. Note that $dz_3 - dz_1 = -(\alpha + \beta)$, so

$$\beta \wedge (-\alpha - \beta) = -\beta \wedge \alpha = \alpha \wedge \beta, \quad (-\alpha - \beta) \wedge \alpha = -\beta \wedge \alpha = \alpha \wedge \beta.$$

Every cyclic term carries the *same* form factor, giving

$$\mathcal{A}_3^{(1)} = [\zeta(u)\zeta(v) + \zeta(v)\zeta(w) + \zeta(w)\zeta(u)] \cdot \alpha \wedge \beta.$$

Step 2: Pole cancellation. Denote the coefficient function $S(u, v) = \sum_{\text{cyc}} \zeta(u)\zeta(v)$. At $z_1 = z_2$ (i.e. $u = 0$), the first and third terms each have a simple pole in u , with residues $\zeta(v)$ and $\zeta(w) = \zeta(-v) = -\zeta(v)$ respectively; the second term is regular. So the residue of S at $u = 0$ vanishes. By symmetry the same holds at $v = 0$ and $w = 0$. Therefore S is an *entire* function of (u, v) .

Step 3: Laurent expansion via Eisenstein summation. The Weierstrass ζ -function admits the Eisenstein-regularised expansion (cf. §G.1):

$$\zeta(z|\tau) = \frac{1}{z} - G_2(\tau)z - G_4(\tau)z^3 - G_6(\tau)z^5 - \dots \quad (16.1)$$

where $G_{2k}(\tau) = \sum'_{(m,n)} (m+n\tau)^{-2k}$ and $G_2(\tau) = \frac{\pi^2}{3} E_2(\tau)$ requires Eisenstein summation (inner sum over m first). The quasi-period is $2\eta_1 = G_2(\tau)$.

Step 4: Constant term of S . Substituting (16.1) into S and collecting powers of (u, v) , the singular terms cancel by Step 2. The leading contributions are:

$$\text{from } 1/(uv) : \quad \sum_{\text{cyc}} \frac{1}{uv} = \frac{u+v+w}{uvw} = 0, \quad (16.2)$$

$$\text{from } G_2 : \quad -G_2 \sum_{\text{cyc}} \left(\frac{u}{v} + \frac{v}{u} \right) = -G_2 \cdot \frac{-(u^3+v^3+w^3)}{uvw} = -G_2 \cdot \frac{-3uvw}{uvw} = 3G_2, \quad (16.3)$$

$$\text{from } G_4, G_2^2 : \quad (5G_4 - G_2^2)(u^2 + uv + v^2) + \dots \quad (16.4)$$

In (16.3) we used Newton's identity $u^3 + v^3 + w^3 = 3uvw$ (valid when $u + v + w = 0$), and in (16.2) the genus-0 Arnold relation.

Step 5: Higher-order terms are cohomologically trivial. The position-dependent corrections (16.4) are polynomial in (u, v) with τ -dependent coefficients. Since $\alpha \wedge \beta = du \wedge dv$ and any polynomial $p(u, v) du \wedge dv$ on $\mathbb{C}^2$ is exact (primitives are $\partial\bar{\partial}$ -exact on the universal cover and descend to exact forms on $C_3(E_\tau)$ because they have at most polynomial growth), they do not contribute to the cohomology class $[\mathcal{A}_3^{(1)}] \in H^{2,0}(C_3(E_\tau))$.

Step 6: The Arnold defect. Combining Steps 4 and 5:

$$\boxed{\mathcal{A}_3^{(1)} = 3 G_2(\tau) \cdot \alpha \wedge \beta + (\text{exact}) = \pi^2 E_2(\tau) \cdot \alpha \wedge \beta + (\text{exact})} \quad (16.5)$$

where $E_2(\tau) = 1 - 24 \sum_{n=1}^{\infty} \sigma_1(n) q^n$ is the weight-2 quasi-modular Eisenstein series ($q = e^{2\pi i \tau}$). The right-hand side is a holomorphic $(2, 0)$ -form on $C_3(\Sigma_\tau)$ whose cohomology class is $\pi^2 E_2(\tau) \cdot [\alpha \wedge \beta]$; the factor π^2 is the residue of the Eisenstein regularisation and is absorbed into $\kappa(\mathcal{A})$ when the Arnold defect is contracted against the OPE data to produce the bar-complex curvature $m_0^{(1)} = \kappa \cdot E_2(\tau)$. The non-holomorphic completion $\hat{E}_2(\tau) = E_2(\tau) - 3/(\pi \operatorname{Im}(\tau))$ governs the single-valued propagator and produces the Arakelov $(1, 1)$ -form $2\pi i \cdot \omega_\tau$ of Theorem 13.5.9(b).

16.2.2 THE CENTRAL EXTENSION AT GENUS ONE

16.2.2.1 The central extension

Consider the Heisenberg vertex algebra $\mathcal{H}_\kappa$ with generators a_n for $n \in \mathbb{Z}$. The commutation relations are:

$$[a_m, a_n] = \kappa m \delta_{m+n, 0}$$

where κ is the level. The central extension is present already at genus zero; it is part of the *definition* of the Heisenberg algebra. What changes at genus one is not the commutation relations themselves, but the *modular properties* of the resulting chiral algebra: the partition function acquires τ -dependence, and correlation functions must be consistent with the quantum-corrected Arnold relations on the torus.

16.2.2.2 The explicit construction of the central element

The deformation of the Arnold relation at genus 1 encodes the *curving obstruction* $m_0^{(1)}$ in the genus-1 bar complex. For the Heisenberg algebra $\mathcal{H}_\kappa$, this obstruction is:

$$m_0^{(1)} = \kappa \cdot E_2(\tau)$$

The factor $E_2(\tau)$ controls the modular dependence of the genus-1 partition function $Z^{(1)} = \eta(\tau)^{-\operatorname{rank}}$, consistent with the identity $\partial_\tau \log \eta(\tau) = \frac{\pi i}{12} E_2(\tau)$. The central charge ($c = 1$ for rank-1 Heisenberg) is a genus-0 datum determined by the Sugawara construction, not by this integral.

16.2.2.3 The cocycle condition

The quantum correction satisfies a cocycle condition. Define:

$$\omega(a_m, a_n) = m \delta_{m+n, 0}$$

This is a 2-cocycle in the Lie algebra cohomology:

$$\omega([a_\ell, a_m], a_n) + \omega([a_m, a_n], a_\ell) + \omega([a_n, a_\ell], a_m) = 0$$

The central extension is the universal one classified by $H^2(\text{Heisenberg}, \mathbb{C})$.

16.2.2.4 Concrete section realizing the extension

The central extension can be realized concretely as follows. Consider the space:

$$\hat{\mathcal{H}} = \mathcal{H} \oplus \mathbb{C}c$$

where $\mathcal{H}$ is the original Heisenberg algebra. The bracket is:

$$[\hat{a}_m, \hat{a}_n] = \widehat{[a_m, a_n]} + \omega(a_m, a_n)c$$

The element c is central: $[c, \hat{a}_n] = 0$ for all n .

16.3 HIGHER GENUS

16.3.1 GENUS 2

The moduli space $\mathcal{M}_2$ is 3-dimensional, parametrized by the period matrix:

$$\Omega = \begin{pmatrix} \tau_{11} & \tau_{12} \\ \tau_{12} & \tau_{22} \end{pmatrix} \in \mathcal{H}_2$$

living in the Siegel upper half-space, the space of symmetric complex 2×2 matrices with positive definite imaginary part.

16.3.1.1 The theta functions

There are 16 theta characteristics at genus 2, corresponding to the 16 spin structures. Of these, 6 are odd (theta function vanishes at the origin) and 10 are even. The even characteristics give rise to quantum corrections.

16.3.1.2 Detailed computation of genus 2 corrections

The prime form at genus 2 is:

$$E(z, w) = \frac{\theta[\delta](z - w|\Omega)}{h_\delta(z)^{1/2} h_\delta(w)^{1/2}}$$

where δ is an odd characteristic and h_δ is the corresponding holomorphic differential.

The logarithmic forms become:

$$\eta_{ij}^{(2)} = d \log E(z_i, z_j) = \partial_i \log E(z_i, z_j) dz_i + \partial_j \log E(z_i, z_j) dz_j$$

The Arnold combination on Σ_2 is

$$\mathcal{A}_3^{(2)} = \sum_{\text{cyclic}} \eta_{ij}^{(2)} \wedge \eta_{jk}^{(2)}.$$

As at genus 1, the singular terms cancel and the defect reduces to a $(2, 0)$ -form on $C_3(\Sigma_2)$ whose cohomology class depends on the period matrix Ω . The genus-2 analogue of the Eisenstein correction $3G_2(\tau)$ of (16.5) involves the Siegel Eisenstein series $E_2^{(2)}(\Omega)$ and determines the genus-2 bar curvature $m_0^{(2)} = \kappa(\mathcal{A}) \cdot \lambda_2$ (Theorem 13.13.16). The explicit graph-sum computation of the planted-forest correction $\delta_{\text{pf}}^{(2,0)}$ at genus 2 appears in §13.21.

16.4 THE A_∞ STRUCTURE

The A_∞ structure (Stasheff [382]) encodes the higher coherences for consistency across genera.

16.4.1 THE COMPLETE A_∞ STRUCTURE

An A_∞ algebra consists of operations $m_n : A^{\otimes n} \rightarrow A[2 - n]$ for $n \geq 1$, satisfying:

$$\sum_{\substack{r+s+t=n \\ r,t \geq 0, s \geq 1}} (-1)^{rs+t} m_{r+1+t}(\text{id}^{\otimes r} \otimes m_s \otimes \text{id}^{\otimes t}) = 0$$

16.4.1.1 For the bar complex

The bar complex of a chiral algebra carries a natural A_∞ structure:

$$\begin{aligned} m_1 &= d_{\text{bar}} \\ m_2(a \otimes b) &= \text{Res}_{z_1=z_2} \left[\frac{a(z_1)b(z_2)}{z_1 - z_2} \right] \\ m_3(a \otimes b \otimes c) &= \int_{\overline{C}_3(X)} a(z_1) b(z_2) c(z_3) \eta_{123}^{\text{FM}} \end{aligned}$$

where η_{123}^{FM} is the propagator form on the Fulton–MacPherson compactification $\overline{C}_3(X)$, defined via homotopy transfer (cf. Appendix 9). Concretely, m_3 sums over binary trees with 3 leaves, each tree contributing an iterated composition of m_2 with the contracting homotopy h :

$$m_3(a, b, c) = m_2(m_2(a, b) \cdot h, c) + m_2(a, h \cdot m_2(b, c))$$

16.4.2 EXPLICIT COMPUTATIONS FOR SPECIFIC ALGEBRAS

16.4.2.1 For the Heisenberg algebra

The A_∞ structure is strict: $m_0 = 0$ (uncurved, so $m_1^2 = 0$), m_2 is the standard product, and $m_n = 0$ for $n \geq 3$. The genus- g corrections for $g \geq 1$ enter not through higher m_n but through the curvature $m_0^{(g)} = \kappa(\mathcal{H}_\kappa) \cdot \lambda_g$ and the cohomology of $\overline{\mathcal{M}}_g$ (cf. Part II).

16.4.2.2 For the $\beta\gamma$ system

With background charge Q : m_0 is the degree-2 curvature element determined by Q and $c_{\beta\gamma}$; m_1 is the BRST differential (satisfying the curved relation $m_1^2(a) = [m_0, a]$); m_2 is the standard OPE product; and m_3 is the transferred ternary operation from homotopy transfer on $\overline{C}_3(\mathbb{C})$, whose coefficient depends on the OPE structure constants of the $\beta\gamma$ system.

16.4.2.3 Explicit computation of m_3 for $\beta\gamma$

The transferred operation m_3 is computed by homotopy transfer from the Fulton–MacPherson compactification $\overline{C}_3(\mathbb{C})$:

$$m_3(a, b, c) = \sum_{T \in \text{PBT}_3} (\pm) p \circ \mu_T \circ i^{\otimes 3}(a, b, c),$$

where PBT_3 is the set of planar binary trees with 3 leaves (two trees), each internal edge carrying the contracting homotopy h , and p, i are the projection and inclusion of the homotopy retract. This is a genus-0 (tree-level) operation; genus $g \geq 1$ corrections enter through the propagator and the cohomology of $\overline{\mathcal{M}}_g$, not through the degree of the A_∞ operations.

16.4.2.4 For $\mathcal{W}$ -algebras

For principal $\mathcal{W}$ -algebras obtained by Drinfeld–Sokolov reduction, the transferred A_∞ operations m_n are determined by the BRST spectral sequence: the ghost-number filtration produces the $\mathcal{W}$ -algebra generators on the E_2 page, and the higher m_n encode the transferred homotopy from the affine Kac–Moody input (Chapter H). The operations m_n are genus-0 (tree-level); their interaction with higher-genus corrections is governed by the curved A_∞ structure described in Part I.

16.5 KOSZUL DUALITY AND COMPLEMENTARY DEFORMATIONS

16.5.1 THE FUNDAMENTAL THEOREM

Remark 16.5.1 (Koszul complementarity at higher genus). For a Koszul dual pair $(\mathcal{A}, \mathcal{A}^\dagger)$ of chiral algebras, the quantum correction spaces at any genus g satisfy:

$$Q_g(\mathcal{A}) \oplus Q_g(\mathcal{A}^\dagger) = H^*(\overline{\mathcal{M}}_g, Z(\mathcal{A})).$$

See Theorem 13.15.14 for the full statement and proof (via Kodaira–Spencer map and Verdier involution on moduli space cohomology).

16.5.2 EXAMPLES OF KOSZUL COMPLEMENTARITY

16.5.2.1 Example 1: free fermions and free bosons

The free fermion system $\mathcal{F}$ with OPE:

$$\psi(z)\psi(w) \sim \frac{1}{z-w}$$

is Koszul dual to the $\beta\gamma$ system with $Q = 1$:

$$\beta(z)\gamma(w) \sim \frac{1}{z-w}$$

At genus g , the quantum corrections decompose according to spin structure parity: $Q_g(\mathcal{F})$ receives contributions from the Pfaffian line bundle over odd spin structures, while $Q_g(\beta\gamma)$ receives contributions from even spin structures. Heuristically, their union covers the spin-structure-dependent part of the moduli space, though the precise relationship to $H^*(\overline{\mathcal{M}}_{g,n})$ involves the tautological ring and requires further analysis.

16.5.2.2 Example 2: $\mathcal{W}$ -algebras and their duals

For the principal $\mathcal{W}$ -algebra $\mathcal{W}^k(\mathfrak{g})$, the chiral Koszul dual is $(\mathcal{W}^k(\mathfrak{g}))^\dagger = \mathcal{W}^{k'}(\mathfrak{g})$ where $k' = -k - 2h^\vee$ is the Feigin–Frenkel involution (Chapter H). This is chiral Koszul duality within the $\mathcal{W}$ -algebra family, not the Feigin–Frenkel–Langlands correspondence (which relates the critical-level center to opers on $\mathfrak{g}^\vee$). Koszul complementarity (Theorem C) then gives

$$\dim Q_g(\mathcal{W}^k(\mathfrak{g})) + \dim Q_g(\mathcal{W}^{k'}(\mathfrak{g})) = \dim H^*(\overline{\mathcal{M}}_g, Z(\mathcal{W}^k(\mathfrak{g})))$$

where $Z(\mathcal{W}^k(\mathfrak{g}))$ is the center, viewed as a local system on $\overline{\mathcal{M}}_g$.

16.6 DICTIONARY

Geometric	Algebraic	Physical

Quantum corrections	Central extensions	Loop corrections
Configuration spaces	Operadic structure	Correlation functions
Theta functions	Spin structures	Fermionic sectors
Period matrices	Moduli parameters	Coupling constants
Koszul duality	$\Lambda^* \leftrightarrow \text{Sym}^*$	S-duality

16.7 THE MODULAR QUANTUM L_∞ COMPLETION

The constructions of this chapter (curved A_∞ operations, genus corrections, and the quantum master equation) assemble into a single algebraic object: the *modular quantum L_∞ completion* of a chiral algebra, the cyclic/modular bar-cobar machine enriched by the BV operator and spectral line-operator data.

16.7.1 THE FULL MODULAR HOMOTOPY OBJECT

Definition 16.7.1 (Modular homotopy package). Let $\mathcal{A}$ be a chiral algebra on a curve X with cyclic pairing, and let $r(z)$ be a spectral twisting datum (Definition O.13.47). The *modular homotopy package* is

$$\mathcal{H}(T, B_\infty) := (\Omega^{\text{mod}} F^{\text{cyc}} \bar{B}(\mathcal{A}_\partial), D),$$

where $D = d_{A_\infty} + d_{\text{sew}} + \hbar \Delta + d_r$ is the total differential, with the four summands playing distinct geometric roles:

1. d_{A_∞} is the bar differential encoding the A_∞ operations $\{m_n\}_{n \geq 0}$;
2. d_{sew} is the sewing differential that glues output legs to input legs using the cyclic pairing and the homotopy propagator h ;
3. Δ is the BV loop-contraction operator, raising the genus by one;
4. d_r inserts the spectral line-operator twisting datum $r(z) \in \mathcal{A}^! \widehat{\otimes} \mathcal{A}^!((z^{-1}))$.

This is the cyclic/modular bar-cobar machine with defect and spectral twisting, strictly richer than a bare modular envelope.

Remark 16.7.2 (Coderivation model of the modular L_∞ structure). The four-component differential $D = d_{A_\infty} + d_{\text{sew}} + \hbar\Delta + d_r$ is the *coderivation model* of the modular L_∞ structure on $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$. Its components are the L_∞ structure maps evaluated on specific graph types: d_{A_∞} encodes tree graphs (genus 0), d_{sew} encodes self-gluing (separating nodes), $\hbar\Delta$ encodes non-separating clutching (genus-raising loops), and d_r encodes spectral twisting (line-operator insertions).

The bar-cobar adjunction (Theorem A) preserves quasi-isomorphisms *because* it is a quantum L_∞ functor: it intertwines the full L_∞ structures on both sides, so homotopy transfer (Appendix 9) produces the correct A_∞ operations: the transferred operations are the L_∞ -functorial image of the original ones, not an ad hoc perturbative approximation.

16.7.2 TREE-LEVEL OPERATIONS: EXPLICIT A_∞ AND L_∞ BRACKETS

At genus zero the modular package reduces to tree-level homotopy transfer. Let (V, d_V, i, p, h) be a contraction of the BV complex onto its cohomology.

Definition 16.7.3 (Tree-level A_∞ operations). For each $n \geq 2$, the transferred A_∞ operation is

$$m_n^{\text{tr}} = \sum_{T \in \text{PBT}_n} (\pm) p \circ \mu_T \circ i^{\otimes n},$$

where PBT_n denotes the set of planar binary rooted trees with n leaves. Internal edges carry the homotopy h , each vertex carries the interaction, each leaf carries i , and the root carries p . The signs are determined by the Koszul rule with respect to the cohomological grading.

Definition 16.7.4 (Tree-level L_∞ brackets). Antisymmetrizing yields the classical L_∞ brackets:

$$\ell_n^{\text{cl}}(x_1, \dots, x_n) = \sum_{\sigma \in S_n} \chi(\sigma) m_n^{\text{tr}}(x_{\sigma(1)}, \dots, x_{\sigma(n)}),$$

where $\chi(\sigma)$ is the Koszul sign of the permutation. This is precisely the homotopy-transfer output of the BV theory: the operations used, for instance, by Zeng after Kaluza–Klein reduction.

Remark 16.7.5 (Two-level convention for quantum corrections). In the two-level convention (§13.22.2), the tree-level L_∞ -brackets ℓ_n^{cl} are Conv_∞ at genus 0; the genus-refined operations $\ell_{g,n}$ of Definition 16.7.6 below are the genus-truncation of $\text{Def}_\infty^{\text{mod}}(\mathcal{A})$.

16.7.3 QUANTUM/MODULAR COMPLETION: WHEELED GRAPHS

Beyond genus zero, the operations acquire loop corrections indexed by stable graphs.

Definition 16.7.6 (Genus-refined L_∞ operations;). For each connected stable graph Γ of genus g with n external legs, define the genus- g , n -ary operation

$$\ell_{g,n}(x_1, \dots, x_n) = \sum_{\Gamma \in \mathcal{G}_{g,n}^{\text{st}}} \frac{\hbar^g}{|\text{Aut } \Gamma|} W_\Gamma \text{Cont}_\Gamma(x_1, \dots, x_n),$$

where:

- classical vertices carry the tree-level operations m_k^{tr} or ℓ_k^{cl} ;

- each internal edge carries the propagator h ;
- internal loops are contracted via the BV pairing;
- W_Γ is the *Feynman weight* of the graph, defined as follows. Assign to each internal edge e the propagator $h_e = K^{(g_e)}(z_s(e), z_t(e))$ (the genus- g_e Cauchy kernel), and to each vertex v the classical operation $m_{|v|}^{\text{cl}}$ evaluated at the adjacent fields. Then

$$W_\Gamma := \prod_{e \in E_{\text{int}}(\Gamma)} h_e \cdot \prod_{v \in V(\Gamma)} m_{|v|}^{\text{cl}},$$

composed via the contraction map Cont_Γ . When Γ has internal loops ($g(\Gamma) > 0$), the loop contractions $\sum_a e_a \otimes e^a$ produce the BV operator Δ . The product is well-defined (finite, no regularization needed) when the OPE has finitely many singular terms, which holds for all chiral algebras with polynomial OPE growth (§K.7.1). The term “regularized” in earlier versions of this chapter referred to this finiteness condition; no analytic regularization (dimensional or otherwise) is used.

16.7.4 THE QUANTUM MASTER EQUATION

THEOREM 16.7.7 (*Quantum L_∞ master equation*;). The genus-refined operations $\{\ell_{g,n}\}$ satisfy the modular L_∞ constraint: for all $g \geq 0$ and $n \geq 0$ with $2g - 2 + n > 0$,

$$\sum_{\substack{g_1+g_2=g \\ I \sqcup J = [n]}} (\pm) \ell_{g_1, |I|+1}(\ell_{g_2, |J|+1}(x_J), x_I) + \Delta \ell_{g-1, n+2}(x_1, \dots, x_n) = 0. \quad (16.6)$$

Proof. The first sum is the genus-splitting term; the second is the loop-contraction/BV term. Together they are the (g, n) -component of $D^2 = 0$, where D is the full modular bar differential (Definition 16.7.1). The identity $D^2 = 0$ is Theorem 13.22.412, which follows from the boundary-of-boundary relation $\partial^2 = 0$ on the stratification of $\overline{\mathcal{M}}_{g,n}$. The (g, n) -component of $D^2 = 0$ is precisely (16.6): the genus-splitting sum encodes self-gluing along separating nodes and the BV term encodes gluing along non-separating nodes. $\square$

Remark 16.7.8 (*Relation to the full modular homotopy type*). The full modular homotopy type combines four layers:

1. the *cyclic/modular bar-cobar complex*, encoding stable-curve gluing via the Feynman transform;
2. *Koszul duality*, producing the dual algebra $\mathcal{A}^!$ and the line-operator category $\mathcal{A}^! \text{-mod}$;
3. the *derived bulk-boundary center* $Z_{\text{der}}(\mathcal{A}_\partial)$, realizing the bulk as the Hochschild cohomology of the boundary (Theorem H);
4. the *spectral $r(z)$ -defect datum*, encoding the OPE of line operators via the dg-shifted Yangian.

The modular envelope alone sees stable-curve gluing; the addition of $r(z)$ sees the spectral OPE of lines. The combined package is precisely the dg-shifted Yangian of Dimofte–Niu–Py for line operators in 3d holomorphic-topological QFT (Definition O.13.48; §O.13). Its consistency condition ($D^2 = 0$ in the d_r -twisted modular bar complex) subsumes both the quantum master equation (16.6) and the A_∞ Yang–Baxter equation of Conjecture O.13.114.

16.8 NON-RENORMALIZATION AND THE EXACTNESS OF TREE-LEVEL OPERATIONS

The modular homotopy package of the previous section splits cleanly into a tree-level piece (the A_∞ operations $\{m_n\}$ and the spectral kernel $r(z)$) and a loop piece (the BV operator Δ and the genus-raising operations $\ell_{g,n}$). A theorem of Dimofte–Niu–Py guarantees that, for a wide class of theories, the tree-level piece receives *no* quantum corrections.

Definition 16.8.1 (*Quasi-linear HT theory*). A holomorphic-topological QFT is *quasi-linear* if the interaction vertices are at most linear in the fields being propagated; that is, each vertex has at most one propagating leg. All HT-twisted 3d $\mathcal{N} = 2$ gauge theories with polynomial superpotential are quasi-linear: the cubic vertex $\text{Tr}(c Z_1 Z_2)$ is linear in the gauge field c being propagated, and similarly for the matter couplings.

THEOREM 16.8.2 (*Non-renormalization at tree level*;). (Dimofte–Niu–Py [130], Theorem 4.1 and Proposition 6.1.) Let $\mathcal{A}$ be a quasi-linear 3d HT QFT. Then:

- (i) The A_∞ operations $\{m_n\}$ on both $\mathcal{A}$ and $\mathcal{A}^!$ are determined exactly at tree level: all loop diagrams contributing to m_n vanish.
- (ii) The line-operator OPE kernel $r(z)$ is determined exactly by tree-level “ladder” diagrams.
- (iii) $r(z)$ is independent of the bulk field interactions; it depends only on the propagator and the boundary coupling.

Remark 16.8.3 (*Validation of tree-level computations*). For quasi-linear theories, the transferred A_∞ operations computed by homotopy transfer (Definition 16.7.3) are exact, not leading-order approximations. The only quantum corrections enter through the genus-raising BV operator Δ (the $\hbar\Delta$ term in $D = d_{A_\infty} + d_{\text{sew}} + \hbar\Delta + d_r$), not through corrections to tree vertices.

COROLLARY 16.8.4 (*Exactness of standard-family r -matrices*;). For the standard families $\mathcal{A} \in \{\mathcal{H}_k, \beta\gamma/bc, \widehat{\mathfrak{g}}_k \text{ at non-critical level, } \text{Vir}_c, \mathcal{W}_N\}$, the r -matrices computed in Part II via the Laplace transform of the λ -bracket are exact: they receive no loop corrections.

Remark 16.8.5 (*Trees vs. loops: chirality vs. modularity*). Physically, loop corrections in the bulk correspond to the genus tower (the $\ell_{g,n}$ operations of Definition 16.7.6), not to renormalization of local vertex data. The separation

$$\text{trees} = \text{chirality}, \quad \text{loops} = \text{modularity}$$

from the modular PVA quantization package (Vol II) is a direct consequence of Theorem 16.8.2.

Remark 16.8.6 (*Consequences for the modular package*). The non-renormalization theorem has three structural consequences for the modular quantization package of Vol II:

- (i) *The PVA λ -bracket is exact.* For every standard family, the classical λ -bracket (Definition G.17.1 for affine, §H.15.3 for Virasoro, §H.14 for $\mathcal{W}_3$) is the *complete* tree-level datum. The 3d HT action reconstructed from the λ -bracket is therefore exact to all orders in perturbation theory, modulo the genus tower.
- (ii) *The bar differential is exact.* For quasi-linear theories, the bar differential $d_{\bar{B}}$ at genus zero receives no corrections: the A_∞ operations $\{m_n\}$ computed by homotopy transfer are final. The only genus-raising corrections enter through the curvature $m_0^{(g)} = \kappa(\mathcal{A}) \cdot \omega_g$ (i.e. $m_1^2(a) = [m_0^{(g)}, a]$), mediated by the BV operator Δ .

- (iii) *The spectral r -matrix is exact.* The line-operator OPE kernel $r(z)$ computed in Part II for each standard family is the tree-level answer, and the tree-level answer *is* the answer. Loop corrections to $r(z)$ vanish identically for quasi-linear theories.

By Proposition 13.22.395, non-renormalization means that the genus filtration of the master MC element $\Theta_{\mathcal{A}}$ separates cleanly:

$$\Theta_{\mathcal{A}} = \underbrace{\Theta_{\mathcal{A}}|_{h=0}}_{\text{tree: } \tau} + \underbrace{\Theta_{\mathcal{A}}|_{hg, g \geq 1}}_{\text{loop: genus tower}},$$

with the tree part τ (the twisting morphism of Theorem A) receiving no corrections from the loop part. These consequences validate every explicit computation in Chapters E–H: the algebraic formulas derived from the bar-cobar engine are not leading-order approximations; they are exact.

16.9 THE JACOBIATOR HOMOTOPY AND THE EILENBERG–ZILBER OPERAD

The homotopy chiral algebra structure (Theorem 8.10.5) equips the Čech resolution of a chiral algebra with higher operations $\{F_n\}_{n \geq 1}$ satisfying an L_∞ master equation. At degree 3, this master equation has a transparent interpretation: it is the *Jacobiator homotopy*, the precise mechanism by which Jacobi fails on the resolution and is restored by a coherent correction. But the Jacobiator does *not* appear for arbitrary covers: on $\mathbb{P}^1$ with the standard two-element cover, it vanishes identically. The obstruction requires triple intersections (three or more overlapping opens) and thus measures a genuine descent obstruction, not just an artifact of the resolution.

The Jacobiator, and all higher F_n , are components of a single master equation $D \cdot \Phi + \frac{1}{2}[\Phi, \Phi] = 0$, where $\Phi = \sum_{n \geq 2} F_n$ is the MC element encoding the entire HCA structure. By Proposition 13.22.395, this is a projection of the master equation $D_{\mathcal{A}}\Theta_{\mathcal{A}} + \frac{1}{2}[\Theta_{\mathcal{A}}, \Theta_{\mathcal{A}}] = 0$ to the Čech site at genus 0.

16.9.1 THE JACOBIATOR ON THE ČECH COMPLEX

Let $\mathcal{A}$ be a chiral algebra on X with cover $\mathcal{U}$, and let $[-, -] = F_2$ denote the binary chiral bracket on the Moore complex $M\check{C}^\bullet(\mathcal{U}; \mathcal{A})$. The Jacobi identity holds *strictly* on each open $U_{i_0 \dots i_p}$ (where the full chiral product is defined), but on the total Čech complex the bracket interacts with the Čech differential, and the Jacobi identity may fail.

Definition 16.9.1 (Jacobiator). For $a, b, c \in M\check{C}^\bullet$, the *Jacobiator* is

$$\text{Jac}(a, b, c) = [a, [b, c]] + (-1)^{|a|(|b|+|c|)} [b, [c, a]] + (-1)^{|c|(|a|+|b|)} [c, [a, b]].$$

On the total Čech complex, Jac is in general *nonzero*: it measures the obstruction to F_2 being a strict Lie bracket on the resolution.

PROPOSITION 16.9.2 (*Two-element covers are strict*;). Let $\mathcal{U} = \{U_0, U_\infty\}$ be a two-element affine open cover of X (e.g., the standard cover of $\mathbb{P}^1$). Then $\check{C}^p(\mathcal{U}; \mathcal{A}) = 0$ for $p \geq 2$, and consequently:

- (i) The Jacobiator vanishes: $\text{Jac}(a, b, c) = 0$ for all a, b, c .
- (ii) All higher operations vanish: $F_n = 0$ for $n \geq 3$.
- (iii) The Čech HCA is *strict*: the binary bracket F_2 is a genuine Lie bracket on $M\check{C}^\bullet$.

Proof. A two-element cover has $\check{C}^0 = \mathcal{A}(U_0) \oplus \mathcal{A}(U_\infty)$, $\check{C}^1 = \mathcal{A}(U_0 \cap U_\infty)$, and $\check{C}^p = 0$ for $p \geq 2$. In particular, the Moore complex is concentrated in degrees 0 and 1. The n -ary operation F_n raises total Čech degree by $n - 2$ (it maps n inputs summing to degree $m_1 + \cdots + m_n$ to degree $m_1 + \cdots + m_n$, while the chain in $\mathcal{Z}(n)$ contributes degree $2 - n$; see Remark 8.10.7). For $n \geq 3$, the output lands in $\check{C}^p$ for $p \geq 2$, which vanishes. Thus $F_n = 0$ for all $n \geq 3$. In particular the Jacobiator, which is the boundary of F_3 (equation (16.7)), vanishes. $\square$

Remark 16.9.3 (When the Jacobiator appears). The vanishing of Proposition 16.9.2 is *not* a feature of the algebra: it is a feature of the *cover*. For the *same* chiral algebra on the same curve X but with a cover $\mathcal{U}' = \{U_0, U_1, U_2\}$ having nontrivial triple intersection $U_0 \cap U_1 \cap U_2 \neq \emptyset$, the Čech complex extends to degree 2 and the Jacobiator can be nonzero. The correction F_3 then measures the *descent obstruction*: the chiral bracket holds strictly on each open, but gluing these local brackets across a triple overlap requires a coherent homotopy.

For $\widehat{\mathfrak{sl}}_2$ at level k on $\mathbb{P}^1$, the two-element cover gives a strict HCA (Example 8.10.13); but refining to a three-element cover (e.g., the standard affine cover of a projective curve of genus $g \geq 1$) produces a nonzero Jacobiator from the non-abelian OPE $[e, f] = h$ (Example 8.10.14). This is the prototypical example: the Jacobiator is a descent obstruction, not a local one.

16.9.2 THE JACOBIATOR AS THE DEGREE-3 MASTER EQUATION

The Jacobiator homotopy is the degree-3 component of the MC equation $D \cdot \Phi + \frac{1}{2}[\Phi, \Phi] = 0$ governing the HCA structure map $\Phi = \sum_{n \geq 2} F_n$. The degree- n component reads:

$$d_M \circ F_n + F_n \circ d_M^{\otimes n} + \sum_{\substack{p+q=n+1 \\ p, q \geq 2}} F_p \circ_{(i)} F_q = 0,$$

where $\circ_{(i)}$ denotes operadic composition at the i -th slot, summed over all i and all (p, q) -shuffles. At degree 3, the quadratic term reduces to $F_2 \circ F_2$ (iterated binary bracket), recovering:

PROPOSITION 16.9.4 (*Jacobiator is nullhomotopic*;). (Malikov–Schechtman [309], §4.1.) There exists a trilinear operation $J': (M\check{C})^{\otimes 3} \rightarrow M\check{C}[-1]$ such that

$$d_M \circ J' + J' \circ d_M^{\otimes 3} = \text{Jac}, \quad (16.7)$$

where $d_M^{\otimes 3}$ is the Leibniz extension of d_M to the triple tensor product. More precisely, J' is the ternary component F_3 of the HCA structure (Theorem 8.10.5), and equation (16.7) is the L_∞ relation at degree 3: the degree-3 projection of the master equation $D \cdot \Phi + \frac{1}{2}[\Phi, \Phi] = 0$.

16.9.3 TRANSLATION TO BAR-SIDE A_∞ OPERATIONS

The bar-side operation m_3 and the Čech-side homotopy F_3 encode the same degree-3 correction, but through different geometric mechanisms. On the bar side, m_3 arises from integration over the Fulton–MacPherson compactification $\overline{\text{FM}}_3(\mathbb{C})$: it is the homotopy-transfer datum obtained by composing binary interactions through the propagator on the configuration space of three points. On the Čech side, F_3 arises from triple intersections of the cover: it measures how local Jacobi identities fail to descend.

The Čech–bar comparison $\Phi: (M\check{C}, \{F_n\}) \xrightarrow{\sim} (\bar{\mathbf{B}}(\mathcal{A}), \{m_n\})$ (Conjecture 8.10.8) translates between these two pictures. Under Φ :

- Φ intertwines F_3 with m_3 : integration over $\overline{\text{FM}}_3(\mathbb{C})$ on the bar side corresponds to the triple-intersection descent correction on the Čech side.
- The A_∞ relation at degree 3,

$$m_1 \circ m_3 + m_3 \circ (m_1 \otimes 1 \otimes 1 + 1 \otimes m_1 \otimes 1 + 1 \otimes 1 \otimes m_1) + m_2 \circ (m_2 \otimes 1 + 1 \otimes m_2) = 0,$$

is the bar-side avatar of (16.7): the first two terms correspond to $d_M \circ F_3 + F_3 \circ d_M$, while $m_2(m_2 \otimes 1 + 1 \otimes m_2)$ is the Jacobiator Jac expressed through iterated binary products.

- More generally, Φ intertwines the full MC equations on both sides: the Čech master equation $D \cdot \Phi_{\check{C}} + \frac{1}{2}[\Phi_{\check{C}}, \Phi_{\check{C}}] = 0$ maps to the bar master equation encoded by $\{m_n\}$.

16.9.4 THE EILENBERG–ZILBER OPERAD AS GENUS-0 SHADOW OF FCom

Remark 16.9.5 (Operadic control at genus 0 and beyond). The Eilenberg–Zilber operad $\mathcal{Y}(n) = \mathcal{Z}(n) \otimes_k \text{Lie}(n)$ of Malikov–Schechtman [309] and the Feynman transform FCom of the commutative modular operad (Theorem 8.2.12) control homotopies at different levels:

	Čech side	Bar side
Genus 0	Eilenberg–Zilber $\mathcal{Y}(n)$	Associahedra $K_n \subset \overline{\text{FM}}_n(\mathbb{C})$
Genus $g \geq 1$	Cosimplicial modular operad	FCom, stable graphs on $\overline{\mathcal{M}}_{g,n}$

At genus 0, the chain complex $\mathcal{Z}(n) = \text{Tot Hom}_\Delta(Z, Z^{\otimes n})$ encodes the combinatorics of the simplicial structure (how sections on intersections compose), while $\text{Lie}(n)$ encodes the chiral bracket. Their tensor product $\mathcal{Y}(n)$ maps quasi-isomorphically to $\text{Lie}(n)$ via the augmentation $\varepsilon: \mathcal{Z}(n) \rightarrow k$, so the HCA is a resolution of a strict chiral algebra.

At genus $g \geq 1$, the Čech homotopies no longer suffice: the bar complex sees the full modular operad, and the homotopies are controlled by the cellular chains on $\overline{\mathcal{M}}_{g,n}$, i.e., by stable-graph compositions in FCom. The Eilenberg–Zilber operad $\mathcal{Y}(n)$ is precisely the genus-0 truncation of FCom: it sees trees (simplicial decompositions of the nerve) where FCom sees stable graphs (including loops). The passage from $\mathcal{Y}(n)$ to FCom is the passage from tree-level (Čech) homotopies to all-genus (bar) homotopies, paralleling the genus expansion $\Theta_{\mathcal{A}} = \Theta_{\mathcal{A}}|_{h=0} + \sum_{g \geq 1} \hbar^g \Theta_{\mathcal{A},g}$ of the master MC element.

Remark 16.9.6 (Precise truncation: EZ chain complex, associahedra, and genus-0 FCom). We make the comparison between $\mathcal{Y}(n)$ and FCom precise at the chain level.

(i) *Genus-0 component of FCom.* The moduli space $\overline{\mathcal{M}}_{0,n+1}$ is the real orientable compactification of $C_n(\mathbb{C})/\text{Aff}$, where $\text{Aff} = \mathbb{C} \rtimes \mathbb{C}^\times$ acts by affine transformations. Its cellular chains $C_*(\overline{\mathcal{M}}_{0,n+1}; k)$ form the genus-0 component of the Feynman transform:

$$\text{FCom}(0, n+1) = C_*(\overline{\mathcal{M}}_{0,n+1}; k),$$

with operadic composition induced by the clutching maps $\overline{\mathcal{M}}_{0,n_1+1} \times \overline{\mathcal{M}}_{0,n_2+1} \rightarrow \overline{\mathcal{M}}_{0,n_1+n_2}$ along boundary divisors.

(ii) *EZ chain complex and the associahedron.* The Eilenberg–Zilber chain complex $\mathcal{Z}(n) = \text{Tot Hom}_\Delta(Z, Z^{\otimes n})$ carries a natural filtration by simplicial degree. The Stasheff associahedron K_n (the convex polytope whose face poset encodes all ways of parenthesizing n letters) provides a geometric

model: its cellular chains $C_*(K_n; k)$ compute the same A_∞ homotopies. The comparison is the classical quasi-isomorphism of Eilenberg–Zilber–Loday type:

$$\alpha_n: \mathcal{Z}(n) \xrightarrow{\sim} C_*(K_n; k),$$

which sends the total complex of cosimplicial Hom to the cellular chains on the associahedron by taking the acyclic-models comparison between the bar construction of the simplicial structure and the CW decomposition of K_n .

(iii) *Associahedra inside $\overline{\mathcal{M}}_{0,n+1}$.* The Stasheff associahedron K_n embeds into $\overline{\mathcal{M}}_{0,n+1}$ as a fundamental domain for the real locus: the real points $\overline{\mathcal{M}}_{0,n+1}(\mathbb{R})$ decompose into $(n-1)!/2$ copies of K_n (one for each dihedral ordering of the marked points), and the inclusion of any single copy induces a chain map

$$\beta_n: C_*(K_n; k) \longrightarrow C_*(\overline{\mathcal{M}}_{0,n+1}; k) = \text{FCom}(0, n+1).$$

This map is a quasi-isomorphism: both sides have homology concentrated in degree $n-2$ (the top cell of K_n and the fundamental class of $\overline{\mathcal{M}}_{0,n+1} \cong \mathbb{CP}^{n-2}$ -bundle quotient), and β_n induces an isomorphism on this class.

(iv) *The truncation chain.* Composing the three maps gives the truncation:

$$\mathcal{Z}(n) \xrightarrow[\text{EZ-Loday}]{\alpha_n} C_*(K_n; k) \xrightarrow[\text{real locus}]{\beta_n} \text{FCom}(0, n+1) \hookrightarrow \text{FCom}(\bullet, n+1).$$

The first two arrows are quasi-isomorphisms; the last is the inclusion of the genus-0 summand into the full modular operad. Tensoring with the Lie operad recovers the Eilenberg–Zilber operad:

$$\mathcal{Y}(n) = \mathcal{Z}(n) \otimes_k \text{Lie}(n) \xrightarrow[\sim]{\alpha_n \otimes \text{id}} C_*(K_n; k) \otimes_k \text{Lie}(n) \xrightarrow[\sim]{\beta_n \otimes \text{id}} \text{FCom}(0, n+1) \otimes_k \text{Lie}(n).$$

Thus $\mathcal{Y}(n)$ sees *exactly* the genus-0 component of FCom, tensored with the bracket symmetry. At genus $g \geq 1$, the summands $\text{FCom}(g, n+1)$ involve stable graphs with loops (corresponding to $\overline{\mathcal{M}}_{g,n+1}$), which have no counterpart in the tree-level simplicial structure underlying $\mathcal{Z}(n)$. This is the precise sense in which the EZ operad is the genus-0 shadow of FCom.

16.9.5 SECONDARY BORCHERDS OPERATIONS

The HCA structure of Theorem 8.10.5 produces not only the Jacobiator homotopy $J' = F_3$ but an entire tower of *secondary Borchers operations* (Malikov–Schechtman [309], §4.5):

Definition 16.9.7 (Secondary Borchers operations). For a cosimplicial translationally invariant chiral algebra $\mathcal{V}^\bullet$ on $C = \text{Spec } k[t]$, the homotopy chiral algebra structure produces ternary operations of degree -1 :

$$j'_{(p,q,r)}: (MV^\bullet)^{\otimes 3} \longrightarrow MV^\bullet[-1], \quad p, q, r \in \mathbb{Z},$$

satisfying the *secondary Borchers identities* ([309], equation (4.5.1)):

$$\begin{aligned} (d \circ_{(p,q,r)} + {}_{(p,q,r)} \circ d)(a \otimes b \otimes c) = \\ \sum_{j \geq 0} \binom{p}{j} ((-1)^j a_{(p+q-j)} b_{(r+j)} c - (-1)^{j+p+|a||b|} b_{(r+p-j)} a_{(q+j)} c) \\ - \sum_{j \geq 0} \binom{q}{j} (a_{(p+q-j)} b)_{(r+j)} c, \quad (16.8) \end{aligned}$$

where $a_{(n)}b = \phi_{[,]}((a \otimes b)(t_1 - t_2)^n)$ denotes the n -th mode product.

Remark 16.9.8 (The n -th product relations as descent data). For translationally invariant chiral algebras on $X = \operatorname{Spec} k[t]$, the n -th products $a_{(n)}b$ satisfy the Jacobi identity family [309]:

$$[a_{(m)}, b_{(n)}]c = \sum_{j \geq 0} \binom{m}{j} (a_{(j)}b)_{(m+n-j)}c \quad (16.9)$$

and the skew-symmetry relation

$$a_{(n)}b = (-1)^{n+1} \sum_{j \geq 0} \frac{(-1)^j}{j!} \partial^j (b_{(n+j)}a).$$

These formulas *are* the n -th product relations of Beilinson–Drinfeld [40]; they hold strictly on each open of the cover. On the Čech complex, however, gluing local brackets across multiple opens introduces a descent obstruction, and the correction terms are precisely the operations F_n for $n \geq 3$. The secondary Borchers identity (16.8) is the explicit formula for this descent correction at degree 3: the right-hand side is the local n -th product relation (which holds on each open), and the left-hand side is the boundary of F_3 , which records how that relation fails to descend.

For two-element covers the descent obstruction vanishes (Proposition 16.9.2); the correction F_n is nonzero precisely when the cover has $(n-1)$ -fold or higher overlaps.

Remark 16.9.9 (Derivation of the vertex Lie Jacobi family from the Borchers identity). We sketch how the Jacobi identity family (16.9) follows from the Borchers identity for the chiral product, applied to three sections on pairwise intersections of a Čech cover. This makes precise the passage from OPE associativity on a single open to the n -th product relations on the Čech complex.

Setup. Let $\mathfrak{U} = \{U_0, U_1, U_2\}$ be a cover of $X = \operatorname{Spec} k[t]$ with pairwise intersections $U_{ij} = U_i \cap U_j$ and triple intersection $U_{012} = U_0 \cap U_1 \cap U_2$. Let a, b, c be sections of a translationally invariant chiral algebra $\mathcal{A}$ on X . On each U_{ij} , the chiral product $\mu: j_*j^*(\mathcal{A} \boxtimes \mathcal{A}) \rightarrow \Delta_*\mathcal{A}$ (where $j: X^2 \setminus \Delta \hookrightarrow X^2$) determines the n -th mode products $a_{(n)}b$ via residues:

$$a_{(n)}b = \operatorname{Res}_{z_1=z_2} \mu(a(z_1) \otimes b(z_2))(z_1 - z_2)^n.$$

Step 1: the Borchers identity on a single open. On U_{012} , OPE associativity for the chiral product gives the *Borchers identity*: for all $m, n \in \mathbb{Z}$,

$$\begin{aligned} \sum_{j \geq 0} \binom{m}{j} (a_{(m+n-j)}b_{(r+j)} - (-1)^{m+|a||b|} b_{(m+r-j)}a_{(n+j)})c \\ = \sum_{j \geq 0} \binom{n}{j} (-1)^j (a_{(n-j)}b)_{(m+r+j)}c. \end{aligned} \quad (16.10)$$

This is the triple-point constraint: it encodes that the two ways of composing three OPEs $((a \cdot b) \cdot c$ versus $a \cdot (b \cdot c)$ minus the transposition) agree as operations on U_{012} . The identity holds on every open of the cover where all three sections are defined.

Step 2: specialization to the commutator. Setting $r = n$ in (16.10) and extracting the $j = 0$ term on the left-hand side (all other terms with $j \geq 1$ contribute higher-order corrections controlled by the binomial coefficients), one obtains the commutator formula:

$$[a_{(m)}, b_{(n)}]c = \sum_{j \geq 0} \binom{m}{j} (a_{(j)}b)_{(m+n-j)}c, \quad (16.11)$$

which is precisely (16.9). The key step: on the left-hand side, the commutator $[a_{(m)}, b_{(n)}] = a_{(m)}b_{(n)} - (-1)^{|a||b|}b_{(n)}a_{(m)}$ arises from the two orderings of evaluation at the pairwise intersections $U_{01} \cap U_{02}$ versus $U_{02} \cap U_{01}$; on the right-hand side, the iterated product $(a_{(j)}b)_{(m+n-j)}c$ arises from first composing on U_{01} and then applying the result on $U_{(01)2}$.

Step 3: the Eilenberg–Zilber correction. The identity (16.11) holds *strictly* on the triple intersection U_{012} , because the Borchers identity (16.10) is a local statement. On the Čech complex, however, passing from the triple intersection to the global Moore complex requires choosing an ordering of the opens and applying the Eilenberg–Zilber shuffle map $\nabla: C_*(\mathfrak{U}) \otimes C_*(\mathfrak{U}) \rightarrow C_*(\mathfrak{U} \times \mathfrak{U})$. The shuffle introduces correction terms of the form $\nabla - \nabla_0$ (where ∇_0 is the Alexander–Whitney map), and these correction terms are precisely the secondary Borchers operations $j'_{(p,q,r)}$ of Definition 16.9.7. Explicitly: the boundary of $j'_{(p,q,r)}$ equals the difference between the local Borchers identity (which holds on each open) and the global identity (which holds only up to homotopy on the Moore complex), giving (16.8).

Remark 16.9.10 (Secondary Borchers and $d_{\text{bracket}}^2 \neq 0$). The proved result that $d_{\text{bracket}}^2 \neq 0$ (all 2048 signs verified; Remark 2.16.1) while the full Borchers differential gives $d^2 = 0$ is *precisely* the Ch_∞ phenomenon: the bracket-level failure is the obstruction to strict chirality, and the secondary Borchers operations $j'_{(p,q,r)}$ are the coherent homotopies that restore $d^2 = 0$ at the full level. In the bar-side language (§16.9.3), the secondary Borchers identities (16.8) are the vertex-algebra avatar of the A_∞ associativity relations for m_3 .

The vanishing pattern of secondary Borchers operations classifies our archetype families:

Family	Vanishing pattern	Archetype
Heisenberg	$j'_{(p,q,r)} = 0$ for all p, q, r	Gaussian (strict)
Affine $\widehat{\mathfrak{sl}}_2$	$j' \neq 0$ at degree 3	Lie/tree
$\beta\gamma$	$j' \neq 0$ at degree 3; $j'_4 = 0$	Contact/quartic
Virasoro/ W_N	$j' \neq 0$ at all degrees	Mixed (infinite tower)

This classification coincides with the shadow-tower termination pattern: the degree at which secondary Borchers operations first vanish equals the degree at which the shadow obstruction tower terminates (Heisenberg at 2, affine at 3, $\beta\gamma$ at 4, Virasoro never).

PROPOSITION 16.9.11 (*Secondary Borchers operations as shadow obstruction tower obstructions;*). Under the genus-0 operadic equivalence between the Malikov–Schechtman HCA operations and the transferred L_∞ brackets on the bar-side minimal model, the HCA operations F_n of [309] at degree $n \geq 3$ are identified with the shadow obstruction tower obstruction classes $o_n(\mathcal{A})$ (Definition 13.22.46) at genus 0. The explicit formula for the secondary Borchers operations [309, formula (4.5.1)] is:

$$\begin{aligned}
 (d \circ_{(p,q,r)} + {}_{(p,q,r)} \circ d)(a, b, c) \\
 = \sum_{j \geq 0} \binom{p}{j} ((-1)^j a_{(p+q-j)} b_{(r+j)} c - (-1)^{j+p+|a||b|} b_{(r+p-j)} a_{(q+j)} c) \\
 - \sum_{j \geq 0} \binom{q}{j} (a_{(p+q-j)} b)_{(r+j)} c,
 \end{aligned}$$

where ${}_{(p,q,r)}$ is the secondary Borchers operation at multi-index (p, q, r) . This is the three-variable refinement of the L_∞ relation at degree 4: the left-hand side is the homotopy boundary of F_4 , and the right-hand side is the secondary Jacobi identity expressed through iterated Borchers products.

The identification is:

- (i) $F_3 = J'$ (Jacobiator homotopy) corresponds to $o_3(\mathcal{A})$ (cubic shadow obstruction).
- (ii) F_4 (secondary Jacobi homotopy) corresponds to $o_4(\mathcal{A})$ (quartic resonance obstruction). The quartic contact invariant $\mathfrak{Q}_{\text{Vir}}^{\text{contact}} = 10/[c(5c + 22)]$ is the normalised coefficient of the secondary Borchers operation $_{(1,0,0)}$ evaluated on the Moore complex of Vir_c .
- (iii) At degree $n \geq 5$, the higher operations F_n encode the higher obstruction classes $o_n(\mathcal{A}) \in H^2(\mathcal{A}_n^{\text{sh}})$ of the shadow obstruction tower.

The identification is structural at genus 0; at genus $g \geq 1$, the bar side includes modular corrections (stable graph sums with loops) that have no Čech counterpart in [309].

Proof. The proof uses only the genus-0 operadic equivalence, not any full Čech–bar L_∞ intertwining statement.

Over a field of characteristic 0, the category of $\tau_{\leq 0}\mathcal{Y}$ -algebras (Malikov–Schechtman’s homotopy Lie operadic model, [309, §2.6]) and the category of L_∞ -algebras (the coalgebraic model, [299, §10.3]) are equivalent: a $\tau_{\leq 0}\mathcal{Y}$ -algebra structure on a complex V is the same as an L_∞ -algebra structure on V with the same MC moduli (Remark 3.1.15(iii)). Under this equivalence, the n -th HCA operation F_n corresponds to the n -th L_∞ bracket ℓ_n on the Moore complex.

At genus 0, the L_∞ brackets on the bar complex are exactly the transferred operations from the minimal model of $C_*(\overline{\mathcal{M}}_{0,n+1})$ (Construction 13.22.7), and the obstruction class $o_n(\mathcal{A})$ is the cohomology class $[\ell_n] \in H^2(\mathcal{A}_n^{\text{sh}})$. The identification $F_n = \ell_n = o_n$ at the cohomological level follows.

Part (i): $F_3 = J'$ is the Jacobiator homotopy (Proposition 16.9.4); $\ell_3 = o_3$ is the cubic shadow (Definition 13.22.46). Part (ii): F_4 is the secondary Borchers homotopy; $\ell_4 = o_4$ is the quartic resonance obstruction. $\square$

Remark 16.9.12 (One-slot functoriality obstruction and MC₃). The Robert–Nicoud–Wierstra theorem (Theorem 3.1.24(iii)) states that the convolution construction hom^α extends to ∞ -morphisms in either slot separately but *not both simultaneously* (it is *not* a bifunctor in ∞ -morphisms). An explicit counterexample is given in [367, §6].

This constrains the MC₃ categorical lift: extending the prefundamental Clebsch–Gordan closure (Proposition O.9.59) from the character level (K_0 , one slot) to the categorical level (both slots) cannot be achieved by a single bifunctorial extension. The categorical lift (Theorem O.9.71) must therefore proceed *one slot at a time*: first extend in the coalgebra slot (via $\text{hom}_\ell^\alpha(\Phi, 1)$), then in the algebra slot (via $\text{hom}_r^\alpha(1, \Psi)$), accepting that the two extensions are compatible only up to higher homotopy.

16.9.6 WHEN DOES FILTERING DEGENERATE TO CURVED?

A chiral algebra with an exhaustive filtration falls into one of three regimes: quadratic (Heisenberg, no completion needed), curved (Virasoro, with curvature scalar $m_0 = \kappa(\text{Vir}_c) \cdot \mathbf{1} = (c/2) \cdot \mathbf{1}$), or genuinely filtered ($\mathcal{W}_3, \mathcal{W}_N$, where composites such as $:LL:$ appear at arbitrarily high weight). The regime determines the convergence criterion (Theorem 8.4.1) and the shadow archetype (Gaussian, Lie, contact, mixed) in Part II.

PROPOSITION 16.9.13 (*Filtered $\Rightarrow$ curved;*). Let $\mathcal{A}$ be a filtered chiral algebra with an *exhaustive, separated, complete* filtration $\{F_k \mathcal{A}\}_{k \geq 0}$. Here: *exhaustive* means $\mathcal{A} = \bigcup_k F_k \mathcal{A}$; *separated* means $\bigcap_k F_k \mathcal{A} = 0$; *complete* means the natural map to the inverse limit $\mathcal{A} \xrightarrow{\sim} \varprojlim_k \mathcal{A}/F_k \mathcal{A}$ is an isomorphism (equivalently, every Cauchy sequence in the filtration topology converges). Assume:

1. each filtration quotient is finite-dimensional:

$$\dim(F_k \mathcal{A}/F_{k-1} \mathcal{A}) < \infty \quad \text{for all } k;$$

2. the associated graded algebra $\text{gr}(\mathcal{A})$ is generated by $\text{gr}^1(\mathcal{A})$ with quadratic defining ideal;
3. every higher relation in $\mathcal{A}$ differs from a quadratic consequence by a central filtration- ≥ 2 correction.

Then there exists a curved presentation of $\mathcal{A}$ with curvature element

$$\mu_0 \in F_2 \mathcal{A}$$

such that $\mathcal{A}$ and this curved model are filtered quasi-isomorphic.

Proof. Write $V := \text{gr}^1(\mathcal{A})$ and choose splittings $s_k: \text{gr}^k(\mathcal{A}) \rightarrow F_k \mathcal{A}$. The *completed free chiral algebra* $\widehat{T}_{\text{ch}}(V) := \varprojlim_N T_{\text{ch}}(V)/F_N$ is the inverse limit of the free chiral algebra $T_{\text{ch}}(V) = \bigoplus_{n \geq 0} V^{\otimes n}$ along its natural filtration by tensor degree; it exists as a complete filtered algebra and satisfies the universal property that any filtered algebra map $V \rightarrow \mathcal{A}$ with $\mathcal{A}$ complete extends uniquely. Completeness and separatedness of $\mathcal{A}$ then produce a filtered surjection

$$\pi: \widehat{T}_{\text{ch}}(V) \rightarrow \mathcal{A}.$$

Let $I = \ker(\pi)$. Its quadratic part is determined by the defining ideal of $\text{gr}(\mathcal{A})$; denote it by I_2 .

Assumption (3) says that every higher relation class in I is a quadratic consequence modulo a central correction of filtration at least 2. Collect these correction terms by filtration degree:

$$\mu_0 = \sum_{k \geq 2} \mu_0^{(k)}, \quad \mu_0^{(k)} \in F_k \mathcal{A}/F_{k-1} \mathcal{A}.$$

The sum converges in $\mathcal{A}$ because $\mathcal{A}$ is complete: each partial sum $\sum_{k=2}^N \mu_0^{(k)}$ lies in $F_2 \mathcal{A}$, and the sequence is Cauchy in the filtration topology (the k -th term has filtration $\geq k$), so the limit exists in $F_2 \mathcal{A}$ by completeness. Thus $\mu_0 \in F_2 \mathcal{A}$ is well-defined.

Equip the quotient $\widehat{T}_{\text{ch}}(V)/I_2$ with a curved A_∞ structure as follows. Define $\mu_1 := d$ (the differential of the quadratic model), with μ_0 the curvature element constructed above. Then the curved A_∞ relation at degree 1 (Definition 8.1.1, Theorem 8.1.5) gives

$$\mu_1^2(a) = \mu_2(\mu_0, a) - \mu_2(a, \mu_0) = [\mu_0, a]_{\mu_2},$$

where $[\mu_0, a]_{\mu_2}$ denotes the commutator with respect to the binary product μ_2 . Assumption (3) ensures that μ_0 is central in the associated graded: $[\mu_0, a]_{\mu_2} \in F_{|a|+2}\mathcal{A}$ for all a . The degree-0 relation $\mu_1(\mu_0) = 0$ holds because the correction terms are cocycles by construction.

For chiral algebras, which are graded-commutative with respect to μ_2 , the commutator $[\mu_0, -]_{\mu_2}$ vanishes identically, so μ_1 is a differential. The curvature enters not through $\mu_1^2 \neq 0$ but through the completed tensor product: the element $\mu_0 \in F_2\mathcal{A}$ is a nontrivial Maurer–Cartan datum that twists the bar complex (Theorem 8.1.5(ii) and the discussion following it).

Quotienting $\widehat{T}_{\text{ch}}(V)$ by the closed ideal generated by I_2 yields a curved model $\mathcal{A}_{\text{curv}}$ together with a filtered morphism

$$\mathcal{A}_{\text{curv}} \rightarrow \mathcal{A}$$

that is an isomorphism on associated graded pieces (the quotient map is filtered and induces the identity on each gr^k by construction). Hence it is a filtered quasi-isomorphism. $\square$

Remark 16.9.14 (Dependencies). Proposition 16.9.13 is the algebra-side input for Theorem 8.1.15. Convergence control: Theorems 8.4.1 and 8.1.18. Completion technology: Appendix K.7.1.

Example 16.9.15 (Virasoro: filtering is auxiliary). For the Virasoro algebra, the conformal-weight filtration records descendants of a single field T . The weight-4 quasi-primary

$$\Lambda = :TT: - \frac{3}{10}\partial^2 T$$

is not a new generator on the same footing as T ; it is the first place where the central term forces a curved correction. Proposition 16.9.13 therefore identifies the filtered presentation with a curved model whose essential datum is the curvature element $m_0 = \kappa(\text{Vir}_c) \cdot \mathbf{1} = (c/2) \cdot \mathbf{1}$.

In particular, Virasoro belongs to the curved regime rather than the genuinely filtered one: completion is needed because one has infinitely many descendants, not because new independent generators appear at each weight.

Example 16.9.16 (W_3 : filtering is intrinsic). The W_3 algebra sits on the other side of the boundary. Besides the fields L and W , the OPE of W with itself produces composite operators such as $:LL:$ that are not descendants of a single generator. The filtration by conformal weight therefore detects genuinely new pieces rather than bookkeeping for one curved field.

Thus W_3 does not collapse to a finite-generator curved model; it requires the completed filtered framework of Section 8.4.

Example 16.9.17 (Calibration by the Heisenberg frame). The Heisenberg algebra from Chapter 2 supplies the quadratic endpoint of the hierarchy: genus-0 bar terms are already finite in each weight, no completion is needed, and higher-genus corrections enter only through the modular curvature package. Together with Examples 16.9.15 and 16.9.16, this gives the three regimes used repeatedly later: quadratic, curved, and genuinely filtered.

THEOREM 16.9.18 (Convergence criterion in the filtered/curved regimes;). Within the hierarchy

$$\text{quadratic} \subset \text{curved} \subset \text{filtered},$$

no new convergence theorem is needed beyond Theorem 8.4.1. More precisely:

1. quadratic finite-type examples such as Heisenberg converge without completion;

2. filtered presentations that collapse to a curved model, such as Virasoro, are governed by the completed curved bar construction;
3. genuinely filtered examples such as W_3 require completion because infinitely many filtration pieces contribute non-descendant composites.

Proof. Part (1) is the quadratic finite-type clause of Theorem 8.4.1. Part (2) combines Proposition 16.9.13 with the same theorem: once the filtered presentation has collapsed to a curved model, convergence is governed by the completed curved bar complex. For Part (3), let $\mathcal{A}$ be genuinely filtered in the sense that non-descendant composites appear in arbitrarily high weights. Then Proposition 16.9.13 does not apply (Assumption (3) fails), and the bar complex has nonzero contributions from arbitrarily high filtration pieces. Convergence therefore requires the completed filtered bar construction of Section 8.4, as W_3 illustrates (Example 16.9.16). $\square$

Remark 16.9.19 (Decision rule). For higher-genus corrections of a non-quadratic algebra, four questions determine the regime.

1. Are all higher-weight terms descendants of finitely many generators? If yes, the filtration is auxiliary.
2. Does the correction lie in the center? If yes, the curved model carries the modular data.
3. Do genuinely new composites appear in arbitrarily high weights? If yes, completion is intrinsic.
4. Does the generating space itself become infinite? If yes, the finite-type theory of this volume does not apply; the completed infinite-generator package (Chapter K.7.1) is required.

Chapter 17

Chiral Hochschild cohomology and deformation theory

The chiral Hochschild cohomology $CH^*(\mathcal{A})$ is the tangent complex to the MC moduli at $\Theta_{\mathcal{A}}$: the cohomology of the convolution L_{∞} -algebra controlling deformations, obstructions, and bulk-field couplings.

The chiral Hochschild complex carries a degree -1 Lie bracket (the chiral Gerstenhaber bracket, Theorem 14.8.10), computed by OPE residues on FM configuration spaces. In the classical limit (fiber at a point), it recovers Gerstenhaber's bracket [197] on associative Hochschild cochains. The chiral bracket is the strict shadow of a full L_{∞} bracket on the chiral Hochschild complex. In the strict model, HH^2 classifies first-order deformations and HH^3 contains obstructions; the L_{∞} extension records coherent homotopies governing convergence of formal deformations and transfer of Koszul properties across quasi-isomorphisms. The cyclic structure (Connes' operator B , the mixed complex, the SBI sequence) is the algebraic shadow of the modular operad's gluing maps. The shadow obstruction tower of Chapter 13.21 projects onto the cyclic deformation complex $\text{Def}_{\text{cyc}}^{\text{mod}}(\mathcal{A})$ defined here.

For all chirally Koszul algebras, $CH^n(\mathcal{A}) = 0$ for $n > 2$ (Theorem H): the Heisenberg has $P(t) = 1 + t + t^2$; the Virasoro and principal W-algebras have $P(t) = 1 + t^2$ at generic level (Theorems 17.2.1 and 17.2.5).

The fiberwise curvature $d_{\text{fib}}^2 = \kappa(\mathcal{A}) \cdot \omega_1$ at genus 1 (Chapter 2) shows that deformations of the bar complex are controlled by a cohomological invariant. Chiral Hochschild cohomology organizes these deformations and obstructions into a single graded object equipped with a Gerstenhaber bracket; the chiral enhancement incorporates OPE data, the geometry of the curve, and the A_{∞} structure of the bar complex.

Remark 17.0.1 (Conventions for HH/HC/HP). The definitions and sign conventions for classical Hochschild cohomology HH^* , classical Hochschild homology HH_* , cyclic homology HC_* , negative cyclic homology HC_*^{neg} , and periodic cyclic homology HP_* are as follows. In particular:

- the chiral Hochschild complex (Definition 17.6.5),
- the cyclic operator and Connes' operator B (Definitions 17.6.8 and 17.6.10),
- the mixed complex (d_{HH}, B) and the SBI exact sequence (Theorem 17.6.11, Corollary 17.6.13),

are all defined here and should be cited from here throughout the text. Other chapters that use chiral Hochschild, topological Hochschild, or cyclic invariants (the deformation theory and Poincaré duality chapters) reference these definitions rather than re-establishing them.

17.1 CLASSICAL TO CHIRAL

17.1.1 REVIEW OF CLASSICAL HOCHSCHILD

For an associative algebra A over $\mathbb{C}$ and an A -bimodule M , the Hochschild cohomology $HH^*(A, M) = \text{Ext}_{A^e}^*(A, M)$ classifies the deformation theory of A : HH^0 is the center, HH^1 classifies outer derivations, HH^2 classifies first-order deformations, and HH^3 contains the obstructions to extending them. The full structure is computed by the bar resolution $\cdots \rightarrow A^{\otimes(n+2)} \xrightarrow{b} A^{\otimes(n+1)} \rightarrow \cdots$ with differential $b(a_0 \otimes \cdots \otimes a_{n+1}) = \sum_{i=0}^n (-1)^i a_0 \otimes \cdots \otimes a_i a_{i+1} \otimes \cdots \otimes a_{n+1}$, and the resulting cohomology carries a Gerstenhaber bracket governing the Maurer–Cartan equation for formal deformations (Gerstenhaber [197]).

17.1.2 CHIRAL ENHANCEMENT

What replaces the bimodule $A \otimes A^{\text{op}}$ when the algebra lives on a curve rather than a point? For chiral algebras, each ingredient of the classical theory acquires a geometric upgrade: the bimodule structure is replaced by the factorization structure on $\text{Ran}(X)$, the bar resolution becomes the geometric bar complex on Fulton–MacPherson configuration spaces, and the Gerstenhaber bracket lifts to a chiral bracket governed by the OPE. The result is a chiral Hochschild complex whose cohomology computes chiral deformations, obstructions, and the center of the chiral algebra simultaneously.

Definition 17.1.1 (Chiral Hochschild complex, derived-functor form). For a chiral algebra $\mathcal{A}$ on X , the chiral Hochschild cohomology with coefficients in a chiral $\mathcal{A}$ -module $\mathcal{M}$ is

$$CH^*(\mathcal{A}, \mathcal{M}) = \text{RHom}_{\mathcal{D}_X}(\bar{\mathbf{B}}(\mathcal{A}), \mathcal{M}).$$

The chain-level model is Definition 17.6.5.

THEOREM 17.1.2 (*Comparison with classical theory [40];*). There is a spectral sequence:

$$E_2^{p,q} = HH^p(\mathcal{A}_0, H^q(\Omega_X^*)) \Rightarrow CH^{p+q}(\mathcal{A})$$

where $\mathcal{A}_0$ is the fiber at a point.

17.2 PERIODICITY PHENOMENA

17.2.1 VIRASORO CHIRAL HOCHSCHILD COHOMOLOGY

THEOREM 17.2.1 (*Virasoro chiral Hochschild cohomology;*). For the Virasoro algebra at generic central charge c (avoiding $c_{p,q} = 1 - 6(p - q)^2/(pq)$ and $c = 1$):

$$CH^n(\text{Vir}_c) = \begin{cases} \mathbb{C} & n = 0 \text{ (center: scalars),} \\ 0 & n = 1 \text{ (no outer derivations at generic } c), \\ \mathbb{C} & n = 2 \text{ (central charge deformation),} \\ 0 & n \geq 3. \end{cases}$$

The Hilbert series is $P(t) = 1 + t^2$.

Proof. The Virasoro algebra is chirally Koszul (Corollary 11.1.33: freely strongly generated implies bar concentration). Theorem H (Theorem 14.4.12) gives concentration: $CH^n(\text{Vir}_c) = 0$ for $n \notin \{0, 1, 2\}$, since the de Rham functor on a curve has cohomological amplitude $[0, 2]$.

For the individual degrees: $CH^0(\text{Vir}_c) = Z(\text{Vir}_c) = \mathbb{C}$ (the center at generic c is one-dimensional: only scalars commute with all modes). $CH^1(\text{Vir}_c) = 0$: at generic c , every Verma module $V(c, h)$ is irreducible (Kac determinant nonvanishing), so all derivations of Vir_c are inner. $CH^2(\text{Vir}_c) = \mathbb{C}$: by the Koszul duality exchange (Theorem 14.4.10), $\dim CH^2(\text{Vir}_c) = \dim Z(\text{Vir}_{26-c}) = 1$. The generator is the central charge deformation $c \mapsto c + \epsilon$. $\square$

Remark 17.2.2 (Relation to Gel'fand–Fuchs cohomology). The continuous Lie algebra cohomology $H_{\text{cont}}^*(L_1; \mathbb{C}) = \mathbb{C}[\Theta]$ is a polynomial ring on a degree-2 generator (Gel'fand–Fuchs [162]). This is *not* the chiral chiral Hochschild cohomology $CH^*(\text{Vir}_c)$: the former is the cohomology of a topological Lie algebra (no curve geometry), while the latter is an Ext-group on the curve X that inherits the de Rham amplitude bound $[0, 2 \dim X] = [0, 2]$ from the $\mathcal{D}_X$ -module structure. The two are related by a spectral sequence (Theorem 17.1.2), but the Gel'fand–Fuchs polynomial ring in all even degrees truncates to the $\{0, 1, 2\}$ range when passing to the chiral Hochschild cohomology on a curve.

17.2.2 AFFINE KAC–MOODY PERIODICITY

THEOREM 17.2.3 (*Critical level Lie algebra cohomology*;). The continuous Lie algebra cohomology of $\widehat{\mathfrak{g}}$ at critical level $k = -h^\vee$ is the exterior-polynomial algebra

$$H_{\text{cont}}^*(\widehat{\mathfrak{g}}_{-h^\vee}, \widehat{\mathfrak{g}}_{-h^\vee, 0}; \mathbb{C}) \cong \Lambda^*(P_1, \dots, P_r) \otimes \mathbb{C}[\Theta_1, \dots, \Theta_r]$$

with $\deg P_i = 2m_i + 1$ and $\deg \Theta_i = 2(m_i + 1)$, where $m_1, \dots, m_r$ are the exponents of $\mathfrak{g}$ (Fuks–Feigin–Tsygan [164], via BD comparison [40]). For rank 1 ($\mathfrak{sl}_2$): $H^{n+4} \cong H^n$ (strict periodicity). For rank $r > 1$: polynomial growth $O(n^{r-1})$ without strict periodicity (Theorem 12.5.3).

Remark 17.2.4 (Critical level: Lie cohomology vs chiral Hochschild). At *generic* level ($k \neq -h^\vee$), chiral Hochschild cohomology and continuous Lie algebra cohomology are different functors: Theorem H (Theorem 14.4.12) bounds $CH^n = 0$ for $n > 2$, while the Lie algebra cohomology extends into arbitrarily high degrees.

At *critical* level ($k = -h^\vee$), chiral Koszulness fails: PBW degeneration (Proposition 11.1.32) still holds, but the Ext algebra $\text{Ext}^{p,q}$ is not diagonally concentrated (the Feigin–Frenkel center $\text{Fun}(\text{Op})$ lives at bar degree $p = 0$ with conformal weight $q > 0$). Since Theorem H requires diagonal Ext concentration (via bar concentration, Theorem 11.1.25), Theorem H does not apply at critical level.

Instead, the Beilinson–Drinfeld comparison theorem ([40], Theorem 4.5.2) identifies the chiral Hochschild cohomology with the continuous Lie algebra cohomology:

$$CH^*(\widehat{\mathfrak{g}}_{-h^\vee}) \cong H_{\text{Lie, cont}}^*(\mathfrak{g} \otimes t\mathbb{C}[[t]]; \mathbb{C}) \cong \Lambda^*(P_1, \dots, P_r) \otimes \mathbb{C}[\Theta_1, \dots, \Theta_r],$$

which is *unbounded* with polynomial growth $O(n^{r-1})$ (Theorem 12.5.3). In particular, $\dim CH^0 = \infty$ (the Feigin–Frenkel center), and $\dim CH^n = \infty$ for all $n \geq 0$.

Summary: at generic level, ChirHoch is bounded in $\{0, 1, 2\}$ and differs from Lie cohomology above degree 2; at critical level, the BD comparison identifies them, and ChirHoch is unbounded.

The exterior-polynomial structure of the Lie algebra cohomology arises from the Coxeter element $w_{\text{Cox}} \in W$ acting on the center at critical level (Feigin–Frenkel [160]; the exterior-polynomial decomposition follows from Feigin–Frenkel's description of the center $\mathfrak{z}(\widehat{\mathfrak{g}})$ at critical level [160]). For simply-laced $\mathfrak{g}$, $\mathfrak{h} = h^\vee$; for non-simply-laced $\mathfrak{g}$, $\mathfrak{h} \neq h^\vee$ in general.

17.2.3 W-ALGEBRA CHIRAL HOCHSCHILD COHOMOLOGY

For W-algebras at generic level, Theorem H gives concentration in $\{0, 1, 2\}$:

THEOREM 17.2.5 (*W-algebra chiral Hochschild cohomology*;). For the principal W-algebra $\mathcal{W}^k(\mathfrak{g}) = \mathcal{W}^k(\mathfrak{g}, f_{\text{prin}})$ at generic level k (away from admissible and critical levels), the chiral Hochschild cohomology is concentrated in degrees $\{0, 1, 2\}$:

$$CH^n(\mathcal{W}^k(\mathfrak{g})) = 0 \quad \text{for } n \notin \{0, 1, 2\}.$$

The nonvanishing degrees are:

- (i) $CH^0(\mathcal{W}^k(\mathfrak{g})) = Z(\mathcal{W}^k(\mathfrak{g})) = \mathbb{C}$ (the center at generic k is one-dimensional);
- (ii) $CH^1(\mathcal{W}^k(\mathfrak{g})) = 0$ at generic k (the Shapovalov form is non-degenerate, all derivations are inner);
- (iii) $CH^2(\mathcal{W}^k(\mathfrak{g})) = \mathbb{C}$ (the level deformation; equivalently, $\dim Z((\mathcal{W}^k(\mathfrak{g}))^\dagger) = 1$ by Theorem 14.4.10).

The Hilbert series is $P(t) = 1 + t^2$.

Proof. The argument has two parts: concentration from Theorem H, and identification of the individual degrees.

Step 1 (Concentration). By the Feigin–Frenkel free-field realization, the universal W-algebra $\mathcal{W}^k(\mathfrak{g})$ is freely strongly generated by $r = \text{rank}(\mathfrak{g})$ fields of conformal weights $h_i = m_i + 1$. Corollary 11.1.33 gives chiral Koszulness. Theorem H (Theorem 14.4.12) then gives $CH^n = 0$ for $n \notin \{0, 1, 2\}$.

Step 2 (Individual degrees). $CH^0 = Z(\mathcal{W}^k) = \mathbb{C}$: at generic k , the W-algebra is simple (Arakawa [12], Theorem 4.1), so the center is one-dimensional. $CH^1 = 0$: at generic k , the Shapovalov form on Verma modules is non-degenerate (no singular vectors), giving Ext-vanishing and hence no outer derivations. $CH^2 = \mathbb{C}$: by the Koszul duality exchange (Theorem 14.4.10), $\dim CH^2(\mathcal{W}^k) = \dim Z((\mathcal{W}^k)^\dagger)$. The Koszul dual of the principal W-algebra at generic level has one-dimensional center. $\square$

Remark 17.2.6 (*Gel’fand–Fuchs cohomology vs chiral Hochschild*). The continuous relative cohomology of the topological Lie algebra $\text{Lie}(\mathcal{W}^k(\mathfrak{g}))$ with r generating currents is a polynomial ring $H_{\text{cont}}^*(\text{Lie}(\mathcal{W}), \text{Lie}(\mathcal{W})_0; \mathbb{C}) = \mathbb{C}[\Theta_1, \dots, \Theta_r]$ with $\Theta_i \in H^{h_i}$ (Fuchs [183], Ch. 2; Feigin–Fuchs [162] for $r = 1$). This is a *different* invariant from $CH^*(\mathcal{W}^k)$: the Gel’fand–Fuchs cohomology is the continuous Lie algebra cohomology (without curve geometry), while the chiral Hochschild cohomology is an Ext on the curve X , bounded by the de Rham amplitude $[0, 2]$. The polynomial ring in all degrees truncates to the range $\{0, 1, 2\}$ when passing to the chiral setting on a curve. For the Virasoro ($r = 1$): $H_{\text{cont}}^*(L_1) = \mathbb{C}[\Theta]$ has Hilbert series $1/(1 - t^2)$, but $CH^*(\text{Vir}_c)$ has Hilbert series $1 + t^2$.

Remark 17.2.7 (*Scope*). The concentration from Theorem H requires chiral Koszulness, which holds for the universal algebra $\mathcal{W}^k(\mathfrak{g})$ at all levels (including admissible) by Feigin–Frenkel free generation. The identification of individual degrees uses generic-level hypotheses (Ext-vanishing, simplicity). At critical level $k = -h^\vee$, the center enlarges to the Feigin–Frenkel center $\mathfrak{z}(\widehat{\mathfrak{g}})$, and the computation changes (Theorem 17.2.3). For non-principal nilpotent orbits (Remark below), the simplicity hypothesis requires case-by-case verification.

Remark 17.2.8 (*Elementary model presentation; Convention 1.10.2*). *Step A* (H-level): $CH^*(\mathcal{A})$ is the endomorphism algebra of the identity functor on factorization $\mathcal{A}$ -modules: it classifies A_∞ -deformations of the chiral algebra $\mathcal{A}$. Concentration in $\{0, 1, 2\}$ (Theorem H) asserts that deformations live in CH^2

and obstructions in $CH^3 = 0$: all first-order deformations are unobstructed, and the formal moduli space is smooth. For the principal W-algebra at generic level: $\dim CH^2(\mathcal{W}^k(\mathfrak{g})) = 1$ (the level deformation $k \mapsto k + \epsilon$).

Step B (M-level): The proof uses the Koszul resolution: the bar-cobar quasi-isomorphism (Theorem B on the Koszul locus) provides a resolution of $\mathcal{A}$ by free chiral algebras generated from $\mathcal{A}^1$. The Hom complex computing the Ext groups is a complex of $\mathcal{D}_X$ -module morphisms on the curve X . The de Rham amplitude bound $[0, 2 \dim X] = [0, 2]$ gives concentration.

Reduction $B \rightarrow A$ (M-level $\rightarrow$ H-level): The M-level bar complex $\bar{B}_{HH}(\mathcal{A}) = (\mathcal{A} \otimes T^c(s^{-1}\bar{\mathcal{A}}) \otimes \mathcal{A}, d)$ is a dg model for the derived endomorphism object $R\text{End}_{\mathcal{A}\text{-}\mathcal{A}}(\mathcal{A})$. By Proposition 6.1.45, the H-level endomorphism algebra is recovered from the M-level bar complex up to contractible ambiguity.

Step C (S-level): The Hilbert series is $P_{\mathcal{W}^k(\mathfrak{g})}(t) = 1 + t^2$ at generic level: $CH^0 = \mathbb{C}$ (center), $CH^1 = 0$ (no outer derivations), $CH^2 = \mathbb{C}$ (level deformation).

Reduction $B \rightarrow C$ (M-level $\rightarrow$ S-level): The S-level Hilbert series is extracted from the M-level concentration: the vanishing $CH^n = 0$ for $n > 2$ (Theorem H) determines the Hilbert polynomial as a degree-2 polynomial in t .

Remark 17.2.9 (Non-principal nilpotent orbits). For general $\mathcal{W}^k(\mathfrak{g}, f)$ with f not necessarily principal, the conformal weights of the generators are determined by the Kazhdan grading associated to the $\mathfrak{sl}_2$ -triple (e, h, f) . The concentration $CH^n = 0$ for $n > 2$ holds whenever the algebra is chirally Koszul (Theorem H); the individual dimensions $\dim CH^0, \dim CH^1, \dim CH^2$ depend on the center, derivations, and Koszul dual center for the specific orbit. For special orbits where Koszulness is open, the concentration bound remains conjectural.

17.3 DEFORMATION THEORY

17.3.1 INFINITESIMAL DEFORMATIONS

THEOREM 17.3.1 (*Deformation classification [197, 297];*). 1. $CH^1(\mathcal{A})$ classifies outer derivations $\text{Der}(\mathcal{A})/\text{Inn}(\mathcal{A})$ (not infinitesimal automorphisms, which are all derivations).

2. $CH^2(\mathcal{A})$ classifies first-order deformations.
3. $CH^3(\mathcal{A})$ contains the primary obstructions to extending deformations.
4. Unobstructed deformations correspond to marginal operators in CFT.

Example 17.3.2 (Marginal deformations of beta-gamma). For the $\beta\gamma$ system:

$$CH^2(\beta\gamma) = \mathbb{C} \cdot [\beta\gamma]$$

The class $[\beta\gamma]$ corresponds to the exactly marginal operator changing the conformal weights.

17.3.2 FORMAL DEFORMATION THEORY

The formal deformation space is controlled by the differential graded Lie algebra $\mathfrak{g}_{\mathcal{A}} = CH^*(\mathcal{A}, \mathcal{A})[1]$ with the Gerstenhaber bracket.

THEOREM 17.3.3 (*Maurer–Cartan equation [273, 278];*). Formal deformations correspond to solutions of:

$$d\alpha + \frac{1}{2}[\alpha, \alpha] = 0, \quad \alpha \in \mathfrak{g}_{\mathcal{A}}^1$$

17.4 PHYSICAL APPLICATIONS

17.4.1 MARGINAL OPERATORS AND RG FLOW

In CFT, marginal operators have dimension $(1, 1)$ and correspond to $CH^2_{\text{marginal}}(\mathcal{A}) = \{\omega \in CH^2 : h(\omega) = 1\}$. The beta function vanishes if and only if the obstruction in CH^3 vanishes.

17.4.2 STRING FIELD THEORY

The conjectural identification of the bar complex with BRST cohomology (Conjecture K.7.1) takes the form:

$$H^*_{\text{BRST}}(\text{String}[\mathcal{A}]) \cong CH^*(\mathcal{A})$$

String vertices are encoded in the A_∞ structure: m_2 gives the three-string vertex, m_3 the four-string contact term, and higher m_k the multi-string interactions.

17.5 COMPUTATIONAL TOOLS

17.5.1 SPECTRAL SEQUENCES

THEOREM 17.5.1 (*Bar spectral sequence* [40, 92];).

$$E_1^{p,q} = H^q(\overline{C}_p(X)(X), \mathcal{A}^{\boxtimes p}) \Rightarrow CH^{p+q}(\mathcal{A})$$

17.5.2 EXPLICIT COMPUTATIONS

For the Heisenberg algebra:

$$CH^n(\text{Heis}_k) = \begin{cases} \mathbb{C} & n = 0 \text{ (center: only scalars commute with all of Heis}_k\text{)} \\ \mathbb{C} & n = 1 \text{ (outer derivation } D(\alpha) = 1; \text{ zero mode is central)} \\ \mathbb{C} & n = 2 \text{ (central extension: the level deformation)} \\ 0 & n \geq 3 \end{cases}$$

For free fermions (with OPE $\psi(z)\psi^*(w) \sim (z-w)^{-1}$):

$$CH^n(\text{Fermions}) = \begin{cases} \mathbb{C} & n = 0 \text{ (center: only scalars)} \\ 0 & n = 1 \text{ (all derivations of the Clifford algebra are inner)} \\ \mathbb{C} & n = 2 \text{ (one-dimensional deformation space)} \end{cases}$$

(The computation follows from the Clifford algebra structure: HH^0 is the center $\mathbb{C}$; $HH^1 = 0$ by the standard result that all derivations of a Clifford algebra are inner [395, Ch. 9]; $HH^2 \cong \mathbb{C}$ represents the unique deformation parametrized by the level.)

17.6 CHIRAL HOCHSCHILD-CYCLIC SPECTRAL SEQUENCE FOR CHIRAL ALGEBRAS

Remark 17.6.1 (*Physical origin*). In 2d CFT on a genus g surface Σ_g , the partition function $Z[\Sigma_g] = \text{Tr}_{\mathcal{H}}(q^{L_0 - c/24})$ is related to the chiral Hochschild-cyclic spectral sequence: the E_1 page gives the tree-level

(genus 0) contribution, E_2 incorporates one-loop corrections, and higher pages capture multi-loop effects. For chirally Koszul algebras at generic level, the spectral sequence degenerates at E_2 by the Ext-vanishing argument (Theorem 17.2.5).

Construction 17.6.2 (Geometric realization via loop spaces). The chiral Hochschild complex of a chiral algebra $\mathcal{A}$ on a curve X is:

$$\mathrm{HC}_n^{\mathrm{ch}}(\mathcal{A}) = \Gamma(C_n(X), \mathcal{A}^{\boxtimes n} \otimes \det(\Omega_{C_n(X)/X}^1))$$

This has a natural S^1 -action (cyclic rotation of points), giving:

$$\mathrm{HC}_n^{\mathrm{ch}}(\mathcal{A}) = [\mathrm{Maps}(S^1, LX) \otimes_{\mathcal{A}} \mathcal{A}^{\otimes n}]^{S^1}$$

where $LX = \mathrm{Maps}(S^1, X)$ is the loop space.

The cyclic spectral sequence computes $H_*(LX, \mathcal{A})$ by first computing $H_*(\mathrm{Maps}(S^1, X), \mathcal{A})$ and then taking S^1 -invariants.

Chiral Hochschild homology computes the homology of the free loop space, and cyclic homology computes the S^1 -equivariant loop space homology. This identification is classical for associative algebras [297]; the chiral extension follows from the factorization structure of the loop space [92, Chapter 5].

COMPUTATION 17.6.3 (Explicit second-page computation;). We compute the E_2 page explicitly for standard examples:

Heisenberg algebra.

$$\mathrm{HH}_*^{\mathrm{ch}}(\mathcal{H}) = \mathbb{C}[c] \otimes \Lambda(\sigma)$$

where $|c| = 2$ (central charge) and $|\sigma| = 1$ (desuspension of S^1).

The Connes operator $B : \mathrm{HH}_n \rightarrow \mathrm{HH}_{n+1}$ (degree +1) satisfies $B(c) = 0$, $B(\sigma) = c$, giving:

$$\mathrm{HC}_*^{\mathrm{ch}}(\mathcal{H}) = \mathbb{C}[c]$$

(polynomials in the central charge).

Free fermion $\beta\gamma$ system.

$$\mathrm{HH}_*^{\mathrm{ch}}(\beta\gamma) = \Lambda(\beta_0, \gamma_0) \otimes \mathbb{C}[c]$$

where β_0, γ_0 are zero modes. Cyclic homology adds periodicity:

$$\mathrm{HC}_*^{\mathrm{ch}}(\beta\gamma) = \mathbb{C}[c] \otimes \mathbb{C}[\beta_0^{-1}, \gamma_0^{-1}]_{\mathrm{formal}}$$

(the localization $\mathbb{C}[\beta_0, \gamma_0][\beta_0^{-1}, \gamma_0^{-1}]$ at the zero-mode variables, completed formally).

The zero-mode periodicity in $\mathrm{HC}_*^{\mathrm{ch}}(\beta\gamma)$ reflects the symplectic pairing of the $\beta\gamma$ system: the localized zero modes span the deformation space of the Lagrangian splitting.

Remark 17.6.4 (Functoriality). The chiral Hochschild-cyclic spectral sequence is functorial: a morphism $f : \mathcal{A} \rightarrow \mathcal{B}$ induces $f_* : E_r(\mathcal{A}) \rightarrow E_r(\mathcal{B})$, tensor products satisfy $E_r(\mathcal{A} \otimes \mathcal{B}) \cong E_r(\mathcal{A}) \otimes E_r(\mathcal{B})$ up to higher structure, and Koszul duality gives $E_r(\mathcal{A}^!) \cong E_r(\mathcal{A})^\vee$. The chiral Hochschild complex represents the functor $\mathrm{Bimod}_{\mathcal{A}} \ni M \mapsto \mathrm{Hom}_{\mathrm{Bimod}}(\mathrm{HH}(\mathcal{A}), M)$.

17.6.1 CHIRAL HOCHSCHILD COMPLEX FOR CHIRAL ALGEBRAS

Definition 17.6.5 (Chiral Hochschild complex). For a chiral algebra $\mathcal{A}$ on a smooth curve X , the *chiral chiral Hochschild complex* is:

$$\mathrm{CH}_n(\mathcal{A}) = \Gamma\left(\overline{C}_{n+1}(X), \mathcal{A}^{\boxtimes(n+1)} \otimes \det\left(\Omega_{\overline{C}_{n+1}(X)/X}^1\right)\right)$$

with differential:

$$d_{\mathrm{HH}}(\omega) = \sum_{i=0}^n (-1)^i [\text{omit } i\text{-th factor}]$$

More explicitly, using the chiral product μ_{ij} :

$$\begin{aligned} d_{\mathrm{HH}}(a_0 \otimes \cdots \otimes a_n) &= \sum_{i=0}^{n-1} (-1)^i (a_0 \otimes \cdots \otimes \mu(a_i, a_{i+1}) \otimes \cdots \otimes a_n) \\ &\quad + (-1)^n (\mu(a_n, a_0) \otimes a_1 \otimes \cdots \otimes a_{n-1}) \end{aligned}$$

The last term implements the *cyclic structure*: a_n wraps around to multiply a_0 .

THEOREM 17.6.6 (*Chiral Hochschild complex is a chain complex*;). The identity $d_{\mathrm{HH}}^2 = 0$ is the chiral Hochschild analogue of the Arnold-relation mechanism that ensured $d^2 = 0$ for the bar differential (§2.2): adjacent face maps cancel in pairs. In the chiral setting, the same cancellation acquires OPE corrections from the higher poles. The differential d_{HH} satisfies $d_{\mathrm{HH}}^2 = 0$, making $(\mathrm{CH}_*(\mathcal{A}), d_{\mathrm{HH}})$ a chain complex.

Proof. We must show that for any $\omega \in \mathrm{CH}_n(\mathcal{A})$:

$$d_{\mathrm{HH}}^2(\omega) = 0$$

Step 1: Expand d_{HH}^2

Applying d_{HH} twice gives:

$$\begin{aligned} d_{\mathrm{HH}}^2(a_0 \otimes \cdots \otimes a_n) &= d_{\mathrm{HH}}\left(\sum_{i=0}^{n-1} (-1)^i (\cdots \otimes \mu(a_i, a_{i+1}) \otimes \cdots)\right) \\ &\quad + (-1)^n (\mu(a_n, a_0) \otimes a_1 \otimes \cdots) \end{aligned}$$

Step 2: Identify canceling pairs

After expanding, terms come in two types:

1. *Type A*: Apply μ at positions $(i, i+1)$ then $(j, j+1)$ with $j \neq i, i+1$
2. *Type B*: Apply μ twice at adjacent triples $(i, i+1, i+2)$

Type A terms cancel because applying μ at position i first reduces the chain length by 1, so the second application at position j (with $j > i+1$) picks up index $j-1$:

$$(-1)^i (-1)^{j-1} (\dots) + (-1)^j (-1)^i (\dots) = (-1)^{i+j-1} + (-1)^{i+j} = 0$$

(the index shift from the first contraction produces the sign difference)

Type B terms cancel by the Borchers identity (the chiral analog of associativity). For three elements a_i, a_{i+1}, a_{i+2} at pairwise distinct points z_i, z_{i+1}, z_{i+2} , the Type B contributions are:

$$\begin{aligned} & (-1)^i (-1)^{i+1} (\cdots \otimes \mu_{z_i, z_{i+2}} (\mu_{z_i, z_{i+1}} (a_i, a_{i+1}), a_{i+2}) \otimes \cdots) \\ & + (-1)^{i+1} (-1)^i (\cdots \otimes \mu_{z_i, z_{i+2}} (a_i, \mu_{z_{i+1}, z_{i+2}} (a_{i+1}, a_{i+2})) \otimes \cdots) \end{aligned}$$

The signs give $(-1)^{2i+1} = -1$ for the first and $(-1)^{2i+1} = -1$ for the second, so the total contribution is:

$$-(\mu(\mu(a_i, a_{i+1}), a_{i+2}) - \mu(a_i, \mu(a_{i+1}, a_{i+2})))$$

By the Borchers identity [40, Section 3.4.7] (equivalently: the factorization algebra structure encodes *homotopy* associativity via the codimension-1 boundary strata of $\overline{\mathcal{C}}_3$), the iterated products $\mu(\mu(a_i, a_{i+1}), a_{i+2})$ and $\mu(a_i, \mu(a_{i+1}, a_{i+2}))$ agree up to the contribution of the boundary stratum $\partial \overline{\mathcal{C}}_3$, which is accounted for by the chiral Hochschild complex structure (the face maps encode precisely these boundary identifications). Thus the two terms cancel in the chiral Hochschild complex, giving $d_{\text{HH}}^2 = 0$.

Note: Unlike the classical case, the chiral product is *not* strictly associative; the Borchers identity provides associativity only up to total derivatives (equivalently, up to homotopy). The cancellation above relies on the factorization algebra axioms rather than strict associativity. $\square$

Definition 17.6.7 (Chiral Hochschild homology). The *chiral Hochschild homology* of $\mathcal{A}$ is:

$$\text{HH}_n^{\text{ch}}(\mathcal{A}) = H_n(\text{CH}_*(\mathcal{A}), d_{\text{HH}})$$

17.6.2 CYCLIC STRUCTURE AND S^1 -ACTION

Definition 17.6.8 (Cyclic operator). The *cyclic operator* $t : \text{CH}_n(\mathcal{A}) \rightarrow \text{CH}_n(\mathcal{A})$ is defined by:

$$t(a_0 \otimes a_1 \otimes \cdots \otimes a_n) = (-1)^n (a_n \otimes a_0 \otimes a_1 \otimes \cdots \otimes a_{n-1})$$

This generates a $\mathbb{Z}/(n+1)$ -action on $\text{CH}_n(\mathcal{A})$.

LEMMA 17.6.9 (Cyclic operator commutes with the chiral Hochschild differential;). The cyclic operator commutes with the chiral Hochschild differential:

$$t \circ d_{\text{HH}} = d_{\text{HH}} \circ t$$

Proof. Direct computation using the definition of d_{HH} :

$$t(d_{\text{HH}}(a_0 \otimes \cdots \otimes a_n)) = t \left(\sum_{i=0}^{n-1} (-1)^i (\cdots \otimes \mu(a_i, a_{i+1}) \otimes \cdots) + (-1)^n (\mu(a_n, a_0) \otimes \cdots) \right)$$

After applying t (cyclic permutation), each term shifts indices: $i \rightarrow i+1 \pmod{n+1}$.

Similarly:

$$d_{\text{HH}}(t(a_0 \otimes \cdots \otimes a_n)) = d_{\text{HH}}((-1)^n (a_n \otimes a_0 \otimes \cdots \otimes a_{n-1}))$$

After accounting for Koszul signs from moving a_n past $a_0, \dots, a_{n-1}$, the two expressions are identical. $\square$

Definition 17.6.10 (Connes operator B). The Connes operator $B : \mathrm{CH}_n(\mathcal{A}) \rightarrow \mathrm{CH}_{n+1}(\mathcal{A})$ is defined as

$$B = (1 - t_{n+1}) \circ s \circ N_n$$

where $N_n = \sum_{i=0}^n t^i$ is the norm operator and $s : \mathrm{CH}_n \rightarrow \mathrm{CH}_{n+1}$ is the extra degeneracy $s(a_0 \otimes \cdots \otimes a_n) = 1 \otimes a_0 \otimes \cdots \otimes a_n$. The identities $B^2 = 0$ and $Bd + dB = 0$ hold (Theorem 17.6.11).

THEOREM 17.6.11 (*Connes mixed-complex structure [88, 297];*). The pair (d_{HH}, B) equips $\mathrm{CH}_*(\mathcal{A})$ with the structure of a *mixed complex*: $d^2 = B^2 = dB + Bd = 0$. This gives rise to a short exact sequence of complexes:

$$0 \rightarrow \mathrm{CC}_*(\mathcal{A}) \rightarrow \mathrm{CC}_*^{\mathrm{per}}(\mathcal{A}) \rightarrow \mathrm{CC}_*^{\mathrm{neg}}(\mathcal{A})[2] \rightarrow 0$$

where:

- $\mathrm{CC}_* = \mathrm{CH}_* \otimes k[u]/(d + uB)$ is the cyclic complex ($|u| = -2$)
- $\mathrm{CC}_*^{\mathrm{per}} = \mathrm{CH}_* \otimes k((u))/(d + uB)$ is the periodic cyclic complex
- $\mathrm{CC}_*^{\mathrm{neg}}$ is the negative cyclic complex

Remark 17.6.12 (Provenance and citation). This theorem is imported and treated as . Standard presentations of Connes' mixed-complex formalism and the associated exact sequence are in [88, 297].

COROLLARY 17.6.13 (*Connes SBI exact sequence [88, 297];*). There is a long exact sequence relating chiral Hochschild and cyclic homology:

$$\cdots \rightarrow \mathrm{HH}_n(\mathcal{A}) \xrightarrow{I} \mathrm{HC}_n(\mathcal{A}) \xrightarrow{S} \mathrm{HC}_{n-2}(\mathcal{A}) \xrightarrow{B} \mathrm{HH}_{n-1}(\mathcal{A}) \rightarrow \cdots$$

where S is the periodicity operator, B is Connes' operator, and I is the natural inclusion. In particular, S is an isomorphism in degrees where HH_* vanishes, yielding 2-periodicity of periodic cyclic homology $\mathrm{HP}_* = \varprojlim_S \mathrm{HC}_{*+2k}$.

17.6.3 THE CHIRAL HOCHSCHILD-CYCLIC SPECTRAL SEQUENCE

THEOREM 17.6.14 (*Chiral Hochschild-cyclic spectral sequence [88, 297];*). The cyclic structure induces a spectral sequence:

$$E_1^{p,q} = \mathrm{HH}_q^{\mathrm{ch}}(\mathcal{A}) \otimes \Lambda^p(\mathbb{C} \cdot \sigma)$$

converging to:

$$E_\infty^{p,q} \Rightarrow \mathrm{HC}_{p+q}^{\mathrm{ch}}(\mathcal{A})$$

The E_1 differential is:

$$\begin{aligned} d_1 : E_1^{p,q} &\rightarrow E_1^{p-1,q} \\ d_1(\omega \otimes \sigma^p) &= B(\omega) \otimes \sigma^{p-1} \end{aligned}$$

where B is Connes' operator.

Remark 17.6.15 (Provenance and citation). This theorem is imported and treated as . The spectral sequence attached to the mixed complex $(\mathrm{CH}_*, d_{\mathrm{HH}}, B)$ is standard in the cyclic-homology literature; see [88, 297].

17.6.4 E_2 PAGE: EXPLICIT COMPUTATION

THEOREM 17.6.16 (*Second-page formula* [297];). The E_2 page of the chiral Hochschild-cyclic spectral sequence is:

$$E_2^{p,q} = \begin{cases} \mathrm{HH}_q(\mathcal{A})^{S^1} & \text{if } p = 0 \\ \mathrm{HH}_{q-1}(\mathcal{A})_{S^1} & \text{if } p = 1 \\ 0 & \text{if } p \geq 2 \end{cases}$$

where:

- $(-)^{S^1}$ denotes S^1 -invariants (fixed points)
- $(-)_{S^1}$ denotes S^1 -coinvariants (S^1 -orbits)

Remark 17.6.17 (*Provenance and citation*). This theorem is imported and treated as . The E_2 identification in terms of invariants/coinvariants of the circle action is the standard computation for the cyclic spectral sequence (see [297]).

Example 17.6.18 (*Second page for the Heisenberg algebra*). For the Heisenberg chiral algebra $\mathcal{H}$ at level k :

Step 1: Compute chiral Hochschild homology

$$\mathrm{HH}_*(\mathcal{H}) = \mathbb{C}[a_{-n}]_{n \geq 1} \otimes \mathbb{C} \cdot 1$$

where a_{-n} are negative modes of the Heisenberg field $a(z) = \sum_n a_n z^{-n-1}$.

In more invariant terms:

$$\mathrm{HH}_*(\mathcal{H}) = \mathrm{Sym}^*(H_1(S^1, \mathbb{C})) \otimes \Lambda(H_0(S^1, \mathbb{C})) = \mathbb{C}[c] \otimes \Lambda(\sigma)$$

where $|c| = 2$ (from the S^1 homology) and $|\sigma| = 1$ (from the constant functions), consistent with the Serre duality computation.

Step 2: S^1 -action

The S^1 -action on $\mathrm{HH}_*(\mathcal{H})$ is trivial on the center, so:

$$\mathrm{HH}_*(\mathcal{H})^{S^1} = \mathbb{C}[c]$$

$$\mathrm{HH}_*(\mathcal{H})_{S^1} = \mathbb{C}[c]$$

Step 3: E_2 page

$$E_2^{0,q} = \mathbb{C}[c] \cap \{|*| = q\} = \begin{cases} \mathbb{C} & \text{if } q = 0, 2, 4, \dots \\ 0 & \text{otherwise} \end{cases}$$

$$E_2^{1,q} = \mathbb{C}[c] \cap \{|*| = q - 1\} = \begin{cases} \mathbb{C} & \text{if } q = 1, 3, 5, \dots \\ 0 & \text{otherwise} \end{cases}$$

The E_2 page is therefore:

$$E_2 = \begin{array}{c|cc} q \backslash p & 0 & 1 \\ \hline 0 & \mathbb{C} & 0 \\ 1 & 0 & \mathbb{C} \\ 2 & \mathbb{C} & 0 \\ 3 & 0 & \mathbb{C} \\ \vdots & \vdots & \vdots \end{array}$$

The spectral sequence *degenerates at E_2* (all higher differentials are zero) because the only possible higher differentials $d_r : E_r^{1,q} \rightarrow E_r^{0,q+r}$ would require $r \geq 2$, but $E_r^{p,q} = 0$ for $p \geq 2$, so all higher differentials vanish.

Comparison with classical Hochschild cohomology. The polynomial E_2 page above should not be confused with the ordinary classical Hochschild cohomology $HH^*(\mathcal{H})$, which is computed in Example 14.8.5. The latter uses the Koszul resolution (length 2) and gives $HH^n(\mathcal{H}) = \mathbb{C}$ for $n = 0, 1, 2$ and $HH^n(\mathcal{H}) = 0$ for $n \geq 3$. The difference is that the E_2 page here is computed from chiral Hochschild *homology* $HH_*(\mathcal{H}) = \mathbb{C}[c] \otimes \Lambda(\sigma)$, which is polynomial and does not vanish in high degrees. Classical Hochschild cohomology (the Ext-computation) and chiral Hochschild homology (the Tor-computation) are distinct invariants; the former detects deformations, while the latter feeds the cyclic spectral sequence.

Example 17.6.19 (Second page for affine sl_3). For $\widehat{\mathfrak{sl}}_3$ at generic level k :

Step 1: Chiral Hochschild homology. By the continuous cohomology of current algebras, $HH_*^{\text{ch}}(\widehat{\mathfrak{sl}}_3)$ is determined by the Lie algebra cohomology $H^*(\mathfrak{sl}_3; \mathbb{C}) = \Lambda(x_3, x_5)$ (exterior algebra on generators of degrees 3 and 5, corresponding to the exponents $m_1 = 1, m_2 = 2$ of $\mathfrak{sl}_3$) tensored with the polynomial algebra from the loop direction. This gives:

$$HH_*^{\text{ch}}(\widehat{\mathfrak{sl}}_3) = \mathbb{C}[\Theta_2, \Theta_3] \otimes \Lambda(\sigma_3, \sigma_5)$$

where $|\Theta_j| = j$ (from the Casimir operators of degrees 2 and 3, corresponding to the exponents $m_1 = 1, m_2 = 2$) and $|\sigma_{2i+1}| = 2i + 1$ (from $H^*(\mathfrak{sl}_3)$).

Step 2: S^1 -action and E_2 page. The S^1 -action on the polynomial part is trivial (Casimirs are invariant). The exterior generators σ_3, σ_5 lie in odd degrees and are S^1 -coinvariants:

$$E_2^{0,*} = \mathbb{C}[\Theta_2, \Theta_3], \quad E_2^{1,*} = \mathbb{C}[\Theta_2, \Theta_3].$$

Step 3: Degeneration. At generic k , $\widehat{\mathfrak{sl}}_3$ is simple (Ext-vanishing in category $\mathcal{O}$), so the spectral sequence degenerates at E_2 by the same argument as for $\widehat{\mathfrak{sl}}_2$. The Hilbert function of $HC_n = E_2^{0,n} \oplus E_2^{1,n-1}$ gives:

$$\dim HC_n^{\text{ch}}(\widehat{\mathfrak{sl}}_3) = \#\{(a, b) : 2a + 3b = n\} + \#\{(a, b) : 2a + 3b = n - 1\}$$

which grows linearly in n (rank 2), in contrast to the constant $\dim HC_n = 1$ for $\widehat{\mathfrak{sl}}_2$ (rank 1).

Example 17.6.20 (Second page for lattice VOAs). For a lattice VOA V_Λ of rank d , the underlying Heisenberg algebra $\mathcal{H}^{\otimes d}$ gives:

$$HH_*^{\text{ch}}(V_\Lambda) = \mathbb{C}[c_1, \dots, c_d] \otimes \Lambda(\sigma_1, \dots, \sigma_d)$$

with $|c_i| = 2, |\sigma_i| = 1$. The lattice vertex operators do not contribute additional chiral Hochschild classes (they are inner automorphisms of the Heisenberg algebra at generic level). Thus $E_2^{0,*} = \mathbb{C}[c_1, \dots, c_d]$ and $E_2^{1,*} = \mathbb{C}[c_1, \dots, c_d]$, with E_2 degeneration.

17.6.5 PHYSICAL INTERPRETATION: ANOMALIES AND PARTITION FUNCTIONS

THEOREM 17.6.21 (*Partition function as cyclic homology* [164, 46];). For a 2d CFT with chiral algebra $\mathcal{A}$ on a genus g surface Σ_g , the partition function is:

$$Z[\Sigma_g] = \int_{\Sigma_g} \mathcal{A} = \text{Tr}_{HC_*(\mathcal{A})}(q^{L_0})$$

The chiral Hochschild-cyclic spectral sequence computes $Z[\Sigma_g]$ with:

- E_1 = tree-level (genus 0 contribution)
- E_2 = one-loop (genus 1 + quantum corrections)
- E_r ($r \geq 3$) = multi-loop corrections (genus ≥ 2)

Remark 17.6.22 (Provenance). The identification of the partition function with cyclic homology is due to Feigin–Tsygan [164]: the factorization homology $\int_{\Sigma_g} \mathcal{A}$ is computed by the cyclic complex $\mathrm{HC}_*(\mathcal{A})$ via the identification of the free loop space LX with the cyclic bar construction. For chiral algebras specifically, the result follows from the equivalence between factorization homology on a closed surface and the trace over the category of modules, established by Ben-Zvi–Francis–Nadler [46].

17.6.6 MASTER COMPUTATION TABLE

Table 17.1: E_2 page computation for standard examples

Chiral Algebra	$E_2^{0,*}$	$E_2^{1,*}$	Degeneration?
Heisenberg $\mathcal{H}_k$	$\mathbb{C}[c]$ (even deg)	$\mathbb{C}[c]$ (odd deg)	Yes (at E_2)
$\beta\gamma$ bosons	$\mathbb{C}[c](1 \oplus \beta_0\gamma_0)$	$\mathbb{C}[c]$	Yes (at E_2)
bc ghosts	Similar to $\beta\gamma$	Similar to $\beta\gamma$	Yes (at E_2)
Virasoro $\mathcal{V}_c$ (generic c)	$\mathbb{C}[\Theta]$ ($ \Theta = 2$)	o	Yes (at E_2 , generic c) [†]
$\widehat{\mathfrak{sl}}_2$ level k	$\mathbb{C}[c]$	$\mathbb{C}[c]$	Yes (at E_2)
$\widehat{\mathfrak{sl}}_3$ level k	$\mathbb{C}[\Theta_2, \Theta_3]$	$\mathbb{C}[\Theta_2, \Theta_3]$	Yes (at E_2 , generic k)
W_3 algebra	$\mathbb{C}[\Theta_2, \Theta_3]$	$\mathbb{C}[\Theta_2]$	Depends on c
W_N algebra ($N \geq 4$)	$\mathbb{C}[\Theta_2, \dots, \Theta_N]$	$\mathbb{C}[\Theta_2, \dots, \Theta_{N-1}]$	Yes (generic c)
Lattice V_Λ (rank d)	$\mathbb{C}[c]^{\otimes d}$	$\mathbb{C}[c]^{\otimes d}$	Yes (at E_2)
$Y(\widehat{\mathfrak{sl}}_2)^{\mathrm{ch}}$	$\mathbb{C}[\Theta_2]$	$\mathbb{C}$	Conjectural

[†] The $E_2^{0,*}$ column records chiral Hochschild *homology* $\mathrm{HH}_*^{\mathrm{ch}}(\mathcal{A})^{S^1}$ (the Tor computation), which is polynomial for the Virasoro. This is distinct from chiral Hochschild *cohomology* $\mathrm{CH}^*(\mathcal{A})$ (the Ext computation), which is concentrated in $\{0, 1, 2\}$ by Theorem H (Theorem 14.4.12). The two invariants coincide in degree 0 ($\mathrm{HH}_0 \cong \mathrm{CH}^0 = Z(\mathcal{A})$) but diverge in higher degrees.

17.6.7 CYCLIC HOMOLOGY EXCHANGE UNDER KOSZUL DUALITY

COROLLARY 17.6.23 (*Cyclic homology duality*;). For a Koszul pair $(\mathcal{A}, \mathcal{A}^!)$, the Connes periodicity operator S intertwines the Koszul duality on chiral Hochschild homology with a $[-2]$ -shifted duality on cyclic homology:

$$\mathrm{HC}_n(\mathcal{A}) \cong \mathrm{HC}_{-n}(\mathcal{A}^!)^{\vee} \quad (17.1)$$

for all n , where HC_* denotes periodic cyclic homology.

Proof. The SBI exact sequence (Corollary 17.6.13) relates HH_* and HC_* via the periodicity operator S . The Koszul duality for chiral Hochschild cohomology (Theorem 14.4.10) gives $\mathrm{HH}^n(\mathcal{A}) \cong \mathrm{HH}^{2-n}(\mathcal{A}^!)^{\vee} \otimes \omega_X$. Inserting this into the SBI sequence for $\mathcal{A}$ and comparing with the SBI sequence for $\mathcal{A}^!$: the periodicity

operator S shifts degree by -2 on both sides, so the duality on HH_* descends to periodic cyclic homology as stated. The shift by 2 in the chiral Hochschild duality is absorbed by the periodicity S , yielding the unshifted duality (17.1) on $\mathrm{HP}_* = \varprojlim_S \mathrm{HC}_{*+2k}$. $\square$

Remark 17.6.24. For the Virasoro algebra Vir_c and its same-family partner Vir_{26-c} : both have CH^* concentrated in $\{0, 2\}$ with $CH^0 = CH^2 = \mathbb{C}$ (Theorem 17.2.1). The deformation class $\Theta \in CH^2(\mathrm{Vir}_c)$ and its dual $\Theta' \in CH^2(\mathrm{Vir}_{26-c})$ are exchanged by the Koszul duality (Theorem 14.4.10), consistent with the Verdier anti-commutativity of the Kodaira–Spencer class (Theorem 13.15.31). The partner Vir_{26-c} is the same-family Koszul dual (Theorem 13.21.44); the infinite-generator realization via the W_∞ completion programme is treated in Chapter K.7.1.

COROLLARY 17.6.25 (*Chiral Hochschild cup product exchange;*). For a Koszul pair $(\mathcal{A}, \mathcal{A}^!)$, let $\Theta \in CH^2(\mathcal{A})$ be a periodicity class (as in Theorem 12.5.1). Under the Koszul duality isomorphism $CH^n(\mathcal{A}) \cong CH^{2-n}(\mathcal{A}^!)^\vee \otimes \omega_X$ (Theorem 14.4.10), the cup product with Θ corresponds to the cup product with the dual class $\Theta' \in CH^2(\mathcal{A}^!)$ up to sign:

$$\Theta \longmapsto -\Theta'$$

under the Verdier anti-commutativity of the Kodaira–Spencer class.

Proof. The Kodaira–Spencer class $\mathrm{KS}_g(\mathcal{A}) \in H^1(\overline{\mathcal{M}}_g, Z(\mathcal{A}))$ satisfies $\mathrm{KS}_g(\mathcal{A}) = -\mathrm{KS}_g(\mathcal{A}^!)$ under the Verdier involution (Theorem 13.15.31, equation (13.35)). The periodicity class Θ arises from the $g = 0$ contribution to the Kodaira–Spencer class via the bar complex on $\overline{\mathcal{M}}_{0,4} \cong \mathbb{P}^1$ (proof of Theorem 12.5.1, Step 1). The Verdier anti-commutativity descends to the periodicity generators: Θ on the $\mathcal{A}$ side corresponds to $-\Theta'$ on the $\mathcal{A}^!$ side. $\square$

Remark 17.6.26 (Virasoro verification). For Vir_c with $CH^2 = \mathbb{C} \cdot \Theta$ and its same-family partner Vir_{26-c} with $CH^2 = \mathbb{C} \cdot \Theta'$: the Koszul duality isomorphism $CH^2(\mathrm{Vir}_c) \cong CH^0(\mathrm{Vir}_{26-c})^\vee \otimes \omega_X$ maps $\Theta \mapsto -\Theta'$ (up to the ω_X twist), where the sign comes from the Verdier anti-commutativity $\Theta \leftrightarrow -\Theta'$. This is consistent with the periodic cyclic duality (Corollary 17.6.23).

17.7 DERIVED CENTER AND TOPOLOGICAL HOCHSCHILD COCHAINS (M4)

The derived center of a dg-category is the derived endomorphisms of the identity functor. For a category with a compact generator, this reduces, via the Morita equivalence, to the topological Hochschild cochain complex of the endomorphism algebra. The argument is categorical in nature and depends on three classical inputs: Morita theory for dg-categories, the identification of endofunctors with bimodules, and the definition of topological Hochschild cochains as bimodule self-Ext. The Hochschild cohomology in this section is the classical (topological) $\mathrm{HH}^\bullet(A, A) = \mathrm{RHom}_{A^e}(A, A)$ of associative dg-algebras; the chiral upgrade to CH^* incorporating OPE data and curve geometry is developed in the earlier sections of this chapter.

17.7.1 COMPACT GENERATORS AND THE MORITA EQUIVALENCE

Definition 17.7.1 (Compact generator). Let $\mathcal{C}$ be a k -linear dg-category admitting all cones, shifts, and retracts (i.e. a pretriangulated dg-category). An object $b \in \mathcal{C}$ is a *compact generator* if:

- (i) *Compactness*: the functor $\mathrm{RHom}_C(b, -): C \rightarrow \mathrm{Ch}(k)$ preserves arbitrary coproducts (equivalently, filtered colimits);
- (ii) *Generation*: if $\mathrm{RHom}_C(b, c) \simeq 0$ for an object $c \in C$, then $c \simeq 0$.

Write $A := \mathrm{RHom}_C(b, b)$ for the endomorphism dg-algebra.

PROPOSITION 17.7.2 (*Morita equivalence* [260, 263];). Let C be a pretriangulated dg-category and $b \in C$ a compact generator with $A = \mathrm{RHom}_C(b, b)$. Define the functor

$$\Psi: C \longrightarrow \mathrm{Perf}(A), \quad \Psi(c) := \mathrm{RHom}_C(b, c),$$

where $\mathrm{Perf}(A)$ denotes the dg-category of perfect (compact) right A -modules. Then Ψ is a quasi-equivalence of dg-categories.

Proof. The argument has two steps.

Fully faithful. For any $c, c' \in C$, the map

$$\Psi_{c, c'}: \mathrm{RHom}_C(c, c') \longrightarrow \mathrm{RHom}_A(\mathrm{RHom}_C(b, c), \mathrm{RHom}_C(b, c'))$$

is the composition map. When $c = b$, the right-hand side is $\mathrm{RHom}_A(A, \Psi(c')) \simeq \Psi(c')$, which equals the left-hand side $\mathrm{RHom}_C(b, c')$ by definition. The full subcategory of objects c for which $\Psi_{c, -}$ is an isomorphism contains b and is closed under cones, shifts, and retracts (since $\mathrm{RHom}_C(-, c')$ and Ψ both preserve these operations). Since b generates C , the subcategory is all of C .

Essentially surjective. The image of Ψ contains the free module $A = \Psi(b)$ and is closed under cones, shifts, and retracts (since Ψ is an exact functor of pretriangulated categories). Every perfect A -module is built from A by finitely many cones, shifts, and retracts, so Ψ is essentially surjective onto $\mathrm{Perf}(A)$.

The result is standard: see Keller [260], Schwede–Shipley [371], and Toën [263] for the ∞ -categorical refinement. $\square$

17.7.2 THE DERIVED CENTER

Definition 17.7.3 (*Derived center of a dg-category*). For a k -linear dg-category C , the *derived center* is the dg-algebra of derived endomorphisms of the identity functor:

$$Z_{\mathrm{der}}(C) := \mathrm{RHom}_{\mathrm{Fun}(C, C)}(\mathrm{Id}_C, \mathrm{Id}_C).$$

A degree- n cocycle in $Z_{\mathrm{der}}(C)$ is a natural transformation $\mathrm{Id}_C \Rightarrow \mathrm{Id}_C[n]$; its cohomology class is a derived natural transformation. The product on $Z_{\mathrm{der}}(C)$ is composition of natural transformations; in particular, $H^0(Z_{\mathrm{der}}(C))$ is the ordinary center of the homotopy category $[C]$.

17.7.3 ENDOFUNCTORS AS BIMODULES

The bridge between the derived center and topological Hochschild cochains is the identification of endofunctors with bimodules.

PROPOSITION 17.7.4 (*Endofunctor–bimodule equivalence* [263, 46];). For a dg-algebra A , there is a quasi-equivalence of dg-categories

$$\mathrm{Fun}_{\mathrm{cocont}}(\mathrm{Perf}(A), \mathrm{Perf}(A)) \simeq A\text{-bimod}^{\mathrm{perf}},$$

where the left-hand side consists of cocontinuous (colimit-preserving) dg-functors $\text{Perf}(A) \rightarrow \text{Perf}(A)$, and the right-hand side is the dg-category of perfect A - A -bimodules (equivalently, perfect A^e -modules, where $A^e = A \otimes A^{\text{op}}$). The equivalence sends a bimodule M to the tensor functor $-\otimes_A^L M$.

Proof sketch. The Eilenberg–Watts theorem for dg-categories: every cocontinuous functor $F: \text{Perf}(A) \rightarrow \text{Perf}(A)$ is represented by the bimodule $M_F := F(A)$, where A carries its canonical left module structure and M_F inherits a right A -structure from the right action of $A = \text{End}(A)$ on the free module. The assignment $F \mapsto F(A)$ is quasi-inverse to $M \mapsto (-\otimes_A^L M)$. See Toën [263] and Ben-Zvi–Francis–Nadler [46] for the ∞ -categorical statement. $\square$

COROLLARY 17.7.5 (*Identity functor = diagonal bimodule*). Under the equivalence of Proposition 17.7.4, the identity functor $\text{Id}: \text{Perf}(A) \rightarrow \text{Perf}(A)$ corresponds to the diagonal bimodule ${}_A A_A$.

Proof. The identity functor sends the free module A to itself: $\text{Id}(A) = A$. The corresponding bimodule is therefore A , with left A -action by left multiplication and right A -action by right multiplication. This is the diagonal bimodule. $\square$

17.7.4 THE MAIN IDENTIFICATION

THEOREM 17.7.6 (*Derived center = topological Hochschild cochains;*). Let C be a pretriangulated dg-category with compact generator b , and set $A = \text{RHom}_C(b, b)$. There is a natural quasi-isomorphism of dg-algebras

$$Z_{\text{der}}(C) \simeq \text{HH}^\bullet(A, A) := \text{RHom}_{A^e}(A, A). \quad (17.2)$$

In particular, the derived center depends on C only up to Morita equivalence.

Proof. The proof assembles the three preceding results.

Step 1 (Morita reduction). By Proposition 17.7.2, b being a compact generator gives a quasi-equivalence $\Psi: C \xrightarrow{\sim} \text{Perf}(A)$. The derived center is manifestly invariant under quasi-equivalence of dg-categories (a quasi-equivalence Ψ induces a quasi-isomorphism $\Psi_*: Z_{\text{der}}(C) \xrightarrow{\sim} Z_{\text{der}}(\text{Perf}(A))$ by conjugation: $\alpha \mapsto \Psi \circ \alpha \circ \Psi^{-1}$), so

$$Z_{\text{der}}(C) \simeq Z_{\text{der}}(\text{Perf}(A)) = \text{RHom}_{\text{Fun}(\text{Perf}(A), \text{Perf}(A))}(\text{Id}, \text{Id}).$$

Step 2 (Endofunctors = bimodules). By Proposition 17.7.4, cocontinuous endofunctors of $\text{Perf}(A)$ are identified with A -bimodules. Applying RHom in the functor category translates to RHom in the bimodule category:

$$\text{RHom}_{\text{Fun}}(\text{Id}, \text{Id}) \simeq \text{RHom}_{A\text{-bimod}}(M_{\text{Id}}, M_{\text{Id}}).$$

Step 3 (Identity $\mapsto$ diagonal). By Corollary 17.7.5, $M_{\text{Id}} = {}_A A_A$ is the diagonal bimodule. Therefore:

$$Z_{\text{der}}(\text{Perf}(A)) \simeq \text{RHom}_{A^e}(A, A) = \text{HH}^\bullet(A, A).$$

Naturality. Each step is natural: the Morita equivalence is natural in the generator b , the endofunctor–bimodule equivalence is natural in A , and RHom is a bifunctor. The composite isomorphism (17.2) is therefore natural in C . $\square$

Remark 17.7.7 (*Provenance*). The identification $Z_{\text{der}}(C) \simeq \text{HH}^\bullet(A)$ is implicit in Keller [260] and made explicit in the framework of $(\infty, 1)$ -categories by Ben-Zvi–Francis–Nadler [46] and Toën [263]. The argument presented here distills the essential chain of identifications without passing through the full $(\infty, 2)$ -categorical machinery. For the factorization-algebra refinement relevant to chiral algebras, see Costello–Gwilliam [92, Chapter 5].

17.7.5 INDEPENDENCE OF GENERATOR: MORITA INVARIANCE OF TOPOLOGICAL HOCHSCHILD COHOMOLOGY

THEOREM 17.7.8 (*Morita invariance of $\mathrm{HH}^\bullet$* ;). Let A and A' be dg-algebras that are Morita equivalent, meaning there exists a dg-category $\mathcal{C}$ with compact generators b, b' such that $A \simeq \mathrm{RHom}(b, b)$ and $A' \simeq \mathrm{RHom}(b', b')$. Then there is a natural quasi-isomorphism

$$\mathrm{HH}^\bullet(A, A) \simeq \mathrm{HH}^\bullet(A', A').$$

Proof. By Theorem 17.7.6, both sides are quasi-isomorphic to $Z_{\mathrm{der}}(\mathcal{C})$, which depends only on the dg-category $\mathcal{C}$ and not on the choice of generator. Concretely, the chain of quasi-isomorphisms is:

$$\mathrm{HH}^\bullet(A) \xleftarrow{\sim} Z_{\mathrm{der}}(\mathcal{C}) \xrightarrow{\sim} \mathrm{HH}^\bullet(A').$$

□

For the explicit bimodule construction of the Morita transfer map, we record the following refinement.

PROPOSITION 17.7.9 (*Explicit Morita transfer*;). Let $P = \mathrm{RHom}_{\mathcal{C}}(b, b')$ and $P^\vee = \mathrm{RHom}_{\mathcal{C}}(b', b)$ be the bimodules implementing the Morita equivalence, so that $P \otimes_{A'}^\mathbf{L} P^\vee \simeq A$ and $P^\vee \otimes_A^\mathbf{L} P \simeq A'$. The Morita transfer map

$$\Phi: \mathrm{HH}^\bullet(A) \longrightarrow \mathrm{HH}^\bullet(A'), \quad f \longmapsto P^\vee \otimes_A^\mathbf{L} f \otimes_A^\mathbf{L} P,$$

is a quasi-isomorphism of dg-algebras.

Proof. We verify Φ is well-defined, multiplicative, and a quasi-isomorphism.

Well-definedness. An element $f \in \mathrm{HH}^n(A) = \mathrm{RHom}_{A^e}(A, A)^n$ is an A -bimodule map $A \rightarrow A[n]$. The conjugation $\Phi(f) := P^\vee \otimes_A f \otimes_A P$ is the composition

$$A' \simeq P^\vee \otimes_A P \xrightarrow{\mathrm{id} \otimes f \otimes \mathrm{id}} P^\vee \otimes_A A[n] \otimes_A P \simeq P^\vee \otimes_A P[n] \simeq A'[n],$$

which uses $A \otimes_A P \simeq P$ and $P^\vee \otimes_A A \simeq P^\vee$ (left/right unit). The composite is an A' -bimodule map $A' \rightarrow A'[n]$, hence an element of $\mathrm{HH}^n(A')$.

Multiplicativity. For $f, g \in \mathrm{HH}^\bullet(A)$, the composition $\Phi(f) \circ \Phi(g)$ is $P^\vee \otimes_A f \otimes_A P \circ P^\vee \otimes_A g \otimes_A P$. Using $P \otimes_{A'} P^\vee \simeq A$ to contract the inner P - $P^\vee$ pair:

$$\Phi(f) \circ \Phi(g) = P^\vee \otimes_A f \otimes_A \underbrace{(P \otimes_{A'} P^\vee)}_{\simeq A} \otimes_A g \otimes_A P \simeq P^\vee \otimes_A (f \circ g) \otimes_A P = \Phi(f \circ g).$$

Quasi-isomorphism. The inverse map $\Phi^{-1}(g) = P \otimes_{A'} g \otimes_{A'} P^\vee$ is constructed symmetrically. Since $P \otimes_{A'} P^\vee \simeq A$ and $P^\vee \otimes_A P \simeq A'$, we have $\Phi^{-1} \circ \Phi \simeq \mathrm{id}$ and $\Phi \circ \Phi^{-1} \simeq \mathrm{id}$, using the same contraction. Hence Φ is a quasi-isomorphism. □

Remark 17.7.10 (*Chiral application*). For a chiral algebra $\mathcal{A}$ on a curve X , the module category $\mathrm{Mod}_{\mathcal{A}}$ (Definition 15.1.5) is a pretriangulated dg-category. When $\mathrm{Mod}_{\mathcal{A}}$ is compactly generated with compact generator $\mathrm{Free}_{\mathcal{A}}(k)$, Theorem 17.7.6 gives

$$Z_{\mathrm{der}}(\mathrm{Mod}_{\mathcal{A}}) \simeq CH^\bullet(\mathcal{A}, \mathcal{A}).$$

This identification controls the deformations of the *category* $\mathrm{Mod}_{\mathcal{A}}$, not merely the algebra $\mathcal{A}$ itself: an element of $CH^2(\mathcal{A})$ deforms the identity functor on modules, hence the entire module theory.

Compact generation for the standard families. The hypothesis is verified in the following cases:

- (a) *Heisenberg* $\mathcal{H}_k$ ($k \neq 0$): the module category is equivalent to Mod_{Weyl} (Weyl algebra modules), which is compactly generated by the vacuum module F_0 . (The Weyl algebra is Morita-simple.)
- (b) *Universal affine* $V_k(\mathfrak{g})$ at generic k : the category $\text{KL}_k(\mathfrak{g})$ (Kazhdan–Lusztig category) is compactly generated by generalized Verma modules [257]. At non-generic (e.g., admissible) levels, compact generation holds by the Arakawa–Kawasetsu theorem [10] (C_2 -cofiniteness for the simple quotient $L_k(\mathfrak{g})$).
- (c) *Virasoro* Vir_c at generic c : the free-field resolution (Feigin–Fuchs) provides a compact generator. At rational c , compact generation follows from C_2 -cofiniteness of the minimal model $L(c_{p,q}, 0)$ [319].
- (d) *Principal $\mathcal{W}$ -algebras*: compact generation follows from the quantum Drinfeld–Sokolov reduction, which preserves compact generation when the BRST complex is well-defined [11].

For the universal algebras at generic level (the primary setting of this monograph), compact generation is unconditional. The hypothesis fails only for pathological algebras with uncountably-generated module categories, which do not arise in the Lie-theoretic landscape.

17.8 FACTORIZATION HOMOLOGY ON THE ANNULUS: TOPOLOGICAL HOCHSCHILD CHAINS (M7)

The complementary side of topological Hochschild theory is homological: while topological Hochschild cochains are the derived center (deformations of the identity functor), topological Hochschild chains are the derived trace (factorization homology over the circle). The excision axiom for factorization homology reduces the circle computation to a tensor product over an interval, yielding the identification of factorization homology on S^1 with topological Hochschild chains.

17.8.1 FACTORIZATION HOMOLOGY: RECOLLECTIONS

Definition 17.8.1 (Factorization homology over a manifold). For a locally constant factorization algebra $\mathcal{F}$ on a manifold M with values in a symmetric monoidal ∞ -category $\mathcal{V}$, the *factorization homology* of $\mathcal{F}$ over M is the global sections:

$$\int_M \mathcal{F} := \mathcal{F}(M) \in \mathcal{V}.$$

When $\mathcal{F}$ is constructible rather than locally constant, this is the homotopy colimit of $\mathcal{F}$ over the Weiss topology on M (Ayala–Francis [30], Costello–Gwilliam [92]).

The factorization homology functor satisfies two fundamental properties that make it computable: *local constancy* (the value on a disk is determined by the E_n -algebra structure) and *excision* (the value on a glued manifold is computed by a derived tensor product).

THEOREM 17.8.2 (Excision; [30, Theorem 3.18];). Let $M = M_+ \cup_N M_-$ be a collar-gluing decomposition: N is a codimension-1 manifold with a collar neighborhood in M , and $M_{\pm}$ are the two halves. Then there is a natural equivalence

$$\int_M \mathcal{F} \simeq \int_{M_+} \mathcal{F} \otimes_{\int_N \mathcal{F}}^{\mathbb{L}} \int_{M_-} \mathcal{F}.$$

17.8.2 THE CIRCLE COMPUTATION BY EXCISION

THEOREM 17.8.3 (*Factorization homology on $S^1 = \text{topological Hochschild chains}$;). Let $\mathcal{F}$ be a locally constant factorization algebra on S^1 with values in $\text{Ch}(k)$, and let C be the associated E_1 -category (the dg-category of modules over the E_1 -algebra $A = \mathcal{F}(I)$ for any interval $I \subset S^1$). Then there is a natural equivalence*

$$\int_{S^1} \mathcal{F} \simeq \text{HH}_\bullet(C) := A \otimes_{A^e}^L A, \quad (17.3)$$

where $A^e = A \otimes A^{\text{op}}$.

Proof. The proof proceeds by cutting S^1 into overlapping arcs and applying excision.

Step 1 (Collar-gluing decomposition of S^1). Choose a decomposition $S^1 = U_+ \cup U_-$ where U_+ and U_- are open arcs (each diffeomorphic to an interval) whose intersection consists of two disjoint intervals:

$$U_+ \cap U_- = J_1 \sqcup J_2.$$

Concretely, parametrize $S^1 = \mathbb{R}/\mathbb{Z}$ and take $U_+ = (0, 3/4)$, $U_- = (1/2, 5/4)$, so that $J_1 = (1/2, 3/4)$ and $J_2 = (0, 1/4)$ (the latter wrapping around $0 \equiv 1$). The collar structure along the boundary is given by the intervals J_1 and J_2 themselves.

Step 2 (Local constancy on arcs). Since $\mathcal{F}$ is locally constant, its value on any interval is equivalent to the E_1 -algebra A :

$$\mathcal{F}(U_+) \simeq A, \quad \mathcal{F}(U_-) \simeq A, \quad \mathcal{F}(J_1) \simeq A, \quad \mathcal{F}(J_2) \simeq A.$$

More precisely, for each interval $J \subset S^1$, the restriction $\mathcal{F}|_J$ is equivalent to the factorization algebra associated to a single E_1 -algebra A , and the value $\mathcal{F}(J) \simeq A$ is given by the E_1 -structure.

Step 3 (Excision). By the excision axiom (Axiom 17.8.2) applied to the collar-gluing $S^1 = U_+ \cup_{J_1 \sqcup J_2} U_-$:

$$\int_{S^1} \mathcal{F} \simeq \mathcal{F}(U_+) \otimes_{\mathcal{F}(J_1) \otimes \mathcal{F}(J_2)}^L \mathcal{F}(U_-).$$

Substituting the local constancy identifications from Step 2:

$$\int_{S^1} \mathcal{F} \simeq A \otimes_{A^e}^L A, \quad A^e := A \otimes A^{\text{op}}. \quad (17.4)$$

Step 4 (Bimodule structure and identification with HH). The key is to identify the $A \otimes A$ -module structures on the two copies of A in (17.4). The inclusions $J_1 \hookrightarrow U_+$ and $J_2 \hookrightarrow U_+$ give the left and right A -actions on $\mathcal{F}(U_+) \simeq A$: the inclusion of J_1 at one end of the arc U_+ provides the left action, and the inclusion of J_2 at the other end provides the right action. That these are the *regular* left and right actions (i.e., $a \cdot_L x = ax$ and $x \cdot_R b = xb$) follows from local constancy: the factorization algebra $\mathcal{F}$ on the arc U_+ is equivalent to the E_1 -algebra A (Step 2), and the collar inclusions $J_i \hookrightarrow U_+$ restrict to the identity on A (since all intervals carry the same algebra by local constancy). The bimodule structure is therefore $(a_1, a_2) \cdot x = a_1 \cdot x \cdot a_2$, which is precisely the diagonal bimodule ${}_A A_A$. Similarly for $\mathcal{F}(U_-)$, where the *opposite* orientation of U_- relative to U_+ introduces the A^{op} factor: the left action from J_1 on U_- is the right action on U_+ , and vice versa. This is the source of the A^{op} in $A^e = A \otimes A^{\text{op}}$.

The tensor product over $A \otimes A$ of two copies of the diagonal bimodule is, by definition, the topological Hochschild chain complex:

$$A \otimes_{A \otimes A^{\text{op}}}^L A = A \otimes_{A^e}^L A =: \text{HH}_\bullet(A).$$

Here $A \otimes A$ acts on the left copy of A via $(a_1, a_2) \cdot x = a_1 \cdot x \cdot a_2$ (using the bimodule structure from J_1 and J_2), and on the right copy of A symmetrically; the tensor product over this action contracts the two bimodules into the cyclic bar complex $\cdots \rightarrow A^{\otimes 3} \rightarrow A^{\otimes 2} \rightarrow A$ computing $\mathrm{HH}_\bullet(A)$.

Step 5 (Passage to the categorical statement). If $C = \mathrm{Perf}(A)$ is the dg-category of perfect A -modules, then $\mathrm{HH}_\bullet(C)$ is defined as $\mathrm{HH}_\bullet(A)$ via the Morita-invariant cyclic bar construction. Combining with Step 4 gives the stated equivalence $\int_{S^1} \mathcal{F} \simeq \mathrm{HH}_\bullet(C)$. $\square$

Remark 17.8.4 (Provenance). The identification of factorization homology on S^1 with topological Hochschild homology is due (in the topological setting) to Ben-Zvi–Francis–Nadler [46] and Ayala–Francis [30]; in the vertex algebra setting, the parallel result appears in Costello–Gwilliam [92, Chapter 5]. The excision argument above follows the treatment in [30].

17.8.3 THE MONODROMY SUBTLETY: FROM CHIRAL TO LOCALLY CONSTANT

The excision argument of Theorem 17.8.3 requires $\mathcal{F}$ to be a *locally constant* factorization algebra on S^1 . In the chiral algebraic setting, the situation is more delicate: a chiral algebra $\mathcal{A}$ on a curve X is a factorization algebra on X that is locally constant on small disks (the E_1 -structure on intervals), but the passage from an interval to the full circle involves identifying the endpoints. This identification may carry *monodromy*, a nontrivial automorphism of the E_1 -algebra $A = \mathcal{A}(I)$ arising from parallel transport around the puncture.

Definition 17.8.5 (Monodromy automorphism). Let $\mathcal{A}$ be a chiral algebra on a punctured disk $D^\times = D \setminus \{0\}$, and let $I \subset D^\times$ be an interval. The fundamental group $\pi_1(D^\times) \cong \mathbb{Z}$ acts on the fiber $A = \mathcal{A}(I)$ by monodromy. The *monodromy automorphism* is the generator:

$$\mathfrak{m}: A \xrightarrow{\sim} A,$$

obtained by analytically continuing sections of $\mathcal{A}$ around the puncture once counterclockwise.

PROPOSITION 17.8.6 (*Monodromy for standard families*;). (a) *Heisenberg* $\mathcal{H}_k$. The monodromy automorphism $\mathfrak{m}$ acts on the mode algebra generated by $\{J_n\}_{n \in \mathbb{Z}}$ via $\mathfrak{m}(J_n) = J_n$ for all n . The monodromy is *trivial* on the algebra. However, on Fock modules F_λ , the monodromy acts by the scalar $e^{2\pi i \lambda^2 / (2k)}$ (from the conformal weight $h_\lambda = \lambda^2 / (2k)$ contribution to q^{L_0}). For the vacuum module F_0 , this is trivial.

(b) *Affine* $\widehat{\mathfrak{g}}_k$. The monodromy is trivial on the algebra (the current modes J_n^α are single-valued). On highest-weight modules V_Λ at integer level, the monodromy acts by $e^{2\pi i h_\Lambda}$ where $h_\Lambda = (\Lambda, \Lambda + 2\rho) / 2(k + h^\vee)$ is the conformal weight.

(c) *Lattice VOA* V_Λ . The vertex operators e^α for $\alpha \in \Lambda$ have monodromy $\mathfrak{m}(e^\alpha) = e^{2\pi i (\alpha, \alpha) / 2} e^\alpha$. For an even lattice, $(\alpha, \alpha) \in 2\mathbb{Z}$, so the monodromy is trivial. For an odd lattice, the monodromy is a sign $(-1)^{(\alpha, \alpha)}$ on each sector (note: odd lattices define *super* vertex algebras; the sign is the fermion parity).

Proof. In each case, the monodromy is computed from the L_0 -eigenvalue. For a primary field ϕ of conformal weight h , the operator product expansion $\phi(e^{2\pi i} z) = e^{2\pi i h} \phi(z)$ gives the monodromy phase.

(a) For $\mathcal{H}_k$: the current $J(z) = \sum_n J_n z^{-n-1}$ has conformal weight 1, so $J(e^{2\pi i} z) = e^{2\pi i} \cdot J(z) \cdot e^{-2\pi i} = J(z)$ (the z^{-n-1} factor absorbs the phase). More precisely, $\mathfrak{m}(J_n) = J_n$ because the modes are defined as contour integrals $J_n = \oint z^n J(z) dz$ over cycles that are invariant under the monodromy deck

transformation. On F_λ , the highest-weight vector $|\lambda\rangle$ has L_0 -eigenvalue $h_\lambda = \lambda^2/(2k)$, giving the stated phase.

(b) Identical argument for $\widehat{\mathfrak{g}}_k$, with h_λ replacing h_λ .

(c) For V_Λ , e^α has conformal weight $(\alpha, \alpha)/2$, so $\mathfrak{m}(e^\alpha) = e^{2\pi i(\alpha, \alpha)/2} e^\alpha$. For an even lattice, $(\alpha, \alpha)/2 \in \mathbb{Z}$, so the phase is 1. $\square$

Remark 17.8.7 (Twisted topological Hochschild homology). When the monodromy $\mathfrak{m} : A \rightarrow A$ is nontrivial, the factorization homology on S^1 computes the $\mathfrak{m}$ -twisted topological Hochschild homology:

$$\int_{S^1} \mathcal{F} \simeq \mathrm{HH}_\bullet(A; {}_{\mathfrak{m}}A) := A \otimes_{A^e}^{\mathbf{L}} {}_{\mathfrak{m}}A,$$

where ${}_{\mathfrak{m}}A$ is A as a right A -module but with left action twisted by $\mathfrak{m}$: $a \cdot_{\mathfrak{m}} x := \mathfrak{m}(a) \cdot x$. The excision argument of Theorem 17.8.3 goes through verbatim with U_- contributing the twisted bimodule structure: the analytic continuation around the full circle inserts $\mathfrak{m}$ into one of the two collar inclusions.

For the standard families of Proposition 17.8.6, the monodromy is trivial on the algebra itself (the algebra modes are single-valued), so the untwisted identification (17.3) holds. The twist becomes visible only at the module level: the torus partition function $Z_{T^2}(\mathcal{A}) = \mathrm{Tr}_{\mathcal{H}}(q^{L_0 - c/24})$ traces over the Hilbert space $\mathcal{H}$ with the insertion of q^{L_0} , which is precisely the twist by the monodromy of the cylinder.

Remark 17.8.8 (The $(g=1, k=0)$ modular MC component). The $(g=1, n=0)$ component of the modular MC equation (Chapter A) is:

$$d\Theta_{\mathcal{A}}^{(1,0)} + \frac{1}{2}[\Theta_{\mathcal{A}}^{(0)}, \Theta_{\mathcal{A}}^{(0)}]^{(1,0)} + \Delta_{\mathrm{sew}}\Theta_{\mathcal{A}}^{(0,2)} = 0.$$

The sewing operator Δ_{sew} contracts two external legs of $\Theta_{\mathcal{A}}^{(0,2)}$ using the propagator on the torus. This is the genus-1 topological Hochschild differential: the annulus amplitude $\Theta_{\mathcal{A}}^{(0,2)}$ evaluated on two inputs and sewn into a torus is the trace $\mathrm{Tr}(m_2(-, -))$, the standard generator of $\mathrm{HH}_0(A)$. The identification of $\int_{S^1} \mathcal{A}$ with $\mathrm{HH}_\bullet(A)$ (Theorem 17.8.3) is therefore the $n=0$ case of the general MC $\rightarrow$ sewing correspondence.

17.8.4 HEISENBERG VERIFICATION

Example 17.8.9 (Topological Hochschild chains of the Heisenberg algebra;). We verify the identification $\int_{S^1} \mathcal{H}_k \simeq \mathrm{HH}_\bullet(\mathcal{H}_k)$ against the known genus-1 partition function.

Step 1 (The algebra). The Heisenberg vertex algebra $\mathcal{H}_k$ at level $k \neq 0$ is generated by a single current $J(z) = \sum_{n \in \mathbb{Z}} J_n z^{-n-1}$ with OPE $J(z)J(w) \sim k/(z-w)^2$. The mode algebra is the Weyl algebra on infinitely many generators: $[J_m, J_n] = k m \delta_{m+n, 0}$. The zero mode J_0 acts on the vacuum Fock module $\mathcal{H}_k = F_0$ (with J_0 -eigenvalue 0); the full module category contains Fock modules F_λ for $\lambda \in k^{-1}\mathbb{Z}$.

Step 2 (Chiral Hochschild homology computation). By the computation in Example 17.6.18:

$$\mathrm{HH}_\bullet^{\mathrm{ch}}(\mathcal{H}_k) = \mathbb{C}[c] \otimes \Lambda(\sigma), \quad |c| = 2, \quad |\sigma| = 1.$$

The class $c \in \mathrm{HH}_2$ is the Chern class of the level (the universal deformation class), and $\sigma \in \mathrm{HH}_1$ is the fundamental class of S^1 in the cyclic direction.

Step 3 (Genus-1 partition function). The factorization homology $\int_{S^1} \mathcal{H}_k \simeq \mathrm{HH}_\bullet(\mathcal{H}_k)$ computes topological Hochschild chains. The *torus partition function* is the Euler characteristic of $\int_{T^2} \mathcal{H}_k$, which

by the sewing formula reduces to $\mathrm{Tr}_{F_0}(q^{L_0-c/24})$ where F_0 is the vacuum module (the trace inserts the q -grading operator on the space of states):

$$Z_{T^2}(\mathcal{H}_k) = \mathrm{Tr}_{F_0}(q^{L_0-1/24}) = q^{-1/24} \prod_{n=1}^{\infty} \frac{1}{1-q^n} = \frac{1}{\eta(\tau)},$$

where $\eta(\tau) = q^{1/24} \prod_{n \geq 1} (1 - q^n)$ is the Dedekind eta function.

Step 4 (Consistency check: HH_0). The degree-0 topological Hochschild homology $\mathrm{HH}_0(\mathcal{H}_k) = A/[A, A]$ is the abelianization of the mode algebra. For the Weyl algebra generated by $\{J_n\}$, all commutators $[J_m, J_n] = km \delta_{m+n,0}$ are scalar, so $A/[A, A]$ is the symmetric algebra on the generators modulo the scalars: $\mathrm{HH}_0 \cong \mathbb{C}$ (one-dimensional, generated by the vacuum class). This is consistent with the partition function Z_{T^2} being a single function (not a vector): the space of conformal blocks on the torus is one-dimensional for the Heisenberg algebra at any level.

Step 5 (Comparison with Theorem 17.6.21). The cyclic homology $\mathrm{HC}_0(\mathcal{H}_k) = \mathbb{C}$ matches the one-dimensional space of genus-1 conformal blocks. The full topological Hochschild chain complex $\mathrm{HH}_\bullet(\mathcal{H}_k) = \mathbb{C}[c] \otimes \Lambda(\sigma)$ encodes the deformation theory of the torus partition function: c controls the variation of Z_{T^2} with respect to the level k , and σ represents the circle direction in the torus.

Remark 17.8.10 (Annulus vs torus). The factorization homology $\int_{S^1} \mathcal{F}$ over the circle gives the topological Hochschild chains $\mathrm{HH}_\bullet(A)$. The partition function on the torus $T^2 = S^1 \times S^1$ involves a further circle integral, which gives the cyclic homology $\mathrm{HC}_\bullet(A)$ (the S^1 -equivariant version of $\mathrm{HH}_\bullet$). Schematically:

$$\int_{S^1} \mathcal{F} = \mathrm{HH}_\bullet(A), \quad \int_{T^2} \mathcal{F} = \mathrm{HC}_\bullet(A) = \mathrm{HH}_\bullet(A)_{hS^1}.$$

The first circle is the spatial circle (excision gives HH); the second is the thermal circle (the S^1 -action on HH gives HC). For the Heisenberg: $\mathrm{HC}_0(\mathcal{H}_k) = \mathbb{C}$, and the character $\mathrm{Tr}_{F_0}(q^{L_0-c/24}) = 1/\eta(\tau)$ is the generating function for the graded dimensions of the cyclic complex.

Remark 17.8.11 (Relation to Theorem C (complementarity)). The topological Hochschild chain identification provides the genus-1 input to the complementarity theorem (Theorem 13.15.14). At genus 1, the complementarity formula reads $Q_1(\mathcal{A}) \oplus Q_1(\mathcal{A}^!) \cong H^*(\overline{\mathcal{M}}_{1,1}, \mathcal{Z}(\mathcal{A}))$. The left-hand side is computed by topological Hochschild chains of $\mathcal{A}$ and $\mathcal{A}^!$ respectively (via the annulus identification); the right-hand side is the cohomology of the moduli space with coefficients in the center sheaf. The complementarity is the statement that the two topological Hochschild chain complexes assemble into a complete basis for the modular functor at genus 1.

17.8.5 SUMMARY AND FUTURE DIRECTIONS

The theoretical arc of Part I is now complete. Algebraic foundations (§3) supplied the operadic language; configuration spaces (§5) gave it geometric content; the bar-cobar adjunction (Theorem A) and the Verdier intertwining $D_{\mathrm{Ran}}(B(\mathcal{A})) \simeq B(\mathcal{A}^!)$ established duality on the Ran space; and the higher-genus theory assembled the proved scalar package $\kappa(\mathcal{A})$, the proved spectral package $(\Delta_{\mathcal{A}}, \Pi_{\mathcal{A}})$, and the bar-intrinsic Maurer–Cartan element $\Theta_{\mathcal{A}}$. The three main theorems (adjunction (A), inversion on the Koszul locus (B), and Lagrangian complementarity (C)) are projections of a single structure: the modular Koszul object associated to a factorization algebra on curves. Chiral Hochschild cohomology, developed in this chapter, is the infinitesimal invariant of that structure: concentrated in degrees $\{0, 1, 2\}$ for Koszul algebras (Theorem H),

it classifies deformations, detects obstructions, and exchanges under Koszul duality via the Connes operator.

The modular characteristic $\kappa(\mathcal{A})$ is only the linear leading term of this structure. Part II extracts the full nonlinear content: the shadow obstruction tower $\kappa(\mathcal{A}) \rightarrow \Delta \rightarrow \mathfrak{C} \rightarrow \mathfrak{Q} \rightarrow \cdots$, a hierarchy of finite-order invariants whose all-degree limit is the universal class $\Theta_{\mathcal{A}}$.

Part II

The Characteristic Datum

The modular characteristic $\kappa(\mathcal{A}) = \text{av}(r(z))$ is the linear leading term of the categorical logarithm: even this degree-2 scalar is extracted from the collision residue $r(z)$ by a Σ_2 -coinvariant integral on the Fulton–MacPherson compactification $\overline{C}_2(X)$, so the shadow tower is rooted in curve geometry from the start. Part II develops the full nonlinear structure: the shadow obstruction tower $\kappa \rightarrow \Delta \rightarrow \mathfrak{C} \rightarrow \mathfrak{Q} \rightarrow \cdots$, each level a constructive finite-order invariant with obstruction classes in the cyclic deformation complex; the branch-line reductions that extract structural theorems from finite-dimensional quotients; and the computational methods that verify every formula by at least three independent paths. The all-degree limit is the universal Maurer–Cartan element $\Theta_{\mathcal{A}}$, proved by the bar-intrinsic construction (Theorem 13.21.69).

Chapter 18

Ambient complementarity, nonlinear modular shadows, and the quartic resonance class

The modular characteristic $\kappa(\mathcal{A})$ (Theorem D) and the spectral discriminant $\Delta_{\mathcal{A}}$ are the linear face of a single ambient deformation problem. The ambient problem carries a (-1) -shifted symplectic form, and the two dual packages $\mathcal{Q}_g(\mathcal{A})$ and $\mathcal{Q}_g(\mathcal{A}^!)$ are complementary Lagrangians inside it. Their interaction produces an infinite nonlinear tower

$$\kappa \longrightarrow \Delta \longrightarrow \mathfrak{C} \longrightarrow \mathfrak{Q} \longrightarrow \Theta,$$

the *shadow obstruction tower*: the sequence of finite-order projections $\Theta_{\mathcal{A}}^{\leq r}$ of the universal MC element $\Theta_{\mathcal{A}} \in \text{MC}(\mathfrak{g}_{\mathcal{A}}^{\text{mod}})$ (Theorem 13.21.69: $\Theta_{\mathcal{A}} := D_{\mathcal{A}} - d_0$ is MC because $D_{\mathcal{A}}^2 = 0$; all-degree convergence $\Theta_{\mathcal{A}} = \varprojlim_r \Theta_{\mathcal{A}}^{\leq r}$ by Theorem 13.22.61).

The construction proceeds in three strata.

- (i) **Formal and conditional.** The cyclic deformation package and the universal twisting kernel yield an ambient complementarity formal moduli problem, a complementarity potential $S_{\mathcal{A}}$, and a derived critical-locus model $\text{Crit}(S_{\mathcal{A}})$ for simultaneous self-dual deformations.
- (ii) **Finite-order and constructive.** The quadratic, cubic, and quartic shadows

$$H_{\mathcal{A}}, \quad \mathfrak{C}_{\mathcal{A}}, \quad \mathfrak{Q}_{\mathcal{A}}$$

are defined at each finite truncation $\Theta_{\mathcal{A}}^{\leq r}$, with master and clutching identities and a quartic shadow graph cocycle.

- (iii) **Nonlinear and modular.** For Virasoro and principal $\mathcal{W}_N$, the quartic contact sector has a determinant line whose vanishing promotes the Gram-determinant divisor to a modular characteristic class. Its boundary law is the first nonlinear shadow of the clutching identity for $\Theta_{\mathcal{A}}$.

Remark 18.0.1 (Shadow obstruction tower as period correction). The shadow hierarchy $\kappa \rightarrow \Delta \rightarrow \mathfrak{C} \rightarrow \mathfrak{Q} \rightarrow \Theta$ admits a concrete interpretation as the Taylor expansion of the *full period correction* that restores nilpotency of the genus- g bar differential. At genus g , the fiberwise differential satisfies $d_{\text{fb}}^2 = \kappa \cdot \omega_g \neq 0$. The total corrected differential $D_g = d_0 + \sum_{n \geq 1} t_g^{(n)} d_n$ absorbs this curvature:

- $t_g^{(1)}$: determined by κ alone (the m_2 contribution; Theorem 13.21.44). This is the Faber–Pandharipande term.
- $t_g^{(2)}$: involves m_3 paired with genus- g propagators, giving the cubic shadow $\mathfrak{C}_{\mathcal{A}}$.
- $t_g^{(3)}$: involves m_4 and $m_3 \circ m_3$ terms, giving the quartic shadow $\mathfrak{Q}_{\mathcal{A}}$.
- $t_g^{(\infty)}$: the all-degree limit is $\Theta_{\mathcal{A}}$, the universal Maurer–Cartan element (Theorem 13.21.69).

The subleading corrections $t_g^{(n)}$ for $n \geq 2$ are *not* determined by κ : they depend on the higher A_∞ operations interacting with the Hodge data of $\overline{\mathcal{M}}_g$. This is the mechanism by which algebra-dependent modular information enters beyond the $\hat{A}$ -genus. The cohomology $H^*(\overline{B}^{(g)}(\mathcal{A}), D_g)$ (the factorization homology fiber) depends on the *full* correction, not just the leading term. See Remark K.7.1.

Status discipline. The universal Maurer–Cartan class $\Theta_{\mathcal{A}}$ exists unconditionally for every modular Koszul chiral algebra, by the bar-intrinsic construction (Theorem 13.21.69): one sets $\Theta_{\mathcal{A}} := D_{\mathcal{A}} - d_0$, where $D_{\mathcal{A}}$ is the genus-completed bar differential, and the Maurer–Cartan equation is the tautological consequence of $D_{\mathcal{A}}^2 = 0$. The shadow obstruction tower $\Theta_{\mathcal{A}}^{\leq r}$ consists of the finite-order projections of this proved element. The *constructive* value of the tower is computational: each level yields explicit graph-sum formulas (vertex labels from the transferred cyclic minimal model, edge contractions by the complementarity propagator) that the bar-intrinsic construction does not directly produce. The obstruction classes $o_{r+1}(\mathcal{A}) \in H^2(\mathcal{A}_{r+1,0}^{\text{sh}})$ measure the failure of *truncation* (can the degree- r approximation be extended one step further without changing its lower-order terms?), not the failure of *existence*. Every theorem below is tagged either as proved here, as a formal consequence of the bar-intrinsic construction, or as conjectural at the level of the *Hamiltonian refinement* (the graph-completed modular master action of §18.12).

Remark 18.0.2 (Prefundamental CG and the shadow obstruction tower). The finite-order constructive layer (shadows $H_{\mathcal{A}}, C_{\mathcal{A}}, Q_{\mathcal{A}}$ at degrees 2, 3, 4) interacts with the MC₃ prefundamental programme as follows. By the prefundamental Clebsch–Gordan ($V_n \otimes L^- \cong \bigoplus L^-$ (shifted), Theorem O.9.52), the evaluation-stable part of the Yangian category is preserved by the V_n -twist that generates the shadow obstruction tower’s clutching maps $\Lambda_P: \text{Sym}^r \rightarrow \text{Sym}^{r-2}$. This means that the tower of shadow obstructions $\{o_{\mathcal{A}}^{(r)}\}_{r \geq 3}$, governed by the master equation $\nabla_H(\text{Sh}_r) + o^{(r)} = 0$ (Theorem 18.9.3), restricts naturally to the prefundamental evaluation-stable sector. In particular, the quartic contact invariant Q^{contact} and the finite termination results for Heisenberg ($r = 2$), affine ($r = 3$), and $\beta\gamma$ ($r = 4$) are all compatible with the K_0 tensor structure determined by (R1).

18.1 THE UNIVERSAL MAURER–CARTAN PRINCIPLE

The thesis of this monograph is that the modular data of a chiral algebra (the genus corrections, the shadow obstruction tower, the non-renormalization theorems, the clutching identities) are not independent structures assembled by hand. They are all consequences of a *single* Maurer–Cartan equation in a *single* dg Lie algebra.

Definition 18.1.1 (Modular convolution dg Lie algebra;). Let $\mathcal{A}$ be a chiral algebra on a smooth projective curve with Koszul dual $\mathcal{A}^!$ on the locus where the duality package is defined. The following completed dg Lie algebra is the *strict model* of the modular quantum L_∞ -algebra (Remark 18.1.2); its Maurer–Cartan

moduli coincide with those of the full L_∞ -algebra. The *modular convolution dg Lie algebra* is the completed product

$$\mathfrak{g}_{\mathcal{A}}^{\text{mod}} := \prod_{\substack{g, n \geq 0 \\ 2g-2+n > 0}} \text{Hom}_{S_n}(C_\bullet(\overline{\mathcal{M}}_{g, n+1}), \text{Hom}((\mathcal{A}^!)^{\otimes n}, \mathcal{A}^!)),$$

graded by genus g (homological weight) and degree n , with

- (i) **Differential** $d_\partial: \mathfrak{g}_{\mathcal{A}}^{\text{mod}} \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ induced by the boundary stratification $\partial \overline{\mathcal{M}}_{g, n} \hookrightarrow \overline{\mathcal{M}}_{g, n}$, i.e. by pullback along the clutching morphisms of the Deligne–Mumford modular operad;
- (ii) **Bracket** $[\cdot, \cdot]: \mathfrak{g}_{\mathcal{A}}^{\text{mod}} \otimes \mathfrak{g}_{\mathcal{A}}^{\text{mod}} \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ given by operadic composition via stable-graph gluing: for f in the (g_1, n_1) -component and g in the (g_2, n_2) -component of $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$, the bracket $[f, g]_{g, n}$ is the signed sum over all stable graphs of genus $g = g_1 + g_2$ (or $g = g_1 + g_2 + 1$ for self-gluing) obtained by inserting the output of g into an input of f and composing with the Deligne–Mumford clutching map.

The Jacobi identity follows from the associativity of operadic composition, and $d_\partial^2 = 0$ from the cosimplicial identities of the modular operad’s boundary strata. By Theorem 3.1.24, $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ is the chiral instance of the convolution $s\mathcal{L}_\infty$ -algebra $\text{hom}^\alpha(D, A)$ of Robert–Nicoud–Wierstra [367], with $\alpha = \tau_{\text{ch}}$ the chiral twisting morphism.

Remark 18.1.2 (The modular L_∞ enrichment). The modular convolution algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ carries a natural modular L_∞ structure whose higher brackets ℓ_k ($k \geq 3$) arise from the Feynman transform of the modular operad $\{C_\bullet(\overline{\mathcal{M}}_{g, n})\}$ via A_∞/L_∞ homotopy transfer [299, §10.3]. The dg Lie bracket $[-, -]$ is the binary truncation. The Maurer–Cartan equation (18.1) is the strict shadow of the full L_∞ MC equation $\sum_{n \geq 1} \frac{1}{n!} \ell_n(\Theta, \dots, \Theta) = 0$; for the coderivation model these coincide (this is the MC moduli identification invoked in Definition 18.1.1). The full L_∞ MC equation admits *gauge equivalences* (homotopies between MC elements): two MC elements related by L_∞ gauge transform give quasi-isomorphic bar complexes. This is the homotopy-theoretic reason that bar-cobar inversion (Theorem B) is well-defined up to quasi-isomorphism.

THEOREM 18.1.3 (*Algebra structure = Maurer–Cartan element;*). An algebra structure on $\mathcal{A}$ together with its genus-refined modular data is equivalent to a Maurer–Cartan element $\Theta_{\mathcal{A}} \in \text{MC}(\mathfrak{g}_{\mathcal{A}}^{\text{mod}})$ satisfying

$$d_\partial \Theta_{\mathcal{A}} + \frac{1}{2} [\Theta_{\mathcal{A}}, \Theta_{\mathcal{A}}] = 0. \quad (18.1)$$

Explicitly: the genus- g , degree- n component of $\Theta_{\mathcal{A}}$ is the multilinear operation $(\mathcal{A}^!)^{\otimes n} \rightarrow \mathcal{A}^!$ obtained by evaluating the A_∞ operations and their modular corrections against the fundamental chain $[\overline{\mathcal{M}}_{g, n+1}]$.

Proof sketch. This is the modular-operad enhancement of the classical fact that an A_∞ -structure is a codifferential on the bar construction (hence a Maurer–Cartan element in the convolution Lie algebra $\text{Hom}(T^c(\mathcal{A}^![1]), \mathcal{A}^!)$). The extension to all genera uses the Deligne–Mumford modular operad structure on $\{\overline{\mathcal{M}}_{g, n}\}$: the codifferential condition $D^2 = 0$ on the modular bar complex is equivalent to the Maurer–Cartan equation (18.1) in $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$. The signs are fixed by the Koszul rule and the orientation conventions of Appendix G. $\square$

PROPOSITION 18.1.4 (*Genus-0 shadow obstruction tower as L_∞ formality obstruction tower;*). The genus-0 projection of the shadow obstruction tower $\Theta_{\mathcal{A}}^{\leq 2} \rightarrow \Theta_{\mathcal{A}}^{\leq 3} \rightarrow \Theta_{\mathcal{A}}^{\leq 4} \rightarrow \dots$ coincides with the L_∞ formality obstruction tower of the genus-0 part of the modular convolution algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$:

- (i) At degree 2: the scalar shadow $\kappa(\mathcal{A}) = \pi_{\text{sc}}(\Theta_{\mathcal{A}}^{\leq 2})$ is the binary L_∞ -bracket $\ell_2^{(0)}$, which equals the classical Lie bracket of $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$.
- (ii) At degree 3: the cubic shadow $[\mathfrak{C}_{\mathcal{A}}]$ is the transferred L_∞ -bracket $\ell_3^{(0),\text{tr}}$, which is gauge-trivial when $H^1(F^3\mathfrak{g}/F^4\mathfrak{g}, d_2) = 0$ (Theorem 13.22.349).
- (iii) At degree 4: the quartic resonance class $[R_4^{\text{mod}}(\mathcal{A})]$ is the first genuine L_∞ obstruction $\ell_4^{(0),\text{tr}}$ after gauge trivialization of the cubic.
- (iv) The genus-0 termination stage $r_{\text{max}}(\mathcal{A})$ equals both the A_∞ -depth $d_\infty(\mathcal{A})$ and the L_∞ -formality level $f_\infty(\mathcal{A})$ (Theorem K.7.1).
- (v) The positive-genus corrections to the full shadow obstruction tower are carried by the quantum operations $\ell_n^{(g)}$ and the BV loop terms; they are not part of the classical genus-0 formality obstruction tower.

Proof. The degree filtration $F^r\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ on the modular convolution algebra induces an obstruction tower on the space of MC elements. The shadow $\Theta_{\mathcal{A}}^{\leq r}$ is by definition the projection of the bar-intrinsic MC element $\Theta_{\mathcal{A}} := D_{\mathcal{A}} - d_0$ (Theorem 18.1.3) to $F^{\leq r}\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$.

At degree 2, the MC equation reduces to the Jacobi identity for $\ell_2^{(0)}$; its scalar trace is $\kappa(\mathcal{A})$. At degree 3, the obstruction to lifting $\Theta_{\mathcal{A}}^{\leq 2}$ to $\Theta_{\mathcal{A}}^{\leq 3}$ lives in $H^2(F^3\mathfrak{g}_{\mathcal{A}}^{\text{mod}}/F^4\mathfrak{g}_{\mathcal{A}}^{\text{mod}}, d_2)$, which is the same cohomology group controlling the transferred L_∞ -bracket $\ell_3^{(0),\text{tr}}$. The gauge triviality theorem (Theorem 13.22.349) identifies the vanishing of H^1 in the same graded piece as the condition for removability.

At degree 4, after gauge-trivializing the cubic term, the residual obstruction class in $H^2(F^4\mathfrak{g}_{\mathcal{A}}^{\text{mod}}/F^5\mathfrak{g}_{\mathcal{A}}^{\text{mod}}, d_2)$ is the canonical quartic $[R_4^{\text{mod}}(\mathcal{A})]$. This is exactly the transferred bracket $\ell_4^{(0),\text{tr}}$ of the homotopy transfer from $(V_{\mathcal{A}}, d_2, \ell_2^{(0)})$ to its cohomology, the standard formula for the first non-trivial L_∞ massey product after a formal bracket.

These three genus-0 identifications are proved at degrees 2, 3, 4 by Proposition 13.22.107, which establishes the coincidence of the shadow obstruction tower with the L_∞ formality obstruction tower at each degree by direct comparison of the graph-sum formulae with the homotopy transfer formulae. The equality $r_{\text{max}} = d_\infty = f_\infty$ extends this to all degrees by Theorem K.7.1. The positive-genus terms belong to the quantum L_∞ structure and the BV loop operator, so they form a parallel correction layer rather than part of the classical formality obstruction tower. $\square$

Remark 18.1.5 (Termination as the new content; genus-0 curve geometry). The identification of the genus-0 shadow obstruction tower with the L_∞ formality obstruction tower is structural: the homological perturbation lemma (HPL) produces a transferred L_∞ -algebra on any retract, and the transferred brackets ℓ_r^{tr} always exist. The genuinely new content of Proposition 18.1.4 is the *termination* phenomenon: the transferred L_∞ -algebra terminates at degree $r_{\text{max}}(\mathcal{A})$, meaning $\ell_r^{\text{tr}} = 0$ for all $r > r_{\text{max}}$. This is a consequence of the shadow obstruction tower analysis (Theorem 13.22.129), not the HPL itself. The HPL is agnostic about termination; it produces infinitely many brackets in general. What forces termination is the specific structure of the modular convolution algebra: the vanishing of obstruction classes $o^{(r+1)}(\mathcal{A})$ in $H^2(F^{r+1}\mathfrak{g}_{\mathcal{A}}^{\text{mod}}/F^{r+2}\mathfrak{g}_{\mathcal{A}}^{\text{mod}}, d_2)$ for $r > r_{\text{max}}$, which reflects the OPE complexity of $\mathcal{A}$.

Two aspects of this deserve emphasis. First, even the degree-2 projection $\kappa(\mathcal{A})$ already depends on curve geometry: the averaging map av is a Σ_2 -coinvariant projection of the meromorphic function $r(z)$ extracted from collision residues on the Fulton–MacPherson compactification $\overline{C}_2(X)$. This is not “Koszul duality

over a point”; the formal-disk restriction that recovers the classical theory is *data* (a homotopy retract of $\overline{C}_2(X) \rightarrow D^\times$ from the global configuration space to the punctured disk), not a tautological identification. Second, the higher-degree transferred brackets ℓ_r^{tr} for $r \geq 3$ use the Arnold forms $\eta_{ij} = d \log(z_i - z_j)$ on $\overline{C}_r(X)$ and the boundary stratification of $\overline{M}_{0,r+1}$ (the Stasheff associahedron K_{r+1}); the termination analysis takes place within this genus-0 curve geometry, not over a point.

PROPOSITION 18.1.6 (*Five-component decomposition;*). Expanding $\Theta_{\mathcal{A}}$ by genus and boundary type yields

$$\Theta_{\mathcal{A}} = \Theta^{\text{tree}} + \Theta^{\text{sew}} + \hbar \Theta^{\text{loop}} + \Theta^r + \Theta^{\text{bdry}},$$

and the Maurer–Cartan equation (18.1) decomposes into five interlocking pieces:

- (1) **Genus 0, tree-level:** the d_{A_∞} piece: the transferred A_∞ operations $\{m_n\}_{n \geq 2}$;
- (2) **Genus 0, self-gluing:** the d_{sew} piece: self-gluing of genus-0 operations (the cyclic A_∞ constraint);
- (3) **Genus $g \geq 1$, non-separating:** the $\hbar \Delta$ piece: BV contraction, the genus-raising operator;
- (4) **Spectral:** the d_r piece: the line-operator twist by $r(z)$;
- (5) **Boundary strata:** the d_{bdry} piece: clutching maps along $\partial \overline{M}_{g,n}$.

In particular, the total differential $D = d_{A_\infty} + d_{\text{sew}} + \hbar \Delta + d_r$ is *not* five independent structures assembled by fiat. It is the single equation (18.1) expanded by stratum.

In the three-pillar framework (§K.7.1): pieces (1)–(2) carry the Pillar B convolution sL_∞ structure (Theorem 3.1.24); piece (3) is the BV operator from the modular operad boundary; pieces (4)–(5) encode the Pillar C log-FM collision geometry, with the planted-forest differential d_{pf} arising as the tropical skeleton of $\overline{FM}_n(C|D)$ (Theorem 13.22.402). Pillar A (the Ch_∞ structure) governs the L_∞ coherence that makes $D^2 = 0$ hold despite these five terms interacting nontrivially.

Proof. Stratify $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ by genus and partition the boundary strata of $\overline{M}_{g,n}$ into separating, non-separating, and tree-level. The Maurer–Cartan equation is additive in genus and boundary type; projecting onto each stratum yields the five terms. The BV operator Δ arises from the non-separating node stratum $\delta_{\text{irr}}: \overline{M}_{g-1,n+2} \rightarrow \overline{M}_{g,n}$, which raises genus by 1. $\square$

THEOREM 18.1.7 (*Shadow obstruction tower from MC evaluation;*). The shadow hierarchy $\kappa \rightarrow \Delta \rightarrow \mathfrak{C} \rightarrow \mathfrak{Q} \rightarrow \Theta$ is the evaluation of $\Theta_{\mathcal{A}}$ on specific moduli classes:

- (i) $\kappa(\mathcal{A}) = \langle \Theta_{\mathcal{A}}, \Theta_{\mathcal{A}} \rangle$ paired with $[\overline{M}_{1,1}]$ (the fundamental class of genus-1 moduli);
- (ii) $\Delta_{\mathcal{A}} = \text{spectral data of } \Theta_{\mathcal{A}}|_{\overline{M}_{1,2}}$ (restriction to 2-pointed genus 1);
- (iii) $\mathfrak{C}_{\mathcal{A}} = \Theta_{\mathcal{A}}|_{\overline{M}_{0,4}}$ (quartic genus-0 boundary stratum);
- (iv) $\mathfrak{Q}_{\mathcal{A}} = \text{the contact term of } \Theta_{\mathcal{A}} \text{ on } \overline{M}_{0,5}$ (quintic boundary);
- (v) the full $\Theta_{\mathcal{A}}$ is the universal Maurer–Cartan element itself.

Proof. Each shadow is by definition the value of the genus-refined multilinear data on an explicit cycle representative in $H_*(\overline{\mathcal{M}}_{g,n})$. Item (i) is Theorem D specialized to genus 1; items (ii)–(iv) are the definitions of $\Delta_{\mathcal{A}}$, $\mathfrak{C}_{\mathcal{A}}$, $\mathfrak{Q}_{\mathcal{A}}$ from Section 18.4. The hierarchy $\kappa \rightarrow \Delta \rightarrow \mathfrak{C} \rightarrow \mathfrak{Q} \rightarrow \Theta$ is the filtration of $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ by degree: each shadow is the next Taylor coefficient of the single element $\Theta_{\mathcal{A}}$. $\square$

COROLLARY 18.1.8 (*All families from universal evaluation;*). For each standard family (Heisenberg, affine Kac–Moody, Virasoro, $\mathcal{W}_3$, Yangian), the specific formulas (κ values, shadow obstruction tower data, genus corrections) computed in the example chapters are obtained by evaluating $\Theta_{\mathcal{A}}$ on explicit cycle representatives in $H_*(\overline{\mathcal{M}}_{g,n})$. No additional input is needed beyond the algebra structure and the moduli geometry.

Remark 18.1.9 (The Chriss–Ginzburg principle). This is the “one object, one equation, everything else is a corollary” paradigm. The modular convolution dg Lie algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ is the single organizing structure. The quantum master equation, the graph sums, the genus tower, the non-renormalization theorems, the shadow projections: all are automatic from $\Theta_{\mathcal{A}} \in \text{MC}(\mathfrak{g}_{\mathcal{A}}^{\text{mod}})$. The explicit consequences follow.

18.2 THE GOVERNING QUESTION FROM FIRST PRINCIPLES

The correct theorem of complementarity is not

$$Q_g(\mathcal{A}) \oplus Q_g(\mathcal{A}^!) \cong C_g(\mathcal{A}).$$

That is only the linear shadow. The correct theorem is that there is a single formal moduli problem carrying a shifted symplectic structure, and the two dual deformation packages are Lagrangian inside it. The first-principles data are therefore not two vector spaces and a bookkeeping identity, but:

- (1) a cyclic deformation complex for $\mathcal{A}$,
- (2) a cyclic deformation complex for $\mathcal{A}^!$,
- (3) a universal twisting kernel relating the two,
- (4) a cyclic pairing turning the total deformation problem into a shifted symplectic formal moduli problem.

This is exactly the geometric shape suggested by the chiral bar–cobar formalism. The bar–cobar kernel is not auxiliary bookkeeping; it is the object whose deformations simultaneously remember the deformation of $\mathcal{A}$, the deformation of $\mathcal{A}^!$, and the compatibility between them.

18.3 AMBIENT COMPLEMENTARITY FROM FIRST PRINCIPLES

Definition 18.3.1 (Ambient complementarity datum). Let $\mathcal{A}$ be a modular Koszul chiral algebra on a smooth projective curve, and let $\mathcal{A}^!$ denote its Koszul dual on the locus where the duality package is defined. An *ambient complementarity datum* consists of:

- (i) two cyclic deformation complexes

$$L_{\mathcal{A}} := \text{Def}_{\text{cyc}}(\mathcal{A}), \quad L_{\mathcal{A}^!} := \text{Def}_{\text{cyc}}(\mathcal{A}^!),$$

viewed as filtered complete cyclic L_{∞} -algebras;

- (ii) a completed kernel object

$$K_{\mathcal{A}} := (\mathcal{A}^! \widehat{\otimes} \mathcal{A})[1]$$

with differential twisted by the universal twisting kernel;

- (iii) a Maurer–Cartan element

$$\tau_{\mathcal{A}} \in \mathrm{MC}(\mathcal{A}^! \widehat{\otimes} \mathcal{A})$$

representing the canonical bar–cobar twisting kernel;

- (iv) linearizations of the kernel in the two deformation directions,

$$\nabla_{\mathcal{A}} : L_{\mathcal{A}} \rightarrow K_{\mathcal{A}}, \quad \nabla_{\mathcal{A}^!} : L_{\mathcal{A}^!} \rightarrow K_{\mathcal{A}};$$

- (v) a degree
- -1
- cyclic pairing on the total complex

$$L_{\mathcal{A}} \oplus K_{\mathcal{A}} \oplus L_{\mathcal{A}^!}$$

for which the kernel differential is skew-adjoint.

Definition 18.3.2 (Ambient complementarity tangent complex). Given an ambient complementarity datum, define the *ambient complementarity tangent complex*

$$T_{\mathrm{comp}}(\mathcal{A}) := \mathrm{fib}\left(\nabla_{\mathcal{A}} - \nabla_{\mathcal{A}^!} : L_{\mathcal{A}} \oplus L_{\mathcal{A}^!} \longrightarrow K_{\mathcal{A}}\right).$$

A tangent vector in $T_{\mathrm{comp}}(\mathcal{A})$ is therefore a first-order deformation of $\mathcal{A}$, a first-order deformation of $\mathcal{A}^!$, and a first-order deformation of the universal kernel, constrained by the linearized Maurer–Cartan equation.

THEOREM 18.3.3 (*Ambient complementarity in tangent form*;). Assume an ambient complementarity datum exists for $\mathcal{A}$. Then:

- (i) the complex $T_{\mathrm{comp}}(\mathcal{A})$ carries a canonical nondegenerate pairing of degree -1 ;
- (ii) the one-sided tangent complexes

$$T_{\mathcal{A}} := \mathrm{fib}(\nabla_{\mathcal{A}} : L_{\mathcal{A}} \rightarrow K_{\mathcal{A}}), \quad T_{\mathcal{A}^!} := \mathrm{fib}(\nabla_{\mathcal{A}^!} : L_{\mathcal{A}^!} \rightarrow K_{\mathcal{A}})$$

are isotropic inside $T_{\mathrm{comp}}(\mathcal{A})$;

- (iii) if the pairing on $L_{\mathcal{A}} \oplus K_{\mathcal{A}} \oplus L_{\mathcal{A}^!}$ is perfect and bar–cobar duality identifies the normal complex of one side with the shifted dual tangent complex of the other, then $T_{\mathcal{A}}$ and $T_{\mathcal{A}^!}$ are complementary Lagrangians in $T_{\mathrm{comp}}(\mathcal{A})$.

Proof. The degree -1 pairing on $T_{\mathrm{comp}}(\mathcal{A})$ is induced from the cyclic pairing on the direct sum by passage to the homotopy fiber. Because the total differential is skew-adjoint, the pairing descends to cohomology and is compatible with the differential.

For the one-sided tangent complex $T_{\mathcal{A}}$, the pullback of the ambient pairing reduces to the quadratic term in the differentiated Maurer–Cartan equation for the universal kernel. That quadratic term vanishes because the Maurer–Cartan equation is exactly the isotropy condition for the graph of the one-sided variation. The same argument applies to $T_{\mathcal{A}^!}$.

If the cyclic pairing is perfect and bar–cobar duality identifies the normal complex of one side with the shifted dual tangent complex of the other, maximal isotropy follows: the two sides are opposite polarizations of a single symplectic deformation problem. $\square$

THEOREM 18.3.4 (*Ambient complementarity as a shifted symplectic formal moduli problem*; (see Theorem 13.19.5)). Assume the tangent complex $T_{\text{comp}}(\mathcal{A})$ integrates to a filtered complete cyclic L_∞ -algebra presenting a formal moduli problem

$$\mathcal{M}_{\text{comp}}(\mathcal{A}).$$

Then $\mathcal{M}_{\text{comp}}(\mathcal{A})$ carries a canonical (-1) -shifted symplectic structure, and the one-sided deformation problems of $\mathcal{A}$ and of $\mathcal{A}^\dagger$ define Lagrangian maps

$$\mathcal{M}_{\mathcal{A}} \longrightarrow \mathcal{M}_{\text{comp}}(\mathcal{A}) \longleftarrow \mathcal{M}_{\mathcal{A}^\dagger}.$$

The genus- g complementarity complex is the linear shadow of this picture.

REMARK 18.3.5 (*Why the theorem is stronger than additive complementarity*). An additive splitting can always be faked by eigenspace decompositions, arbitrary direct sums, or linear bookkeeping identities. The ambient theorem is harder to fake because it requires:

- (i) a single deformation problem rather than two unrelated ones,
- (ii) a shifted symplectic pairing on that problem,
- (iii) isotropicity of the one-sided packages,
- (iv) maximality of the isotropicity,
- (v) compatibility with clutching, factorization, and duality.

The last item is decisive: the theorem is not only about tangent complexes at one point, but about a modular geometry stable under the basic operations of the theory.

18.3.1 COTANGENT NORMAL FORM AND THE COMPLEMENTARITY POTENTIAL

THEOREM 18.3.6 (*Shifted cotangent normal form*;). Let $\mathcal{M}$ be a pointed (-1) -shifted symplectic formal moduli problem, and let

$$i_+ : \mathcal{L}_+ \rightarrow \mathcal{M}, \quad i_- : \mathcal{L}_- \rightarrow \mathcal{M}$$

be pointed Lagrangian maps through the base point. Assume the induced tangent map

$$T_0 \mathcal{L}_+ \oplus T_0 \mathcal{L}_- \xrightarrow{\sim} T_0 \mathcal{M}$$

is a quasi-isomorphism. Then there exists a pointed formal symplectomorphism

$$(\mathcal{M}, i_+) \simeq (T^*[-1]\mathcal{L}_+, 0\text{-section})$$

under which $\mathcal{L}_-$ becomes the graph of a closed degree-zero one-form

$$\alpha_+ \in \Omega^1(\mathcal{L}_+)^0.$$

In the pointed formal neighborhood this one-form is exact:

$$\alpha_+ = dS_+$$

for a degree-zero formal function S_+ , unique up to an additive constant.

Proof. Because i_+ is Lagrangian, the normal complex of $\mathcal{L}_+$ in $\mathcal{M}$ is canonically identified with $T^*[-1]\mathcal{L}_+$. Formally along $\mathcal{L}_+$, the symplectic neighborhood theorem gives a pointed equivalence with the shifted cotangent bundle. Under this identification, $\mathcal{L}_+$ becomes the zero section. Since $\mathcal{L}_-$ is complementary to the zero section, it is the graph of a one-form α_+ . The graph of a one-form in a cotangent bundle is Lagrangian if and only if the one-form is closed, because the pullback of the canonical symplectic form is exactly $d\alpha_+$. In a pointed formal neighborhood every closed one-form is exact, which produces S_+ . $\square$

Definition 18.3.7 (Complementarity potential). Assume the ambient complementarity formal moduli problem exists. The formal function

$$S_{\mathcal{A}} \in \widehat{\mathcal{O}}(\mathcal{M}_{\mathcal{A}})^0$$

produced by Theorem 18.3.6 for the pair

$$\mathcal{L}_+ = \mathcal{M}_{\mathcal{A}}, \quad \mathcal{L}_- = \mathcal{M}_{\mathcal{A}^\dagger}$$

is called the *complementarity potential* of the Koszul pair $(\mathcal{A}, \mathcal{A}^\dagger)$.

PROPOSITION 18.3.8 (Legendre duality of the two potentials;). Assume the ambient complementarity formal moduli problem exists. Let $S_{\mathcal{A}}$ and $S_{\mathcal{A}^\dagger}$ be the complementarity potentials constructed from the two cotangent charts centered at $\mathcal{M}_{\mathcal{A}}$ and $\mathcal{M}_{\mathcal{A}^\dagger}$. Then $S_{\mathcal{A}}$ and $S_{\mathcal{A}^\dagger}$ are formal Legendre transforms of one another.

Proof. The two functions generate the same formal Lagrangian subspace of the same shifted symplectic ambient moduli problem, viewed from the two opposite cotangent charts. The coordinate change between these two charts is the formal Legendre transform. $\square$

PROPOSITION 18.3.9 (Legendre duality of cubic tensors;). Let $H_{\mathcal{A}}$ be the complementarity Hessian. Then the cubic shadows of $\mathcal{A}$ and $\mathcal{A}^\dagger$ are related by formal Legendre duality:

$$\mathfrak{C}_{\mathcal{A}^\dagger}(p, p, p) = -\mathfrak{C}_{\mathcal{A}}(H_{\mathcal{A}}^{-1}p, H_{\mathcal{A}}^{-1}p, H_{\mathcal{A}}^{-1}p).$$

More generally, at quartic order the Legendre transform gives

$$S_{\mathcal{A}}^\vee(p) = \frac{1}{2}H_{\mathcal{A}}^{-1}(p, p) - \frac{1}{6}\mathfrak{C}_{\mathcal{A}}(H_{\mathcal{A}}^{-1}p, H_{\mathcal{A}}^{-1}p, H_{\mathcal{A}}^{-1}p) + O(p^4).$$

Since $S_{\mathcal{A}}^\vee = S_{\mathcal{A}^\dagger}$, the cubic shadow on the dual side is the Hessian-transported negative of the cubic shadow on the primal side.

Proof. Write $S_{\mathcal{A}}(x) = \frac{1}{2}H_{\mathcal{A}}(x, x) + \frac{1}{6}\mathfrak{C}_{\mathcal{A}}(x, x, x) + O(x^4)$. The critical point of $\langle p, x \rangle - S_{\mathcal{A}}(x)$ is $x = H_{\mathcal{A}}^{-1}p + O(p^2)$. Substituting into the Legendre formula and collecting through cubic order yields the displayed identity. $\square$

THEOREM 18.3.10 (Derived critical locus of self-dual deformations;). Assume the ambient complementarity formal moduli problem exists. Then there is a canonical equivalence

$$\mathcal{M}_{\mathcal{A}} \times_{\mathcal{M}_{\text{comp}}(\mathcal{A})}^h \mathcal{M}_{\mathcal{A}^\dagger} \simeq \text{Crit}(S_{\mathcal{A}}).$$

Simultaneous deformations of $\mathcal{A}$ and $\mathcal{A}^\dagger$ preserving complementarity are governed by the derived critical locus of the complementarity potential.

Proof. In the cotangent normal form of Theorem 18.3.6, one Lagrangian is the zero section and the other is the graph of $dS_{\mathcal{A}}$. Their derived intersection is by definition the derived zero locus of $dS_{\mathcal{A}}$, which is the derived critical locus of $S_{\mathcal{A}}$. $\square$

PROPOSITION 18.3.11 (*Criterion for fake complementarity*). In the cotangent chart centered at $\mathcal{M}_{\mathcal{A}}$, the following are equivalent.

- (i) The dual Lagrangian $\mathcal{M}_{\mathcal{A}^\dagger}$ is linear.
- (ii) The complementarity potential $S_{\mathcal{A}}$ is quadratic.
- (iii) The derived critical locus $\text{Crit}(S_{\mathcal{A}})$ is controlled entirely by its Hessian complex, with no higher nonlinear operations.

Consequently, the first obstruction to fake complementarity is the first nonzero higher jet of $S_{\mathcal{A}}$ beyond its quadratic part.

Proof. In the cotangent chart, $\mathcal{M}_{\mathcal{A}^\dagger}$ is the graph of $dS_{\mathcal{A}}$. The graph is linear if and only if $dS_{\mathcal{A}}$ is linear, hence if and only if $S_{\mathcal{A}}$ is quadratic. When $S_{\mathcal{A}}$ is quadratic, its critical locus is cut out by a linear differential and is therefore governed by the Hessian complex alone. Conversely, any cubic or higher term in $S_{\mathcal{A}}$ produces a nonlinear contribution to $dS_{\mathcal{A}}$ and therefore to the critical locus. $\square$

18.4 FINITE-ORDER NONLINEAR SHADOW CALCULUS

The full universal class $\Theta_{\mathcal{A}}$ globalizes the entire modular deformation theory (Theorem 13.21.69). Its first visible jets are accessible before the full globalization.

Definition 18.4.1 (*Degree shadows of the universal class*). By the bar-intrinsic construction (Theorem 13.21.69), the universal Maurer–Cartan class

$$\Theta_{\mathcal{A}} \in \text{MC}(\text{Def}_{\text{cyc}}(\mathcal{A}) \widehat{\otimes} \mathbb{G}_{\text{mod}}),$$

exists for every modular Koszul chiral algebra, where $\mathbb{G}_{\text{mod}}$ denotes the completed modular coefficient ring. In a cyclic minimal model the class determines a Hamiltonian modular master potential

$$\mathfrak{S}_{\mathcal{A}} = \sum_{r \geq 2} \frac{1}{r!} \text{Sh}_r(\Theta_{\mathcal{A}}),$$

where $\text{Sh}_r(\Theta_{\mathcal{A}})$ denotes the homogeneous degree- r Taylor coefficient on the tangent space of the minimal model. We call $\text{Sh}_r(\Theta_{\mathcal{A}})$ the *degree- r shadow* of the universal class.

Remark 18.4.2 (*Quadratic, cubic, and quartic shadows as degree-2, 3, and 4 pieces*). Since the universal class $\Theta_{\mathcal{A}}$ exists (Theorem 13.21.69), the three tensors

$$H_{\mathcal{A}}, \quad \mathfrak{C}_{\mathcal{A}}, \quad \mathfrak{Q}_{\mathcal{A}}$$

are nothing but the first three nontrivial shadows of $\Theta_{\mathcal{A}}$:

$$H_{\mathcal{A}} = \text{Sh}_2(\Theta_{\mathcal{A}}), \quad \mathfrak{C}_{\mathcal{A}} = \text{Sh}_3(\Theta_{\mathcal{A}}), \quad \mathfrak{Q}_{\mathcal{A}} = \text{Sh}_4(\Theta_{\mathcal{A}}).$$

The entire finite-order theory developed below is therefore the visible degree- ≤ 4 face of the universal Maurer–Cartan class.

18.4.1 QUADRATIC, CUBIC, AND QUARTIC SHADOWS

Setup 18.4.3 (*Finite-dimensional cyclic slice*). Fix a finite-dimensional graded subspace

$$V_{\mathcal{A}} \subset H^*(\text{Def}_{\text{cyc}}(\mathcal{A}), \ell_1)$$

closed under all transferred operations needed through quartic order. Assume that the cyclic pairing restricts to a nondegenerate quadratic form on $V_{\mathcal{A}}$; write

$$H_{\mathcal{A}}: V_{\mathcal{A}} \xrightarrow{\sim} V_{\mathcal{A}}^*[-1]$$

for the induced Hessian, and let $P_{\mathcal{A}} := H_{\mathcal{A}}^{-1}$ denote the propagator.

Definition 18.4.4 (Shadow jets). The *quadratic*, *cubic*, and *quartic* shadows of $\mathcal{A}$ on $V_{\mathcal{A}}$ are the tensors determined by the Taylor expansion

$$S_{\mathcal{A}}^{\leq 4}(x) = \frac{1}{2}H_{\mathcal{A}}(x, x) + \frac{1}{3!}\mathfrak{C}_{\mathcal{A}}(x, x, x) + \frac{1}{4!}\mathfrak{Q}_{\mathcal{A}}(x, x, x, x).$$

Equivalently, if $(V_{\mathcal{A}}, \ell_n^{\text{tr}})$ is the transferred cyclic minimal model, then

$$\begin{aligned} \mathfrak{C}_{\mathcal{A}}(x, y, z) &:= \sum_{\text{cyc}} \langle x, \ell_2^{\text{tr}}(y, z) \rangle, \\ \mathfrak{Q}_{\mathcal{A}}(x_1, x_2, x_3, x_4) &:= \sum_{\text{cyc}} \langle x_1, \ell_3^{\text{tr}}(x_2, x_3, x_4) \rangle. \end{aligned} \tag{18.2}$$

Define the quartic obstruction

$$\mathfrak{o}_{\mathcal{A}}^{(4)} := \frac{1}{2}\{\mathfrak{C}_{\mathcal{A}}, \mathfrak{C}_{\mathcal{A}}\}_{H_{\mathcal{A}}},$$

where the bracket is the Hamiltonian bracket induced by the propagator $P_{\mathcal{A}}$.

THEOREM 18.4.5 (*Quartic shadow master equations*). Assume the truncated Hamiltonian $S_{\mathcal{A}}^{\leq 4}$ satisfies the classical master equation modulo quintic terms:

$$\{S_{\mathcal{A}}^{\leq 4}, S_{\mathcal{A}}^{\leq 4}\}_{H_{\mathcal{A}}} = O(5).$$

Then the shadow jets satisfy

$$\{H_{\mathcal{A}}, \mathfrak{C}_{\mathcal{A}}\}_{H_{\mathcal{A}}} = 0, \tag{18.3}$$

$$\{H_{\mathcal{A}}, \mathfrak{Q}_{\mathcal{A}}\}_{H_{\mathcal{A}}} + \mathfrak{o}_{\mathcal{A}}^{(4)} = 0. \tag{18.4}$$

Equivalently, if one writes

$$\nabla_{H_{\mathcal{A}}}(X) := \{H_{\mathcal{A}}, X\}_{H_{\mathcal{A}}},$$

then

$$\nabla_{H_{\mathcal{A}}}\mathfrak{C}_{\mathcal{A}} = 0, \quad \nabla_{H_{\mathcal{A}}}\mathfrak{Q}_{\mathcal{A}} + \mathfrak{o}_{\mathcal{A}}^{(4)} = 0.$$

Proof. Expand the master equation by homogeneous degree. The cubic term is exactly (18.3); the quartic term is exactly (18.4). No other contributions occur through quartic order. $\square$

Construction 18.4.6 (Separating sewing product). Let $P_{\mathcal{A}} = H_{\mathcal{A}}^{-1}$ be the propagator. For symmetric tensors $\alpha \in \text{Sym}^p(V_{\mathcal{A}}^*)$ and $\beta \in \text{Sym}^q(V_{\mathcal{A}}^*)$, define the *single-edge sewing product*

$$\alpha \star_{P_{\mathcal{A}}} \beta \in \text{Sym}^{p+q-2}(V_{\mathcal{A}}^*)$$

by contracting one leg of α with one leg of β using $P_{\mathcal{A}}$ and symmetrizing over the remaining external legs. This is the tensor-level realization of separating clutching by one internal edge.

THEOREM 18.4.7 (*Separating boundary recursion through quartic order;*). Since the shadow jets are the degree- ≤ 4 projections of the bar-intrinsic MC element $\Theta_{\mathcal{A}}$ (Theorem 13.21.69), which satisfies the modular clutching identity, on every separating clutching map ξ one has

$$\xi^* H_{\mathcal{A}} = H_{\mathcal{A}} \star_{P_{\mathcal{A}}} H_{\mathcal{A}}, \quad (18.5)$$

$$\xi^* \mathfrak{C}_{\mathcal{A}} = H_{\mathcal{A}} \star_{P_{\mathcal{A}}} \mathfrak{C}_{\mathcal{A}} + \mathfrak{C}_{\mathcal{A}} \star_{P_{\mathcal{A}}} H_{\mathcal{A}},$$

$$\xi^* \mathfrak{Q}_{\mathcal{A}} = H_{\mathcal{A}} \star_{P_{\mathcal{A}}} \mathfrak{Q}_{\mathcal{A}} + \mathfrak{C}_{\mathcal{A}} \star_{P_{\mathcal{A}}} \mathfrak{C}_{\mathcal{A}} + \mathfrak{Q}_{\mathcal{A}} \star_{P_{\mathcal{A}}} H_{\mathcal{A}}. \quad (18.6)$$

Proof. These are the degree-2, degree-3, and degree-4 components of the clutching identity for the universal class:

$$\xi^*(\Theta_{\mathcal{A}}) = \Theta_{\mathcal{A}} \star \Theta_{\mathcal{A}}.$$

At quartic order only the three displayed contractions survive. □

18.4.2 THE QUARTIC SHADOW GRAPH COCYCLE

Definition 18.4.8 (Quartic shadow graph complex). Let $\mathcal{G}_{\mathcal{A}}^{\leq 4}$ denote the completed span of stable graphs whose vertices are decorated as follows:

- (i) a 2-valent vertex is decorated by the Hessian $H_{\mathcal{A}}$,
- (ii) a 3-valent vertex is decorated by the cubic tensor $\mathfrak{C}_{\mathcal{A}}$,
- (iii) a 4-valent vertex is decorated by the quartic tensor $\mathfrak{Q}_{\mathcal{A}}$,
- (iv) every internal edge is contracted with the propagator $P_{\mathcal{A}}$.

Let d_{graph} be the differential obtained by summing over separating edge insertions together with the internal differential induced by the Hamiltonian bracket with $H_{\mathcal{A}}$.

Construction 18.4.9 (The quartic shadow cocycle). Define

$$\Theta_{\mathcal{A}}^{\leq 4} := H_{\mathcal{A}} + \mathfrak{C}_{\mathcal{A}} + \mathfrak{Q}_{\mathcal{A}} \in \mathcal{G}_{\mathcal{A}}^{\leq 4}.$$

THEOREM 18.4.10 (*Finite-order realization of the universal class;*). The element $\Theta_{\mathcal{A}}^{\leq 4}$ is a cocycle in $\mathcal{G}_{\mathcal{A}}^{\leq 4}$ if and only if the quartic shadow master equations (18.3)–(18.4) and the separating boundary recursion (18.5)–(18.6) hold.

Proof. The graph differential on the one-vertex generators reproduces the three sewing terms of Theorem 18.4.7; the Hamiltonian part of the differential reproduces Theorem 18.4.5. Matching homogeneous degrees 2, 3, and 4 yields the claim. □

Remark 18.4.11 (Tree terms versus obstruction terms). There are two different quartic descendants of a cubic tensor $\mathfrak{C}$.

(i) The *tree term*

$$T_{\mathfrak{C}} := \mathfrak{C} \star_P \mathfrak{C}$$

records the quartic geometry created by sewing two cubic vertices with one propagator.

(ii) The *quartic obstruction*

$$J_{\mathfrak{C}} := \frac{1}{2} \{\mathfrak{C}, \mathfrak{C}\}_H$$

records the Hamiltonian failure of a quartic primitive to exist.

These two contractions are conceptually different. In particular, a family can have nontrivial quartic boundary geometry even when the quartic obstruction vanishes.

18.4.3 THE QUARTIC SHADOW ENVELOPE

Definition 18.4.12 (Primary–composite quartic shadow envelope). Let $\mathcal{A}$ be strongly generated by primaries

$$W^{(d_1)}, \dots, W^{(d_r)}, \quad d_1 < \dots < d_r.$$

The *primary–composite quartic shadow envelope* is the graded vector space

$$E_{\mathcal{A}}^{[4]} := V_{\text{prim}} \oplus V_{\text{comp}},$$

where

$$V_{\text{prim}} := \bigoplus_{i=1}^r \mathbb{C} e_i$$

is the span of the strong generators and V_{comp} is the span of all quasi-primary projections

$$\Pi_{\text{qp}}(\cdot W^{(d_i)} W^{(d_j)} \cdot)$$

that occur in the singular or regular parts of pairwise OPEs of strong generators. It is the minimal envelope on which the quartic shadow calculus closes.

PROPOSITION 18.4.13 (*Quartic closure of the shadow envelope*;). The local quartic shadow differential and the quartic separating sewing recursion preserve $E_{\mathcal{A}}^{[4]}$.

Proof. Through quartic order, every local one-vertex contribution comes from a single pairwise OPE of strong generators. Such an OPE can produce only another strong generator, its descendants, or a normal-ordered bilinear composite. After quasi-primary projection, descendants are absorbed into the strong-generator/composite span. No trilinear composite is needed before quintic order. The boundary terms are obtained by gluing either two cubic vertices or one quartic vertex with one propagator, so they also remain in the same envelope. $\square$

18.5 THE THREE PRIMITIVE NONLINEAR ARCHETYPES

The quartic shadow calculus isolates three primitive patterns of nonlinear behavior in the standard low-rank families.

- (i) *Gaussian*: no nonlinear jet survives through quartic order. OPE is abelian: output is vacuum and derivatives of inputs. Shadow depth ≤ 2 .
- (ii) *Lie/tree*: a cubic tensor is present, the quartic obstruction vanishes, and quartic nonlinearity appears first on the boundary as a tree term. OPE creates new fields (root vertex operators), but no generator has a direct self-loop ($a \notin a_{(k)}a$). Shadow depth 3.
- (iii) *Contact/quartic*: the cubic tensor vanishes on the chosen slice, and the first nonlinear local term is quartic. OPE is abelian but a weight deformation activates the quartic shadow. Shadow depth 4.

A fourth pattern, *mixed/infinite* ($r_{\max} = \infty$), arises when a strong generator belongs to its own self-OPE: $T_{(1)}T = 2T$ for Virasoro. This direct self-referentiality drives an infinite A_∞ cascade (Proposition S.6.4). At higher rank, lattice vertex algebras achieve finite depths 5, 6, 7, . . . through independent cusp forms in $M_{r/2}$ (Theorem S.0.1). We now compute the three low-rank patterns in the frame families.

18.5.1 HEISENBERG

THEOREM 18.5.1 (*Heisenberg exact linearity*;). On the Heisenberg deformation line one has

$$\mathfrak{C}_{\mathcal{H}} = 0, \quad \mathfrak{o}_{\mathcal{H}}^{(4)} = 0, \quad \mathfrak{Q}_{\mathcal{H}} = 0.$$

Equivalently,

$$\Theta_{\mathcal{H}}^{\leq 4} = H_{\mathcal{H}}.$$

Proof. On the Heisenberg line the deformation problem is governed by a constant Poisson structure and the corresponding Moyal quantization is exact at first order. On the bar side, no higher operations m_n with $n \geq 3$ appear on this slice. Therefore the transferred binary and ternary nonlinear operations vanish, and hence so do the cubic and quartic shadow tensors. $\square$

COROLLARY 18.5.2 (*Gaussian boundary law*;). For the Heisenberg family the separating boundary recursion is purely Gaussian:

$$\xi^* H_{\mathcal{H}} = H_{\mathcal{H}} \star H_{\mathcal{H}}, \quad \xi^* \mathfrak{C}_{\mathcal{H}} = 0, \quad \xi^* \mathfrak{Q}_{\mathcal{H}} = 0.$$

Remark 18.5.3 (Class G is not “classical Koszul duality over a point”). The Gaussian class G (shadow depth 2, $\Delta = 0$) is sometimes described as the stratum where “chiral Koszul duality reduces to classical Koszul duality.” This is imprecise. In class G the shadow tower terminates at degree 2 *on the curve*: the collision residue $r(z)$ is scalar, the averaging map $\text{av}(r(z)) = \kappa$ is a Σ_2 -coinvariant integral on $\overline{C}_2(X)$, and the bar differential uses the Arnold form $\eta = d \log(z_1 - z_2)$. The coincidence with the classical theory is mediated by the formal-disk restriction $\overline{C}_n(X) \rightarrow D^\times$, which is a homotopy retract carrying nontrivial data (the retraction depends on choosing a local coordinate on the curve). The formal disk is not a point; $\mathbb{P}^1$ has nontrivial global topology (the exceptional divisors of $\overline{C}_n(\mathbb{P}^1)$ are not contractible); and “Koszul duality over $\mathbb{P}^1$ reduces to Koszul duality over a point” is false without the retract data. Class G is the simplest stratum of the *chiral* theory, not a return to the classical one.

Remark 18.5.4 (Derived center interpretation: Gaussian class). In the chiral derived center $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{H}_k)$ (Definition A.17.7), the Gaussian archetype manifests as follows: the open/closed quartic resonance class $\mathfrak{R}_4^{\text{oc}}(\mathcal{H}_k) = 0$ (Theorem A.17.30(i)), so the universal bulk is purely quadratic. The completed modular Koszul datum $\Pi_X^{\text{oc}}(\mathcal{H}_k)$ reduces to the linear holographic transform $\mathbb{H}_X(\mathcal{H}_k)$ of §K.7.1.

18.5.2 AFFINE $\widehat{\mathfrak{sl}}_2$

Definition 18.5.5 (Strict current-level sector). For the affine current algebra $\widehat{\mathfrak{sl}}_{2,k}$, let

$$V_{\text{aff}} := \mathfrak{sl}_2[1] \oplus \mathbb{C}K[1]$$

be the strict current-level sector generated by the current algebra and the level direction.

THEOREM 18.5.6 (*Affine cubic normal form;*). On the strict current-level sector one has

$$\mathfrak{C}_{\text{aff}}(x, y, z) = \kappa(x, [y, z]), \quad \mathfrak{d}_{\text{aff}}^{(4)} = 0.$$

Consequently there exists a quartic gauge in which

$$\mathfrak{Q}_{\text{aff}} = 0, \quad \Theta_{\text{aff}}^{\leq 4} = H_{\text{aff}} + \mathfrak{C}_{\text{aff}}.$$

Proof. The simple pole in the current algebra OPE is the Lie bracket, and the double pole is the invariant bilinear form. Therefore the cubic Hamiltonian on the strict sector is the cyclic Lie Hamiltonian

$$\frac{1}{6}\kappa(a, [a, a]).$$

The Hamiltonian self-bracket of this cubic term is the Jacobiator, which vanishes identically. Thus the quartic obstruction vanishes. Through quartic order one may therefore choose the minimal gauge in which no local quartic vertex remains. $\square$

COROLLARY 18.5.7 (*Boundary-generated quartic nonlinearity;*). Even though the local quartic vertex vanishes on the strict current-level sector, the quartic boundary shadow is generally nonzero:

$$\xi^* \mathfrak{Q}_{\text{aff}} = \mathfrak{C}_{\text{aff}} \star_{P_{\text{aff}}} \mathfrak{C}_{\text{aff}}.$$

Explicitly,

$$(\mathfrak{C}_{\text{aff}} \star_{P_{\text{aff}}} \mathfrak{C}_{\text{aff}})(x_1, x_2, x_3, x_4) = \frac{1}{k_{\text{eff}}} \sum_{\text{channels}} \kappa([x_i, x_j], [x_k, x_\ell]),$$

where k_{eff} is the normalization of the Hessian on the strict sector.

Proof. Apply the quartic boundary recursion with $\mathfrak{Q}_{\text{aff}} = 0$. The displayed formula is the definition of sewing two cubic current vertices with one propagator. $\square$

Conjecture 18.5.8 (Critical-level emergence;). For affine Kac–Moody $\widehat{\mathfrak{g}}_k$, assume the ambient complementarity package exists. At the critical level $k = -h^\vee$, the quadratic/Hessian shadow vanishes:

$$H_{\widehat{\mathfrak{g}}_{-h^\vee}} = 0,$$

while the cubic shadow survives:

$$\mathfrak{C}_{\widehat{\mathfrak{g}}_{-h^\vee}}(x, y, z) = \kappa(x, [y, z]).$$

The complementarity potential is therefore cubic at leading order:

$$S_{\widehat{\mathfrak{g}}_{-h^\vee}}(a) = \frac{1}{6}\kappa(a, [a, a]) + O(a^4).$$

Remark 18.5.9 (Evidence). The quadratic part is governed by the shifted-level factor $k + h^\vee$, which vanishes at the critical level. The simple-pole bracket remains, so the first surviving homogeneous term is the Lie-theoretic cubic tensor.

Conjecture 18.5.10 (Critical self-duality as Maurer–Cartan;). At the critical level, the derived self-intersection of the two modular Lagrangians has leading critical equation

$$[a, a] = 0.$$

The cubic truncation of the derived critical locus is the Maurer–Cartan locus for the underlying Lie bracket.

Remark 18.5.11 (Evidence). Differentiate the critical-level cubic action: $dS(a) = \frac{1}{2}[a, a] + O(a^3)$. The cubic truncation of $\text{Crit}(S)$ is therefore $\{a : [a, a] = 0\}$, which is the Maurer–Cartan locus.

Remark 18.5.12 (Critical level is purely nonlinear). The critical level is not “more linear” than generic level; it is the opposite. At the critical level, complementarity becomes purely nonlinear at leading order, connecting complementarity geometry to critical-level representation theory (the Feigin–Frenkel center).

Remark 18.5.13 (Derived center interpretation: Lie/tree class). In the chiral derived center, the cubic shadow $\mathfrak{C}_{\text{aff}} \in \mathcal{Z}^1$ is a degree-1 Gerstenhaber algebra element (a bulk derivation), and the quartic contact vanishes in the standard gauge: $[\mathfrak{D}_{\text{aff}}^{\text{ct}}] = 0$ in $\mathcal{Z}^2$. The open/closed quartic resonance class reduces to the tree correction: $\mathfrak{R}_4^{\text{oc}}(\widehat{\mathfrak{g}}_k) = [\mathfrak{C} \star_P \mathfrak{C}] \in \mathcal{Z}^2$ (Theorem A.17.30(ii)). This is the trace of cubic graviton exchange across a boundary node.

18.5.3 THE $\beta\gamma$ SYSTEM

Definition 18.5.14 (Weight/contact slice). Let $V_{\beta\gamma}$ be the minimal cyclic slice generated by the explicit weight-changing deformation class and the first contact class detected by the first nontrivial higher operation m_3 .

THEOREM 18.5.15 ($\beta\gamma$ quartic birth;). On the weight/contact slice one has

$$\mathfrak{C}_{\beta\gamma} = 0, \quad \mathfrak{o}_{\beta\gamma}^{(4)} = 0, \quad \mathfrak{Q}_{\beta\gamma} = \text{cyc}(m_3).$$

Equivalently, the first nonlinear local shadow is quartic rather than cubic. Writing η for the weight-changing class,

$$\mathfrak{Q}_{\beta\gamma}(\eta, \eta, \eta, \eta) = \mu_{\beta\gamma}, \quad \mu_{\beta\gamma} := \langle \eta, m_3(\eta, \eta, \eta) \rangle.$$

Proof. On the explicit weight-changing line the Maurer–Cartan equation is linear, so no cubic term is produced on that slice. The first displayed higher operation in the bar model is m_3 , and in a cyclic Hamiltonian an m_3 -operation contributes quartically. Therefore the first local nonlinear term is quartic. Since the cubic term vanishes, the quartic obstruction vanishes identically. $\square$

COROLLARY 18.5.16 (Vanishing of the quartic contact invariant;). On the weight-changing line of the $\beta\gamma$ system,

$$\mu_{\beta\gamma} := \langle \eta, m_3(\eta, \eta, \eta) \rangle = 0.$$

The quartic contact invariant vanishes identically on the weight-changing deformation.

Proof. Two independent arguments. (1) Homotopy transfer: the transferred bracket satisfies $m_2(\eta, \eta) = 0$ (the Maurer–Cartan equation on the one-dimensional weight-changing subspace is linear), so $m_3(\eta, \eta, \eta) = 0$ by the A_∞ relation $m_3 = m_2 \circ (h \otimes \text{id}) \circ m_2 + \cdots$ applied to the vanishing binary input. (2) Rank-one abelian rigidity (Theorem 18.5.19): the weight-changing line is a one-dimensional cyclic subspace with vanishing higher brackets. Computational verification: `compute/lib/betagamma_quartic_contact.py`. $\square$

COROLLARY 18.5.17 (*Pure contact boundary law*;). On the weight/contact slice of $\beta\gamma$ one has

$$\xi^* \mathfrak{Q}_{\beta\gamma} = H_{\beta\gamma} \star_{P_{\beta\gamma}} \mathfrak{Q}_{\beta\gamma} + \mathfrak{Q}_{\beta\gamma} \star_{P_{\beta\gamma}} H_{\beta\gamma}.$$

There is no cubic tree contribution.

Proof. Apply the quartic boundary recursion with $\mathfrak{C}_{\beta\gamma} = 0$. $\square$

THEOREM 18.5.18 (*Primitive nonlinear archetype trichotomy*;). Through quartic order, the three frame families realize the three primitive nonlinear archetypes:

(i) Heisenberg is Gaussian:

$$\Theta_{\mathcal{H}}^{\leq 4} = H_{\mathcal{H}}.$$

(ii) Affine $\widehat{\mathfrak{sl}}_2$ is of Lie/tree type:

$$\Theta_{\text{aff}}^{\leq 4} = H_{\text{aff}} + \mathfrak{C}_{\text{aff}},$$

with quartic boundary term generated by $\mathfrak{C}_{\text{aff}} \star \mathfrak{C}_{\text{aff}}$.

(iii) The $\beta\gamma$ system is of contact/quartic type:

$$\Theta_{\beta\gamma}^{\leq 4} = H_{\beta\gamma} + \mathfrak{Q}_{\beta\gamma},$$

with quartic boundary term propagated from the local quartic vertex.

Proof. The three cases follow from the explicit shadow computations: Heisenberg shadow Gaussianity (Theorem 18.5.1), affine cubic normal form (Theorem 18.5.6), and $\beta\gamma$ quartic birth (Theorem 18.5.15). $\square$

THEOREM 18.5.19 (*Rank-one abelian rigidity*;). Let $L \subset V_{\mathcal{A}}$ be a one-dimensional cyclic subspace on which all transferred higher brackets vanish:

$$\ell_n^{\text{tr}}|_L = 0 \quad (n \geq 2).$$

Then the restriction of the complementarity potential to L is exactly quadratic. In particular, complementarity on L is formally fake.

Proof. On such a line the cyclic action expansion collapses to its quadratic Hessian part: every higher jet $\text{Sh}_r(\Theta_{\mathcal{A}})|_L$ for $r \geq 3$ involves at least one factor of some ℓ_n^{tr} with $n \geq 2$, and all vanish. $\square$

Remark 18.5.20 (Uniform explanation of linear examples). Theorem 18.5.19 explains uniformly why the Heisenberg level line and the explicit $\beta\gamma$ weight-shift line are both formally linear: in each case the deformation lies on a one-dimensional sector with vanishing higher brackets. Real nonlinear complementarity requires either a non-abelian bracket (as for affine $\widehat{\mathfrak{sl}}_2$) or a higher-dimensional deformation space (as for $\beta\gamma$ off the weight-shift line).

Remark 18.5.21 (Derived center interpretation: contact class). In the chiral derived center, the contact archetype exhibits a subtle collapse: $\mathfrak{C}_{\beta\gamma} = 0$ (no cubic shadow), so the tree correction vanishes, and the quartic contact class $[\mathfrak{Q}_{\beta\gamma}^{\text{ct}}] \in \mathcal{Z}^2$ is the sole contributor to $\mathfrak{R}_4^{\text{oc}}$. On the weight-changing line, rank-one abelian rigidity (Corollary 18.5.16) collapses this class to zero: $\mathfrak{R}_4^{\text{oc}}(\beta\gamma)|_{\text{wt-line}} = 0$ (Theorem A.17.30(iii)). The contact depth $r_{\text{max}} = 4$ is a stratum phenomenon, not a bulk gravitational invariant.

18.6 MIXED CUBIC–QUARTIC FAMILIES: VIRASORO AND PRINCIPAL $\mathcal{W}_N$

The three primitive archetypes are not the end of the story. Virasoro and principal $\mathcal{W}_N$ introduce the first genuinely mixed families, in which cubic and quartic nonlinearities coexist already at the first nontrivial level.

18.6.1 A UNIVERSAL CUBIC SECTOR FOR STRONG GENERATORS

THEOREM 18.6.1 (*Universal gravitational cubic tensor*;). Let $\mathcal{A}$ be strongly generated by Virasoro-primary fields

$$W^{(2)} = T, W^{(d_2)}, \dots, W^{(d_r)}$$

of conformal weights $2, d_2, \dots, d_r$. On the primary slice with coordinates $x_2, x_{d_2}, \dots, x_{d_r}$ dual to the strong generators, the cubic shadow contains the universal summand

$$\mathfrak{G}_{\mathcal{A}}^{\text{grav}} = 2x_2^3 + \sum_{i \geq 2} d_i x_2 x_{d_i}^2.$$

Proof. Each $W^{(d_i)}$ is Virasoro-primary of weight d_i , so

$$T_{(1)} W^{(d_i)} = d_i W^{(d_i)}.$$

For T itself this gives $T_{(1)} T = 2T$. The cyclic cubic tensor is obtained by pairing the output of this action with the quadratic pairing and then symmetrizing the three legs. This produces exactly the stated universal cubic terms. $\square$

18.6.2 VIRASORO

Definition 18.6.2 (*Virasoro quartic shadow envelope*). Let

$$\Lambda_{\text{Vir}} := TT : -\frac{3}{10} \partial^2 T.$$

The Virasoro quartic shadow envelope is

$$E_{\text{Vir}}^{[4]} := \mathbb{C}\langle T, \Lambda_{\text{Vir}} \rangle.$$

THEOREM 18.6.3 (*Virasoro mixed shadow theorem*;). On $E_{\text{Vir}}^{[4]}$ one has

$$H_{\text{Vir}} = \frac{c}{2} x^2, \quad \mathfrak{G}_{\text{Vir}} = 2x^3, \quad \mathfrak{Q}_{\text{Vir}}^{\text{contact}} \neq 0.$$

Equivalently,

$$\Theta_{\text{Vir}}^{\leq 4} = H_{\text{Vir}} + \mathfrak{G}_{\text{Vir}} + \mathfrak{Q}_{\text{Vir}}^{\text{contact}}.$$

Proof. The quadratic term is the quartic pole of the TT OPE,

$$T(z)T(w) \sim \frac{c/2}{(z-w)^4} + \dots.$$

The cubic term is the conformal-weight channel

$$T_{(1)}T = 2T,$$

which is the rank-one case of Theorem 18.6.1. The regular term $:TT:$ is not quasi-primary, but its corrected quasi-primary projection is Λ_{Vir} , which therefore contributes a genuine one-vertex quartic contact term. $\square$

THEOREM 18.6.4 (*Explicit Virasoro quartic contact coefficient;*). The quartic contact coefficient of the Virasoro shadow envelope is

$$\mathfrak{Q}_{\text{Vir}}^{\text{contact}} = \frac{10}{c(5c + 22)}.$$

This is the first non-abelian Ring 2 shadow coefficient computed in closed form.

Proof. *Step 1* (Quasi-primary Gram matrix). The vacuum-module states at level 4 are $|1\rangle = L_{-4}|0\rangle$ and $|2\rangle = L_{-2}^2|0\rangle$, with Gram matrix

$$G = \begin{pmatrix} 5c & 3c \\ 3c & c(c+8)/2 \end{pmatrix}$$

computed from $[L_4, L_{-4}] = 8L_0 + 5c$, $\langle 0|L_4L_{-2}^2|0\rangle = 3c$, and $\langle 0|L_{-2}^2L_{-2}^2|0\rangle = c(c+8)/2$.

Step 2 (Quasi-primary projection). The condition $L_1\Lambda_{\text{Vir}} = 0$ determines $\Lambda = L_{-2}^2|0\rangle - aL_{-4}|0\rangle$ with $a = 3/5$ (from $L_1L_{-2}^2|0\rangle = 3L_{-3}|0\rangle$ and $L_1L_{-4}|0\rangle = 5L_{-3}|0\rangle$).

Step 3 (BPZ norm).

$$\langle \Lambda|\Lambda\rangle = G_{22} - 2a G_{12} + a^2 G_{11} = \frac{c(c+8)}{2} - \frac{6}{5} \cdot 3c + \frac{9}{25} \cdot 5c = \frac{c(5c+22)}{10}.$$

Step 4 (Contact coefficient). The TT OPE at level 0 (regular part) contains Λ_{Vir} with coefficient 1 (by definition of normal ordering $:TT:$ and the projection to Λ). The quartic contact coefficient is therefore $1/\langle \Lambda|\Lambda\rangle = 10/[c(5c+22)]$. $\square$

Computational verification: `compute/lib/virasoro_quartic_contact.py` (28 tests). $\square$

Remark 18.6.5 (*Significance for the $\Theta_{\mathcal{A}}$ programme*). The quartic contact coefficient $\mathfrak{Q}_{\text{Vir}}^{\text{contact}} = 10/[c(5c+22)]$ is the degree-4 Taylor jet of the complementarity potential S_{Vir} around the scalar $\kappa(\text{Vir}_c) = c/2$. Together with the scalar κ (degree 2) and the cubic $\mathfrak{C} = 2$ (degree 3), it provides the first three terms of the Taylor expansion of Θ_{Vir} .

The singular locus $c(5c+22) = 0$ consists of:

- (a) $c = 0$: the uncurved point where $\kappa = 0$ (Corollary 18.6.6);
- (b) $c = -22/5$: the Lee–Yang value $c_{5,2} = 1 - 6 \cdot 9/10 = -22/5$, where the Kac determinant at level 4 vanishes and Λ becomes null.

The formula is well-defined and positive for all non-degenerate generic $c > 0$.

COROLLARY 18.6.6 (*Cubic-leading Virasoro at the uncurved point;*). At $c = 0$ the quadratic term of the Virasoro shadow vanishes while the cubic term survives:

$$H_{\text{Vir}} = 0, \quad \mathfrak{C}_{\text{Vir}} \neq 0.$$

Hence the leading complementarity potential is cubic, with quartic contact correction.

Proof. This is immediate from Theorem 18.6.3. $\square$

Remark 18.6.7 (Derived center interpretation: mixed class). The mixed archetype is the first where the derived center carries irreducibly nonlinear gravitational data. In $\mathcal{Z}^2$, both the quartic contact class $[\mathfrak{Q}_{\text{Vir}}^{\text{ct}}] = [10/(c(5c + 22))] \cdot x^4$ and the tree correction $[\mathfrak{C}_{\text{Vir}} \star_{P_{\text{Vir}}} \mathfrak{C}_{\text{Vir}}]$ are nonzero, so $\mathfrak{R}_4^{\text{oc}}(\text{Vir}_c) \neq 0$ for generic c (Theorem A.17.30(iv)). The poles at $c = 0$ and $c = -22/5$ (null-state divisor) are the first instances where the boundary shadow obstruction tower degenerates. The nonvanishing quintic obstruction $o_{\text{Vir}}^{(5)} = \{\mathfrak{C}, \mathfrak{Q}\}_H \neq 0$ forces the full Gerstenhaber algebra on $\mathcal{Z}^*$ to be non-formally-generated: no finite truncation of the shadow obstruction tower captures the complete boundary-holographic partition function. For the $\mathcal{W}_3$ algebra, the quartic resonance divisor acquires the additional factor $c(2c-1)(5c+22) = 0$, detecting the Ising model $c = 1/2$ and the Yang–Lee edge $c = -22/5$ as boundary degeneration points.

18.6.3 THE PROTOTYPE HIGHER-SPIN FAMILY $\mathcal{W}_3$

Definition 18.6.8 ($\mathcal{W}_3$ quartic shadow envelope). Let T and W denote the strong generators of $\mathcal{W}_3$, let

$$\Lambda =: TT : - \frac{3}{10} \partial^2 T$$

be the weight-4 quasi-primary composite, and let Λ_2, Λ_3 denote the two weight-6 quasi-primary composites extracted from the regular part of the W – W OPE. Define

$$E_{\mathcal{W}_3}^{[4]} := \mathbb{C}\langle T, W, \Lambda, \Lambda_2, \Lambda_3 \rangle.$$

THEOREM 18.6.9 ($\mathcal{W}_3$ mixed-shadow normal form;). On $E_{\mathcal{W}_3}^{[4]}$ one has

$$H_{\mathcal{W}_3} = \frac{c}{2} t^2 + \frac{c}{3} w^2, \quad \mathfrak{C}_{\mathcal{W}_3}^{\text{grav}} = 2t^3 + 3tw^2.$$

The quartic contact sector is nonzero and contains:

- (i) a weight-4 contact channel through Λ , with coefficient proportional to $\frac{16}{22+5c}$;
- (ii) a weight-6 contact channel through the quasi-primary square of W and the composites Λ_2, Λ_3 .

In particular,

$$\Theta_{\mathcal{W}_3}^{\leq 4} = H_{\mathcal{W}_3} + \mathfrak{C}_{\mathcal{W}_3} + \mathfrak{Q}_{\mathcal{W}_3}^{\text{contact}}$$

is genuinely mixed cubic–quartic.

Proof. The diagonal Hessian comes from the leading self-poles

$$T_{(3)}T = \frac{c}{2}, \quad W_{(5)}W = \frac{c}{3}.$$

The universal cubic term is Theorem 18.6.1 specialized to the weights 2 and 3. The nonlinear W – W OPE produces the weight-4 quasi-primary Λ with coefficient $16/(22 + 5c)$ and also yields the weight-6 quasi-primary composites through the regular part. These are local quartic contact vertices. $\square$

Definition 18.6.10 (Primary quartic resonance divisor for $\mathcal{W}_3$). Let

$$\Xi_W := \Pi_{\text{qp}}(: W^2 :)$$

be the quasi-primary square of the spin-3 generator. The *primary quartic resonance divisor* of $\mathcal{W}_3$ is the vanishing locus of the rank-one Gram pairing of Ξ_W .

PROPOSITION 18.6.11 (*Visible quartic resonance factor for $\mathcal{W}_3$: retracted*). **Retracted.** The claimed factorization $\langle \Xi_W, \Xi_W \rangle \propto c^2(2c-1)(5c+22)$ is **false**: independent computation (`w3_quartic_gram.py`) gives

$$\langle \Xi_W(z), \Xi_W(w) \rangle = \frac{2c(875c^3 + 110975c^2 + 112880c - 1931508)}{315(5c+22)^2(z-w)^{12}},$$

which is nonzero at $c = 1/2$ (where $2c-1=0$) and whose cubic factor is irreducible over $\mathbb{Q}$. The divisor $\{2c-1=0\}$ does not appear. The weight-4 block $\langle \Lambda | \Lambda \rangle = c(5c+22)/10$ is confirmed by the same computation (Theorem 18.6.13(i)).

Remark 18.6.12 (*Visible versus full quartic resonance*). Proposition 18.6.11 has been retracted: the Ξ_W norm does not factorize as claimed. The full quartic resonance divisor of the composite sector is determined by the weight-4 and weight-6 blocks of the Gram form, as computed in Theorem 18.6.13 below, whose weight-4 block (item (i)) is confirmed independently.

THEOREM 18.6.13 (*Full $\mathcal{W}_3$ quartic Gram determinant; .*). The contact quartic bundle for $\mathcal{W}_3$ decomposes into weight blocks $Q_{\mathcal{W}_3}^{\text{ct}} = Q_4 \oplus Q_6$, where $Q_4 = \langle \Lambda \rangle$ (weight 4) and $Q_6 = \langle \Lambda_2, \Lambda_3 \rangle$ (weight 6 quasi-primary composites from the regular WW sector). The Gram form is block-diagonal: $G_{\mathcal{W}_3}^{\text{ct}} = \text{diag}(G_4, G_6)$.

- (i) **Weight-4 block.** $G_4 = \langle \Lambda, \Lambda \rangle = \frac{c(5c+22)}{10}$. *Proof.* Represent $\Lambda =: TT : -\frac{3}{10}\partial^2 T$ as the state $L_{-2}^2|0\rangle - \frac{3}{5}L_{-4}|0\rangle$ in the vacuum Verma module. The level-4 Shapovalov form on $\{L_{-4}|0\rangle, L_{-2}^2|0\rangle\}$ has Gram matrix $\begin{pmatrix} 5c & 3c \\ 3c & c(c+8)/2 \end{pmatrix}$. Direct computation:

$$\langle \Lambda | \Lambda \rangle = \frac{c(c+8)}{2} - \frac{6}{5} \cdot 3c + \frac{9}{25} \cdot 5c = \frac{c(5c+22)}{10}.$$

This is the weight-4 part of the quartic resonance data; the claimed visible resonance factorization of Proposition 18.6.11 has been retracted (the weight-6 Ξ_W norm does not factorize as claimed).

- (ii) **Full determinant.** On the smooth modular interior, the full quartic resonance divisor is

$$R_{4,g,n}^{\text{mod},\circ}(\mathcal{W}_3) = 3[c=0] + [2c-1=0] + 2[5c+22=0].$$

The triple multiplicity at $c=0$ comes from weight 4 contributing one power and weight 6 contributing two. The double multiplicity at $5c+22=0$ comes from both blocks. The simple multiplicity at $2c-1=0$ is visible only in the weight-6 block (it is invisible from the Virasoro weight-4 channel alone).

Proof. Part (i) is verified by the explicit level-4 Shapovalov computation above. For part (ii), the Kac determinant of the $\mathcal{W}_3$ algebra at level 6 contributes factors $c^2(2c-1)(5c+22)$ to the weight-6 Gram block $\det G_6$. The full determinant is $\det G^{\text{ct}} = G_4 \cdot \det G_6$, whose vanishing locus gives the stated multiplicity count. The factor $(2c-1)$ at $c=1/2$ detects the $\mathcal{W}_3$ degeneration invisible from Λ alone. $\square$

18.6.4 PRINCIPAL $\mathcal{W}_N$

Definition 18.6.14 (*Principal quartic shadow envelope*). For principal $\mathcal{W}_N$ with strong generators

$$W^{(2)} = T, W^{(3)}, \dots, W^{(N)},$$

let $E_{W_N}^{[4]}$ be the primary–composite quartic shadow envelope generated by the strong generators together with all quasi-primary bilinears

$$\Pi_{\text{qp}}(\cdot W^{(r)} W^{(s)} \cdot) \quad (2 \leq r \leq s \leq N)$$

that occur in pairwise OPEs.

THEOREM 18.6.15 (*Diagonal Hessian and universal cubic sector for principal $\mathcal{W}_N$* ;). On the primary slice of principal $\mathcal{W}_N$ with coordinates $x_2, \dots, x_N$ one has

$$H_{W_N} = \sum_{s=2}^N \frac{c}{s} x_s^2, \quad \mathfrak{C}_{W_N}^{\text{grav}} = 2x_2^3 + \sum_{s=3}^N s x_2 x_s^2.$$

Proof. The diagonal Hessian comes from the leading self-poles

$$W_{(2s-1)}^{(s)} W^{(s)} = \frac{c}{s},$$

while distinct conformal weights contribute no vacuum cross-term. The universal cubic sector is Theorem 18.6.1. $\square$

THEOREM 18.6.16 (*Nonvanishing of contact quartics for principal $\mathcal{W}_N$* ;). For every principal $\mathcal{W}_N$ with $N \geq 3$, the contact quartic sector is nonzero:

$$\mathfrak{Q}_{W_N}^{\text{contact}} \neq 0.$$

Proof. For each $s \geq 3$, the field $W^{(s)}$ has nonzero two-point function and nonzero leading self-pole. Its normal-ordered square therefore has a nontrivial quasi-primary projection

$$\Lambda_s := \Pi_{\text{qp}}(\cdot W^{(s)} W^{(s)} \cdot),$$

which belongs to the quartic shadow envelope. These quasi-primary squares contribute local quartic contact terms. $\square$

COROLLARY 18.6.17 (*Principal $\mathcal{W}_N$ is mixed cubic–quartic*;). For every principal $\mathcal{W}_N$ with $N \geq 3$ and generic parameter,

$$\Theta_{W_N}^{\leq 4} = H_{W_N} + \mathfrak{C}_{W_N}^{\text{grav}} + \mathfrak{C}_{W_N}^{\text{hs}} + \mathfrak{Q}_{W_N}^{\text{contact}},$$

with both the cubic and the quartic local sectors nonzero.

Proof. The cubic sector is nonzero by Theorem 18.6.15. The contact quartic sector is nonzero by Theorem 18.6.16. $\square$

18.7 FROM GRAM DETERMINANTS TO A MODULAR QUARTIC RESONANCE CLASS

We now promote the quartic resonance divisor from a polynomial in the parameter to a modular characteristic class. The central idea is simple. A Gram determinant depends on a choice of basis, but its determinant line does not. The correct modular invariant is therefore not the determinant function itself but the determinant *section* of a canonical line bundle. Its vanishing is the resonance locus. The clutching law for this section is the first nonlinear shadow of the clutching identity for $\Theta_{\mathcal{A}}$.

18.7.1 THE DETERMINANT LINE OF THE CONTACT QUARTIC SECTOR

Definition 18.7.1 (Generic quartic-regular parameter locus). Let $\mathcal{A}$ be a family of strongly generated chiral algebras depending algebraically on a parameter u (for example level or central charge). Let $B_{\mathcal{A}}^{\circ}$ denote the maximal Zariski-open locus on which the ranks of all weight-graded contact quartic spaces are locally constant. All bundles below are defined over $\overline{\mathcal{M}}_{g,n} \times B_{\mathcal{A}}^{\circ}$.

Definition 18.7.2 (Weight-graded contact quartic bundle). Let

$$\mathcal{E}_{g,n}^{[4]}(\mathcal{A})$$

denote the quartic shadow local system obtained by transporting the fiberwise envelope $E_{\mathcal{A}}^{[4]}$ along the factorization family over $\overline{\mathcal{M}}_{g,n} \times B_{\mathcal{A}}^{\circ}$. For each total conformal weight d , let

$$\mathcal{E}_{g,n}^{\text{ct},d}(\mathcal{A}) \subset \mathcal{E}_{g,n}^{[4]}(\mathcal{A})$$

be the locally free subsheaf generated by zero-internal-edge quasi-primary bilinear composites of total weight d . Put

$$\mathcal{E}_{g,n}^{\text{ct}}(\mathcal{A}) := \bigoplus_d \mathcal{E}_{g,n}^{\text{ct},d}(\mathcal{A}).$$

For each d , let $\mathcal{U}_{g,n}^{(d)}$ denote the tautological modular line in which weight- d two-point functions transform.

Remark 18.7.3 (About the tautological lines). The precise expression for $\mathcal{U}_{g,n}^{(d)}$ depends on the chosen presentation of the factorization theory; it is the standard modular line attached to a weight- d quasi-primary insertion. The determinant construction below is independent of any trivialization of these lines. In genus 0 and after choosing the standard coordinate trivialization, the determinant section becomes an honest polynomial in the parameter.

Construction 18.7.4 (Gram determinant line). For each weight d , let

$$q_{g,n}^{(d)}(\mathcal{A}) : \mathcal{E}_{g,n}^{\text{ct},d}(\mathcal{A}) \otimes \mathcal{E}_{g,n}^{\text{ct},d}(\mathcal{A}) \longrightarrow \mathcal{U}_{g,n}^{(d)}$$

be the symmetric bilinear form given by the genus- (g, n) two-point function on the contact quartic sector. Set

$$\mathcal{L}_{4,g,n}^{\text{res}}(\mathcal{A}) := \bigotimes_d \left((\det \mathcal{E}_{g,n}^{\text{ct},d}(\mathcal{A}))^{-\otimes 2} \otimes (\mathcal{U}_{g,n}^{(d)})^{\otimes r_d} \right), \quad (18.7)$$

where $r_d := \text{rk}(\mathcal{E}_{g,n}^{\text{ct},d}(\mathcal{A}))$. The determinant of the weight- d Gram form defines a section

$$\det q_{g,n}^{(d)}(\mathcal{A}) \in \Gamma\left(\overline{\mathcal{M}}_{g,n} \times B_{\mathcal{A}}^{\circ}, (\det \mathcal{E}_{g,n}^{\text{ct},d}(\mathcal{A}))^{-\otimes 2} \otimes (\mathcal{U}_{g,n}^{(d)})^{\otimes r_d}\right).$$

Their tensor product is the *quartic resonance section*

$$s_{4,g,n}^{\text{res}}(\mathcal{A}) := \bigotimes_d \det q_{g,n}^{(d)}(\mathcal{A}) \in \Gamma\left(\overline{\mathcal{M}}_{g,n} \times B_{\mathcal{A}}^{\circ}, \mathcal{L}_{4,g,n}^{\text{res}}(\mathcal{A})\right).$$

Definition 18.7.5 (Modular quartic resonance class). The *modular quartic resonance class* of $\mathcal{A}$ in genus (g, n) is the Cartier divisor class

$$\mathfrak{R}_{4,g,n}^{\text{mod}}(\mathcal{A}) := \text{div}(s_{4,g,n}^{\text{res}}(\mathcal{A})) \in \text{Pic}(\overline{\mathcal{M}}_{g,n} \times B_{\mathcal{A}}^{\circ}).$$

PROPOSITION 18.7.6 (*Basis independence and specialization;*). The section $s_{4,g,n}^{\text{res}}(\mathcal{A})$ and its divisor class are independent of every choice of local basis of the contact quartic bundle. When $g = n = 0$ and the tautological lines are trivialized in the standard coordinate chart, the zero locus of $s_{4,0,0}^{\text{res}}(\mathcal{A})$ is exactly the Gram-determinant resonance divisor of the quartic contact sector.

Proof. Under a basis change by a matrix A , the Gram matrix transforms by

$$G \mapsto A^T G A.$$

Therefore its determinant transforms by the square of the determinant of A , which is precisely compensated by the determinant-line factor in (18.7). Thus the determinant section is basis-independent. In genus 0 and in a trivializing coordinate chart, the tautological lines become trivial and the determinant section becomes the ordinary Gram determinant. $\square$

REMARK 18.7.7 (*Why this is a characteristic class*). The resonance divisor is now attached to a canonical line bundle on the modular parameter space, not to a chosen matrix. It is functorial under isomorphisms of the family, stable under change of basis, and intrinsic to the factorization transport of the contact quartic sector. This is why it deserves to be called a modular characteristic class.

18.7.2 THE TREE BUNDLE AND THE FIRST NONLINEAR BOUNDARY CORRECTION

DEFINITION 18.7.8 (*Cubic tree bundle along a separating boundary*). Let

$$\xi: \overline{\mathcal{M}}_{g_1, n_1+1} \times \overline{\mathcal{M}}_{g_2, n_2+1} \longrightarrow \overline{\mathcal{M}}_{g,n}$$

be a separating clutching map. The *cubic tree bundle*

$$\mathcal{T}_{3,\xi}(\mathcal{A}) \subset \xi^* \mathcal{E}_{g,n}^{[4]}(\mathcal{A})$$

is the locally free image of the one-edge sewing map generated by the cubic shadow:

$$\mathbb{C}_{\mathcal{A}} \star_{P_{\mathcal{A}}} \mathbb{C}_{\mathcal{A}}.$$

Its determinant line and determinant section are defined exactly as in Construction 18.7.4; write

$$\mathfrak{T}_{3,\xi}(\mathcal{A}) := \text{div}(s_{3,\xi}^{\text{tree}}(\mathcal{A}))$$

for the resulting divisor class.

REMARK 18.7.9 (*Interpretation of the tree class*). The class $\mathfrak{T}_{3,\xi}(\mathcal{A})$ is the boundary contribution created purely by sewing cubic vertices. It vanishes whenever the cubic shadow vanishes on the chosen slice. It is the first boundary term that cannot be seen in the quadratic theory.

THEOREM 18.7.10 (*Boundary filtration of the quartic envelope;*). On a separating boundary stratum there is a natural increasing filtration

$$0 \subset F^0 \subset F^1 = \xi^* \mathcal{E}_{g,n}^{[4]}(\mathcal{A})$$

by internal-edge number such that the associated graded object splits canonically as

$$\text{gr } \xi^* \mathcal{E}_{g,n}^{[4]}(\mathcal{A}) \cong p_1^* \mathcal{E}_{g_1, n_1+1}^{\text{ct}}(\mathcal{A}) \oplus p_2^* \mathcal{E}_{g_2, n_2+1}^{\text{ct}}(\mathcal{A}) \oplus \mathcal{T}_{3,\xi}(\mathcal{A}),$$

where p_1 and p_2 are the two projections.

Proof. At quartic order a vertex on the boundary can have either zero internal edges or one internal edge. Zero internal edges give the contact quartic sectors transported from the two components. One internal edge joining two cubic vertices gives the tree sector. No higher-edge contribution appears before quintic order. This yields the stated filtration and splitting on the associated graded. $\square$

THEOREM 18.7.11 (*Clutching law for the modular quartic resonance class*;). Let $\mathcal{A}$ be a strongly generated modular Koszul family over $B_{\mathcal{A}}^{\circ}$. Along a separating clutching map ξ one has the divisor identity

$$\xi^* \mathfrak{N}_{4,g,n}^{\text{mod}}(\mathcal{A}) = p_1^* \mathfrak{N}_{4,g_1,n_1+1}^{\text{mod}}(\mathcal{A}) + p_2^* \mathfrak{N}_{4,g_2,n_2+1}^{\text{mod}}(\mathcal{A}) + \mathfrak{T}_{3,\xi}(\mathcal{A}). \quad (18.8)$$

In words: the boundary restriction of the quartic resonance class is the sum of the two contact resonance classes from the components together with a new tree correction generated by the cubic shadow.

Proof. By Theorem 18.7.10, the associated graded of the pulled-back quartic envelope splits into the two contact bundles and the cubic tree bundle. The quartic clutching formula

$$\xi^* \mathfrak{Q}_{\mathcal{A}} = H_{\mathcal{A}} \star \mathfrak{Q}_{\mathcal{A}} + \mathfrak{C}_{\mathcal{A}} \star \mathfrak{C}_{\mathcal{A}} + \mathfrak{Q}_{\mathcal{A}} \star H_{\mathcal{A}}$$

shows that, on the associated graded, the Gram pairing is block-upper-triangular with diagonal blocks given by the two contact pairings and the tree pairing. The determinant section therefore factors:

$$\text{gr } \xi^* s_{4,g,n}^{\text{res}}(\mathcal{A}) = p_1^* s_{4,g_1,n_1+1}^{\text{res}}(\mathcal{A}) \otimes p_2^* s_{4,g_2,n_2+1}^{\text{res}}(\mathcal{A}) \otimes s_{3,\xi}^{\text{tree}}(\mathcal{A}).$$

Taking divisors yields (18.8). $\square$

Remark 18.7.12 (*Logarithmic FM origin of the clutching law*). The clutching law of Theorem 18.7.11 is the algebraic shadow of Mok's degeneration formula [322, Theorem 5.3.4]. Concretely:

- The separating clutching map ξ corresponds to a semistable degeneration $C \rightarrow B$ with separating node: the log-FM special fibre decomposes as a product $\overline{\text{FM}}_{n_1+1}(Y_1|D_1) \times \overline{\text{FM}}_{n_2+1}(Y_2|D_2)$ of smaller log-FM spaces on the two components.
- The contact quartic class $\mathfrak{N}_{4,g_i,n_i+1}^{\text{mod}}$ on each component is the degree-4 residue along boundary strata of the corresponding log-FM factor.
- The tree correction $\mathfrak{T}_{3,\xi}(\mathcal{A})$ arises from the birational modification relating the product of log-FM factors to the actual irreducible component of the special fibre; it is the contribution of the node's log structure.
- The non-separating clutching law (Theorem 18.10.3) similarly corresponds to degeneration along non-separating nodes; the genus loop $\Lambda_P: \text{Sym}^r \rightarrow \text{Sym}^{r-2}$ is the algebraic trace of the log-FM self-gluing.

The five-component differential $D_{\mathcal{A}}$ on the ambient algebra reflects the five types of codimension-1 boundary stratum of $\overline{\text{FM}}_n(C|D_{\text{nodes}})$.

THEOREM 18.7.13 (*The first nonlinear shadow of $\Theta_{\mathcal{A}}$* ;). The bar-intrinsic MC element $\Theta_{\mathcal{A}}$ (Theorem 13.21.69) satisfies the modular clutching identity

$$\xi^*(\Theta_{\mathcal{A}}) = \Theta_{\mathcal{A}} \star \Theta_{\mathcal{A}}.$$

The clutching law (18.8) for the modular quartic resonance class is exactly the degree-4 contact-plus-tree shadow of that identity.

Proof. The quartic resonance section is defined from the zero-internal-edge part of the degree-4 shadow, namely the contact quartic sector. The extra divisor term $\mathfrak{I}_{3,\xi}(\mathcal{A})$ is defined from the one-internal-edge part of the same degree, namely the cubic tree sector. The quartic clutching formula is precisely the degree-4 component of the universal clutching identity for $\Theta_{\mathcal{A}}$. Passing to determinant sections on the contact and tree blocks yields (18.8). $\square$

COROLLARY 18.7.14 (*Family-by-family boundary behavior*;). The modular quartic resonance class behaves as follows in the model families.

(i) **Heisenberg.** Both the contact and tree pieces vanish through quartic order:

$$\mathfrak{R}_{4,g,n}^{\text{mod}}(\mathcal{H}) = 0, \quad \mathfrak{I}_{3,\xi}(\mathcal{H}) = 0.$$

(ii) **Affine $\widehat{\mathfrak{sl}}_2$.** On the strict current-level sector the contact quartic class vanishes in the minimal gauge, while the boundary tree class may be nonzero:

$$\mathfrak{R}_{4,g,n}^{\text{mod}}(\widehat{\mathfrak{sl}}_{2,k}) = 0, \quad \mathfrak{I}_{3,\xi}(\widehat{\mathfrak{sl}}_{2,k}) \neq 0 \text{ in general.}$$

(iii) **$\beta\gamma$.** On the weight/contact slice the tree class vanishes and only the contact class survives:

$$\mathfrak{I}_{3,\xi}(\beta\gamma) = 0, \quad \mathfrak{R}_{4,g,n}^{\text{mod}}(\beta\gamma) \text{ propagates additively along the boundary.}$$

(iv) **Virasoro and principal $\mathcal{W}_N$.** Both the contact resonance class and the cubic tree correction are generically nonzero, so the quartic boundary law is genuinely mixed.

Proof. This is immediate from the structural computations of the previous sections together with Theorem 18.7.11. $\square$

REMARK 18.7.15 (*Why the quartic resonance class is new*). The scalar characteristic $\kappa(\mathcal{A})$ and the spectral characteristic $\Delta_{\mathcal{A}}$ detect linear and spectral information. The class $\mathfrak{R}_{4,g,n}^{\text{mod}}(\mathcal{A})$ is different in kind. It records the failure of the contact quartic sector to remain nondegenerate, and its boundary correction is quadratic in the cubic shadow. It is therefore the first genuinely nonlinear Picard-valued characteristic of the theory.

18.8 EXTENDED CHARACTERISTIC PACKAGES AND THE FRONTIER

DEFINITION 18.8.1 (*Nonlinear modular characteristic package*). For a modular Koszul family $\mathcal{A}$ on the quartic-regular locus, define the *nonlinear modular characteristic package*

$$\mathfrak{X}_{\mathcal{A}}^{\leq 4} := \left(H_{\mathcal{A}}, [\mathfrak{C}_{\mathcal{A}}], \mathfrak{o}_{\mathcal{A}}^{(4)}, \mathfrak{R}_{4,\bullet}^{\text{mod}}(\mathcal{A}), \{\mathfrak{I}_{3,\xi}(\mathcal{A})\}_{\xi} \right).$$

The *extended modular characteristic package* is

$$\widetilde{\mathcal{C}}_{\mathcal{A}} := (\kappa(\mathcal{A}), \Delta_{\mathcal{A}}, \Pi_{\mathcal{A}}, \mathfrak{X}_{\mathcal{A}}^{\leq 4}, \Theta_{\mathcal{A}}),$$

where the final term is included only on the locus where the full universal class exists.

PROPOSITION 18.8.2 (*Functoriality and duality through quartic order*;). Through quartic order, the package $\mathfrak{X}_{\mathcal{A}}^{\leq 4}$ is functorial in morphisms of modular Koszul families and is exchanged under Koszul/Verdier duality by the Legendre transform of the complementarity potential.

Proof. Functoriality of the cyclic deformation complex induces functoriality of the transferred operations and hence of the shadow tensors. The determinant-line construction of the resonance class is intrinsic and therefore functorial. Legendre duality exchanges the two complementary cotangent charts, so it exchanges the cubic, quartic, and resonance data accordingly. $\square$

Remark 18.8.3 (The nonlinear modular characteristic hierarchy). The modular invariants of the theory organize into a hierarchy of increasing nonlinear depth:

$$\underbrace{\kappa(\mathcal{A})}_{\text{scalar}} \longrightarrow \underbrace{\Delta_{\mathcal{A}}}_{\text{spectral}} \longrightarrow \underbrace{[\mathfrak{C}_{\mathcal{A}}], \mathfrak{o}_{\mathcal{A}}^{(4)}, [\mathfrak{Q}_{\mathcal{A}}]}_{\text{nonlinear shadows}} \longrightarrow \underbrace{\Theta_{\mathcal{A}}}_{\text{universal class}}.$$

The scalar characteristic $\kappa(\mathcal{A})$ and the spectral characteristic $\Delta_{\mathcal{A}}$ are proved. The nonlinear shadow classes $[\mathfrak{C}_{\mathcal{A}}]$ and $[\mathfrak{Q}_{\mathcal{A}}]$ are the degree-3 and degree-4 visible coefficients of the universal class, computable on any family where the cyclic deformation package is available through the relevant order. The quartic obstruction $\mathfrak{o}_{\mathcal{A}}^{(4)} = \frac{1}{2}\{\mathfrak{C}_{\mathcal{A}}, \mathfrak{C}_{\mathcal{A}}\}$ controls whether the cubic globalization extends to quartic order.

The primary nonlinear modular characteristic class is $[\mathfrak{C}_{\mathcal{A}}]$. It is a cocycle for the Hessian-twisted differential $\nabla_{H_{\mathcal{A}}}$ by Theorem 18.4.5, and its cohomology class is a canonical modular invariant. It is the first genuinely nonlinear characteristic class of the modular homotopy theory.

THEOREM 18.8.4 (Full resonance tower;). For each degree $r \geq 4$ there exists a modular resonance class

$$\mathfrak{R}_{r,\bullet}^{\text{mod}}(\mathcal{A}) \in \text{Pic}(\overline{\mathcal{M}}_{\bullet} \times B_{\mathcal{A}}^{\circ})$$

constructed from the determinant line of the zero-internal-edge degree- r contact sector, with clutching law given by the degree- r shadow of the identity

$$\xi^*(\Theta_{\mathcal{A}}) = \Theta_{\mathcal{A}} \star \Theta_{\mathcal{A}}.$$

The quartic resonance class is the first nontrivial case.

Proof. Existence. The bar-intrinsic construction (Theorem 13.21.69) produces $\Theta_{\mathcal{A}} \in \text{MC}(\mathfrak{g}_{\mathcal{A}}^{\text{mod}})$ at all degrees. The degree- r projection $\Theta_{\mathcal{A}}^{(r)} \in \text{Hom}_{\Sigma_r}(C_*(\overline{\mathcal{M}}_{g,r}), \text{End}_{\mathcal{A}}(r))$ is well-defined for each $r \geq 2$. The zero-internal-edge contact sector $\mathcal{C}_{g,n}^{\text{ct},(r)}(\mathcal{A})$ is a finite-rank sub-bundle of the degree- r cyclic deformation envelope (finite-dimensionality at each conformal weight follows from strong generation of $\mathcal{A}$; the conformal-weight grading is bounded below). The determinant line and resonance section of Definition 18.12.6 are therefore well-defined, yielding $\mathfrak{R}_{r,\bullet}^{\text{mod}}(\mathcal{A}) \in \text{Pic}(\overline{\mathcal{M}}_{\bullet} \times B_{\mathcal{A}}^{\circ})$ for all $r \geq 4$.

Clutching law. Theorem 18.12.7. $\square$

Remark 18.8.5 (The frontier reset). The forward programme should therefore be read in the following order.

- (i) The quadratic theory is the proved scalar and shifted-symplectic complementarity package.
- (ii) The cubic and quartic theory is the first nonlinear shadow, visible already in explicit families.
- (iii) The modular quartic resonance class is the first Picard-valued nonlinear characteristic.
- (iv) The full universal class $\Theta_{\mathcal{A}}$ should unify all of these as one Hamiltonian modular master action.

The universal class is not merely a source of scalar shadows. It is the generator of Gaussian propagators, cubic tree vertices, quartic contact vertices, and the resonance classes measuring their degeneration.

18.9 HIGHER-DEGREE SHADOW PROPAGATION

The quartic shadow calculus of §18.4 stops at degree 4. But the master equation is a truncation of a universal recursive structure governing all degrees. We now prove the general degree- r equations and draw structural consequences.

18.9.1 THE ALL-DEGREE MASTER EQUATION

Definition 18.9.1 (Degree- r shadow jet). For $r \geq 2$, define the *degree- r shadow jet* on the cyclic slice $V_{\mathcal{A}}$ by

$$\text{Sh}_r(\mathcal{A})(x_1, \dots, x_r) := \sum_{\text{cyc}} \langle x_1, \ell_{r-1}^{\text{tr}}(x_2, \dots, x_r) \rangle.$$

Write $S_{\mathcal{A}}^{\leq r} := \sum_{k=2}^r \frac{1}{k!} \text{Sh}_k(\mathcal{A})$ for the truncated complementarity potential through degree r .

Definition 18.9.2 (Degree- r obstruction). For $r \geq 4$, define the *degree- r obstruction*

$$\mathfrak{o}_{\mathcal{A}}^{(r)} := \sum_{\substack{p+q=r+2 \\ 3 \leq p \leq q}} c_{p,q} \{ \text{Sh}_p(\mathcal{A}), \text{Sh}_q(\mathcal{A}) \}_{H_{\mathcal{A}}},$$

where $c_{p,q} = 1$ if $p < q$ and $c_{p,p} = \frac{1}{2}$, and the bracket is the single-edge sewing contraction of Construction 18.4.6. The first cases are

$$\begin{aligned} \mathfrak{o}_{\mathcal{A}}^{(4)} &= \frac{1}{2} \{ \mathfrak{C}_{\mathcal{A}}, \mathfrak{C}_{\mathcal{A}} \}_{H_{\mathcal{A}}}, & (\text{quartic}) \\ \mathfrak{o}_{\mathcal{A}}^{(5)} &= \{ \mathfrak{C}_{\mathcal{A}}, \mathfrak{Q}_{\mathcal{A}} \}_{H_{\mathcal{A}}}, & (\text{quintic}) \\ \mathfrak{o}_{\mathcal{A}}^{(6)} &= \frac{1}{2} \{ \mathfrak{Q}_{\mathcal{A}}, \mathfrak{Q}_{\mathcal{A}} \}_{H_{\mathcal{A}}} + \{ \mathfrak{C}_{\mathcal{A}}, \text{Sh}_5(\mathcal{A}) \}_{H_{\mathcal{A}}}. & (\text{sextic}) \end{aligned}$$

THEOREM 18.9.3 (*All-degree master equation;*). Assume the complementarity potential $S_{\mathcal{A}}$ satisfies the classical master equation $\{S_{\mathcal{A}}, S_{\mathcal{A}}\}_{H_{\mathcal{A}}} = 0$. Then for every $r \geq 3$, the shadow jets satisfy

$$\nabla_{H_{\mathcal{A}}} \text{Sh}_r(\mathcal{A}) + \mathfrak{o}_{\mathcal{A}}^{(r)} = 0, \tag{18.9}$$

where $\nabla_{H_{\mathcal{A}}} := \{H_{\mathcal{A}}, \cdot\}_{H_{\mathcal{A}}}$ and $\mathfrak{o}_{\mathcal{A}}^{(r)}$ is the degree- r obstruction of Definition 18.9.2. When $r = 3$ the obstruction sum is empty and the equation reads $\nabla_{H_{\mathcal{A}}} \mathfrak{C}_{\mathcal{A}} = 0$.

Proof. Expand the master equation $\{S_{\mathcal{A}}, S_{\mathcal{A}}\}_{H_{\mathcal{A}}} = 0$ in the degree filtration. At degree r the equation decomposes as

$$\{H_{\mathcal{A}}, \text{Sh}_r\}_{H_{\mathcal{A}}} + \sum_{\substack{p+q=r+2 \\ 3 \leq p \leq q}} c_{p,q} \{ \text{Sh}_p, \text{Sh}_q \}_{H_{\mathcal{A}}} = 0,$$

where the first term is $\nabla_{H_{\mathcal{A}}} \text{Sh}_r$ and the remaining terms comprise $\mathfrak{o}_{\mathcal{A}}^{(r)}$. The coefficients $c_{p,q}$ arise from collecting equivalent unshuffle summands: when $p < q$ the two orderings (p, q) and (q, p) contribute equally, giving $c_{p,q} = 1$; when $p = q$ only one pairing appears, giving $c_{p,p} = \frac{1}{2}$. At $r = 3$ the sum is empty; at $r = 4$ one recovers Theorem 18.4.5. $\square$

COROLLARY 18.9.4 (*The quintic master equation;*). At degree 5,

$$\nabla_{H_{\mathcal{A}}} \text{Sh}_5(\mathcal{A}) + \{ \mathfrak{C}_{\mathcal{A}}, \mathfrak{Q}_{\mathcal{A}} \}_{H_{\mathcal{A}}} = 0.$$

The quintic shadow is determined by the cubic and quartic shadows up to a cocycle of $\nabla_{H_{\mathcal{A}}}$.

Proof. Set $r = 5$ in (18.9). The obstruction sum has $p+q = 5$ with $3 \leq p \leq q$, giving only $(p, q) = (3, 4)$ with $c_{3,4} = 1$. $\square$

18.9.2 QUINTIC BEHAVIOR OF THE MODEL FAMILIES

THEOREM 18.9.5 (*Quintic shadow for the three frame families;*). Through quintic order:

- (i) **Heisenberg.** $\mathfrak{C}_{\mathcal{H}} = \mathfrak{Q}_{\mathcal{H}} = 0$, so $\mathfrak{o}_{\mathcal{H}}^{(5)} = 0$ and $\text{Sh}_5(\mathcal{H}) = 0$.
- (ii) **Affine $\widehat{\mathfrak{sl}}_2$.** $\mathfrak{Q}_{\text{aff}} = 0$ in minimal gauge, so $\mathfrak{o}_{\text{aff}}^{(5)} = 0$ and $\text{Sh}_5(\text{aff}) = 0$.
- (iii) **$\beta\gamma$ system.** $\mathfrak{C}_{\beta\gamma} = 0$, so $\mathfrak{o}_{\beta\gamma}^{(5)} = 0$. By rank-one abelian rigidity (Theorem 18.5.19), $\text{Sh}_5(\beta\gamma)|_L = 0$ on the weight-changing line.

Proof. Each case follows from Corollary 18.9.4 and the vanishing established in Theorems 18.5.1, 18.5.6, and 18.5.15. $\square$

THEOREM 18.9.6 (*The Virasoro quintic is forced;*). On the Virasoro quartic shadow envelope $E_{\text{Vir}}^{[4]}$, the quintic obstruction is generically nonzero:

$$\mathfrak{o}_{\text{Vir}}^{(5)} = \{\mathfrak{C}_{\text{Vir}}, \mathfrak{Q}_{\text{Vir}}^{\text{contact}}\}_{H_{\text{Vir}}} \neq 0 \quad \text{for generic } c.$$

Consequently $\text{Sh}_5(\text{Vir}) \neq 0$ generically: the Virasoro shadow obstruction tower does not terminate at quartic order.

Proof. The gravitational cubic is $\mathfrak{C}_{\text{Vir}} = 2x^3$ and the contact quartic is $\mathfrak{Q}_{\text{Vir}}^{\text{contact}} = Q_0 x^4$ with $Q_0 = 10/[c(5c + 22)] \neq 0$ for generic c . Their single-edge sewing contraction on the one-generator primary line with propagator $P = 2/c$ produces a nonzero rank-5 tensor proportional to Q_0/c . $\square$

THEOREM 18.9.7 (*Finite termination for primitive archetypes;*). For the three frame families, the shadow obstruction tower terminates at finite degree.

- (i) **Heisenberg:** $\text{Sh}_r(\mathcal{H}) = 0$ for all $r \geq 3$. The tower is exactly Gaussian.
- (ii) **Affine $\widehat{\mathfrak{sl}}_2$ (strict sector, minimal gauge):** $\text{Sh}_r(\text{aff}) = 0$ for $r \geq 4$.
- (iii) **$\beta\gamma$ (weight-changing line):** $\text{Sh}_r(\beta\gamma)|_L = 0$ for $r \geq 3$ by rank-one abelian rigidity.

In contrast, Virasoro has $\text{Sh}_5 \neq 0$ (Theorem 18.9.6), and by induction on the all-degree master equation, the tower is generically infinite.

Proof. For each primitive archetype, finite termination follows from vanishing of all obstruction sources at the relevant degree. For the Heisenberg, all higher brackets vanish. For affine $\widehat{\mathfrak{sl}}_2$, the Jacobiator vanishes and the quartic gauge freedom absorbs all remaining terms. For $\beta\gamma$, Theorem 18.5.19 gives vanishing on the rank-one line.

For Virasoro, Theorem 18.9.6 gives $\text{Sh}_5 \neq 0$. Then $\mathfrak{o}^{(6)}$ contains $\{\mathfrak{C}, \text{Sh}_5\} \neq 0$, forcing $\text{Sh}_6 \neq 0$, and so on by induction. $\square$

Remark 18.9.8 (The Virasoro shadow obstruction tower is the first infinite one). Theorem 18.9.7 reveals a structural divide. The primitive archetypes terminate: Gaussian at degree 2, Lie/tree at degree 3, contact at degree 4. Their complementarity potentials are polynomial. Virasoro, the first genuinely mixed family, has a non-polynomial complementarity potential. This is the mechanism by which the Virasoro modular package carries strictly more information than the $\hat{A}$ -genus.

18.9.3 THE ALL-DEGREE SEPARATING BOUNDARY RECURSION

THEOREM 18.9.9 (*All-degree separating boundary recursion;*). Since the shadow jets are projections of the bar-intrinsic MC element $\Theta_{\mathcal{A}}$ (Theorem 13.21.69), which satisfies the modular clutching identity, for every $r \geq 2$ and every separating clutching map ξ ,

$$\xi^* \text{Sh}_r(\mathcal{A}) = \sum_{\substack{p+q=r+2 \\ p, q \geq 2}} \text{Sh}_p(\mathcal{A}) \star_{P_{\mathcal{A}}} \text{Sh}_q(\mathcal{A}). \quad (18.10)$$

Proof. This is the degree- r component of $\xi^*(\Theta_{\mathcal{A}}) = \Theta_{\mathcal{A}} \star \Theta_{\mathcal{A}}$. $\square$

COROLLARY 18.9.10 (*Quintic separating boundary recursion;*). At degree 5:

$$\xi^* \text{Sh}_5(\mathcal{A}) = H_{\mathcal{A}} \star \text{Sh}_5(\mathcal{A}) + \mathfrak{C}_{\mathcal{A}} \star \mathfrak{Q}_{\mathcal{A}} + \mathfrak{Q}_{\mathcal{A}} \star \mathfrak{C}_{\mathcal{A}} + \text{Sh}_5(\mathcal{A}) \star H_{\mathcal{A}}.$$

Proof. Set $r = 5$ in (18.10); the pairs with $p + q = 7$ and $p, q \geq 2$ are $(2, 5), (3, 4), (4, 3), (5, 2)$. $\square$

18.10 THE GENUS LOOP OPERATOR AND NON-SEPARATING CLUTCHING

The separating clutching keeps genus constant and distributes shadow legs across two components. The non-separating clutching increases genus by one by identifying two marked points. Its action on the shadow obstruction tower *traces out* two shadow legs, converting higher-degree genus-0 data into lower-degree genus-1 corrections. This is the mechanism by which the modular homotopy theory goes beyond the $\bar{A}$ -genus.

18.10.1 DEFINITION AND BASIC PROPERTIES

Definition 18.10.1 (*The genus loop operator*). Let $V_{\mathcal{A}}$ be a finite-dimensional cyclic slice with propagator $P_{\mathcal{A}} = H_{\mathcal{A}}^{-1}$. The *genus loop operator* is the linear map

$$\Lambda_{P_{\mathcal{A}}} : \text{Sym}^r(V_{\mathcal{A}}^*) \longrightarrow \text{Sym}^{r-2}(V_{\mathcal{A}}^*)$$

defined by contracting over all $\binom{r}{2}$ pairs of symmetric legs with the propagator:

$$(\Lambda_{P_{\mathcal{A}}} \alpha)(x_1, \dots, x_{r-2}) := \sum_{1 \leq s < t \leq r} \sum_{i, j} \alpha(x_1, \dots, \widehat{x}_s, \dots, \widehat{x}_t, \dots, e_i, e_j) P_{\mathcal{A}}^{ij},$$

where $\{e_i\}$ is any basis of $V_{\mathcal{A}}$ and $P_{\mathcal{A}}^{ij}$ are the components of the propagator. For a symmetric tensor this is $\binom{r}{2}$ times the single-pair contraction.

PROPOSITION 18.10.2 (*Basic properties of the genus loop operator;*). Let $d := \dim V_{\mathcal{A}}$.

- (i) $\Lambda_{P_{\mathcal{A}}}(H_{\mathcal{A}}) = d$.
- (ii) $\Lambda_{P_{\mathcal{A}}}(\mathfrak{C}_{\mathcal{A}}) \in V_{\mathcal{A}}^*$ is a linear form on $V_{\mathcal{A}}$.
- (iii) $\Lambda_{P_{\mathcal{A}}}(\mathfrak{Q}_{\mathcal{A}}) \in \text{Sym}^2(V_{\mathcal{A}}^*)$ is a rank-2 tensor defining a correction to the Hessian at the next genus.

Proof. Immediate from Definition 18.10.1. $\square$

18.10.2 NON-SEPARATING CLUTCHING OF THE SHADOW OBSTRUCTION TOWER

THEOREM 18.10.3 (*Non-separating clutching law for the shadow obstruction tower;*). Along the non-separating clutching map $\xi_{\text{ns}}: \overline{\mathcal{M}}_{g-1,n+2} \rightarrow \overline{\mathcal{M}}_{g,n}$, the shadow obstruction tower satisfies

$$\xi_{\text{ns}}^*(\text{Sh}_r^{(g)}) = \Lambda_{P_{\mathcal{A}}}(\text{Sh}_{r+2}^{(g-1)}) + (\text{mixed sewing corrections}),$$

where the leading term traces two legs of the genus- $(g-1)$ shadow at degree $r+2$.

Proof. The non-separating clutching identity for the universal class reads $\xi_{\text{ns}}^* \Theta_{\mathcal{A}}^{(g)} = \Lambda_{P_{\mathcal{A}}}(\Theta_{\mathcal{A}}^{(g-1)})$. Expanding both sides in the degree filtration: the degree- r component of the left side is $\text{Sh}_r^{(g)}$, while the degree- r component of $\Lambda_P(\Theta^{(g-1)})$ is $\Lambda_P(\text{Sh}_{r+2}^{(g-1)})$ since Λ_P lowers degree by 2. $\square$

COROLLARY 18.10.4 (*Genus-1 Hessian correction from genus-0 quartic shadow;*). In the one-vertex sector, the genus-1 correction to the Hessian is

$$\delta H_{\mathcal{A}}^{(1)} = \Lambda_{P_{\mathcal{A}}}(\mathfrak{Q}_{\mathcal{A}}^{(0)}).$$

This is a rank-2 tensor determined entirely by the genus-0 quartic shadow and the propagator.

Proof. Set $g = 1$ and $r = 2$ in Theorem 18.10.3. $\square$

REMARK 18.10.5 (*Why this goes beyond the $\hat{A}$ -genus*). The scalar modular characteristic $\kappa(\mathcal{A})$ is the trace of the genus-0 Hessian. The genus-1 Hessian correction $\delta H^{(1)} = \Lambda_P(\mathfrak{Q}^{(0)}) \in \text{Sym}^2(V_{\mathcal{A}}^*)$ is a rank-2 tensor, not determined by κ .

18.10.3 EXPLICIT GENUS LOOP FOR THE MODEL FAMILIES

THEOREM 18.10.6 (*Genus loop operator on the model families;*). In the one-vertex sector:

- (i) **Heisenberg.** $\delta H_{\mathcal{H}}^{(1)} = 0$. The modular invariants at all genera are determined by κ alone.
- (ii) **Affine $\widehat{\mathfrak{sl}}_2$.** $\delta H_{\text{aff}}^{(1)} = 0$ (since $\mathfrak{Q}_{\text{aff}} = 0$), and the cubic loop also vanishes:

$$\Lambda_{P_{\text{aff}}}(\mathfrak{C}_{\text{aff}}) = 0.$$

This is because the structure constants f_{ab}^c are antisymmetric while the propagator P^{ab} is symmetric, so their contraction vanishes identically.

- (iii) **$\beta\gamma$ system.** $\Lambda_P(\mathfrak{C}_{\beta\gamma}) = 0$, but the quartic loop gives a Hessian correction proportional to $(2/c)\mathfrak{Q}_{\beta\gamma}(\eta, \eta, \cdot, \cdot)$.
- (iv) **Virasoro.** Both loops are nonzero. On the primary line with $H = (c/2)x^2$, $\mathfrak{C} = 2x^3$, $\mathfrak{Q}^{\text{contact}} = Q_0 x^4$ where $Q_0 = 10/[c(5c+22)]$:

$$\begin{aligned} \Lambda_P(\mathfrak{C}_{\text{Vir}})(x) &= \frac{12}{c} x, \\ \delta H_{\text{Vir}}^{(1)} &= \frac{120}{c^2(5c+22)} x^2. \end{aligned}$$

The genus-1 loop ratio is $\rho_{\text{Vir}}^{(1)} = \delta H^{(1)}/H^{(0)} = 240/[c^3(5c+22)]$, independent of $\kappa = c/2$.

Proof. (i) is immediate from $\mathfrak{C}_{\mathcal{H}} = \mathfrak{Q}_{\mathcal{H}} = 0$.

For (ii), $\mathfrak{C}_{\text{aff}}(x, y, z) = \kappa(x, [y, z])$ is cyclically symmetric by ad-invariance. The genus loop contracts two slots with the symmetric propagator $P^{ab} = (1/k_{\text{eff}})(\kappa^{-1})^{ab}$. Since $[e_a, e_b]^c = f_{ab}^c$ is antisymmetric in (a, b) while $(\kappa^{-1})^{ab}$ is symmetric, the contraction $\sum_{a,b} f_{ab}^c (\kappa^{-1})^{ab} = 0$, giving $\Lambda_P(\mathfrak{C}_{\text{aff}}) = 0$.

For (iii) and (iv), the one-generator primary line has $P = 2/c$. For a symmetric rank- r tensor $\alpha_0 x^r$ on a one-dimensional space, $\Lambda_P(\alpha_0 x^r) = \binom{r}{2} P \alpha_0 x^{r-2}$. Thus $\Lambda_P(2x^3) = 3 \cdot (2/c) \cdot 2 \cdot x = 12x/c$, and $\Lambda_P(Q_0 x^4) = 6 \cdot (2/c) \cdot Q_0 x^2 = 12Q_0 x^2/c = 120x^2/[c^2(5c + 22)]$. $\square$

Remark 18.10.7 (The modular invariant ratio). Define the *genus-1 loop ratio* $\rho_{\mathcal{A}}^{(1)} := \Lambda_P(\mathfrak{Q}_{\mathcal{A}})/H_{\mathcal{A}}$. For the Virasoro, $\rho_{\text{Vir}}^{(1)} = 240/[c^3(5c + 22)]$, a nontrivial function of c . Two algebras with the same κ but different $\rho^{(1)}$ are distinguished by the modular homotopy theory even though their $\hat{A}$ -genera agree.

18.10.4 THE MODULAR SHADOW CHARACTERISTIC

Definition 18.10.8 (The full modular shadow characteristic). For a modular Koszul chiral algebra $\mathcal{A}$ with cyclic slice $V_{\mathcal{A}}$, define

$$\mathfrak{ch}_{\text{mod}}(\mathcal{A}; \hbar) := \sum_{g \geq 0} \hbar^g \sum_{r \geq 2} \frac{1}{r!} \text{Sh}_r^{(g)}(\mathcal{A}).$$

Its scalar trace is $\text{tr}(\mathfrak{ch}_{\text{mod}}) = \sum_g \hbar^g \kappa(\mathcal{A}) \lambda_g$, recovering the $\hat{A}$ -genus tower.

THEOREM 18.10.9 (*The modular invariant hierarchy beyond $\hat{A}$; .*) Let $\mathcal{A}$ be a modular Koszul chiral algebra whose shadow obstruction tower does not terminate at quadratic order. Then $\mathfrak{ch}_{\text{mod}}(\mathcal{A}; \hbar)$ carries strictly more information than $\kappa(\mathcal{A})$. Specifically:

- (i) If $\mathfrak{C}_{\mathcal{A}} \neq 0$, the cubic shadow class is a non-scalar modular invariant, and $\Lambda_P(\mathfrak{C}_{\mathcal{A}})$ gives a canonical linear form not determined by κ .
- (ii) If $\mathfrak{Q}_{\mathcal{A}} \neq 0$, the genus-1 Hessian correction $\delta H^{(1)} = \Lambda_P(\mathfrak{Q}_{\mathcal{A}})$ is a tensorial modular invariant invisible to κ .
- (iii) The derived ratio $\rho_{\mathcal{A}}^{(1)} = \Lambda_P(\mathfrak{Q}_{\mathcal{A}})/H_{\mathcal{A}}$ distinguishes algebras with identical $\hat{A}$ -genera.

Proof. Suppose $\kappa(\mathcal{A}) = \kappa(\mathcal{A}')$ but the quartic shadows differ. Then $\Lambda_P(\mathfrak{Q}_{\mathcal{A}}) \neq \Lambda_P(\mathfrak{Q}_{\mathcal{A}'})$ and $\rho_{\mathcal{A}}^{(1)} \neq \rho_{\mathcal{A}'}^{(1)}$: the full modular characteristic distinguishes the two algebras. $\square$

Remark 18.10.10 (Summary of the invariant hierarchy). The full modular invariant hierarchy:

$$\underbrace{\kappa(\mathcal{A})}_{\text{scalar}} \longrightarrow \underbrace{\Delta_{\mathcal{A}}}_{\text{spectral}} \longrightarrow \underbrace{[\mathfrak{C}_{\mathcal{A}}], [\mathfrak{Q}_{\mathcal{A}}]}_{\text{nonlinear shadows}} \longrightarrow \underbrace{\Lambda_P(\mathfrak{Q}_{\mathcal{A}})}_{\text{genus loop}} \longrightarrow \underbrace{\Theta_{\mathcal{A}}}_{\text{universal class}}.$$

The first three levels are genus-0 data. The genus loop correction is the first genuinely higher-genus modular invariant. The full universal class unifies all levels.

18.11 A UNIFIED SUMMARY THEOREM

THEOREM 18.11.1 (*Ambient complementarity and nonlinear modular shadows*;). Let $\mathcal{A}$ be a modular Koszul family on a quartic-regular parameter locus, and suppose the cyclic deformation package is available through quartic order on a chosen cyclic slice. Then:

- (i) the finite-order deformation theory is governed by a quartic shadow cocycle

$$\Theta_{\mathcal{A}}^{\leq 4} = H_{\mathcal{A}} + \mathfrak{C}_{\mathcal{A}} + \mathfrak{Q}_{\mathcal{A}};$$

- (ii) its local behavior is controlled by the master equations

$$\nabla_{H_{\mathcal{A}}} \mathfrak{C}_{\mathcal{A}} = 0, \quad \nabla_{H_{\mathcal{A}}} \mathfrak{Q}_{\mathcal{A}} + \frac{1}{2} \{ \mathfrak{C}_{\mathcal{A}}, \mathfrak{C}_{\mathcal{A}} \} = 0;$$

- (iii) its separating-boundary behavior is controlled by the recursion

$$\xi^* \mathfrak{Q}_{\mathcal{A}} = H_{\mathcal{A}} \star \mathfrak{Q}_{\mathcal{A}} + \mathfrak{C}_{\mathcal{A}} \star \mathfrak{C}_{\mathcal{A}} + \mathfrak{Q}_{\mathcal{A}} \star H_{\mathcal{A}};$$

- (iv) Heisenberg, affine $\widehat{\mathfrak{sl}}_2$, and $\beta\gamma$ realize the Gaussian, Lie/tree, and contact/quartic archetypes respectively;

- (v) Virasoro and principal $\mathcal{W}_N$ are the first genuinely mixed cubic–quartic families;

- (vi) the determinant line of the contact quartic sector carries a canonical modular section whose divisor is the quartic resonance class

$$\mathfrak{R}_{4,g,n}^{\text{mod}}(\mathcal{A}),$$

and whose clutching correction is the cubic tree divisor $\mathfrak{T}_{3,\xi}(\mathcal{A})$;

- (vii) since the full universal class $\Theta_{\mathcal{A}}$ exists (Theorem 13.21.69), this clutching correction is the first non-linear modular shadow of its universal clutching identity;

- (viii) the shadow obstruction tower extends to all degrees: the all-degree master equation $\nabla_{H_{\mathcal{A}}} \text{Sh}_r + \mathfrak{o}^{(r)} = 0$ governs Sh_r for every $r \geq 3$, with the primitive archetypes terminating (Gaussian at 2, Lie/tree at 3, contact at 4) while Virasoro is the first genuinely infinite tower;

- (ix) the genus loop operator $\Lambda_P : \text{Sym}^r \rightarrow \text{Sym}^{r-2}$ implements non-separating clutching on the shadow obstruction tower, and the genus-1 Hessian correction $\delta H_{\mathcal{A}}^{(1)} = \Lambda_P(\mathfrak{Q}_{\mathcal{A}}^{(0)})$ is the first tensorial modular invariant beyond the $\hat{A}$ -genus;

- (x) for the Virasoro, $\delta H_{\text{Vir}}^{(1)} = 120/[c^2(5c + 22)] \cdot x^2$, and the loop ratio $\rho_{\text{Vir}}^{(1)} = 240/[c^3(5c + 22)]$ distinguishes algebras invisible to κ .

Proof. Parts (i)–(iii) are Theorems 18.4.5, 18.4.7, and 18.4.10. Part (iv) is Theorem 18.5.18. Part (v) is Theorems 18.6.3 and 18.6.16 together with Corollary 18.6.17. Part (vi) is Construction 18.7.4 and Definition 18.7.5. Part (vii) is Theorems 18.7.11 and 18.7.13. Part (viii) is Theorems 18.9.3 and 18.9.7. Parts (ix) and (x) are Theorem 18.10.3, Corollary 18.10.4, and Theorem 18.10.6. $\square$

Remark 18.11.2 (What remains to be done). The universal class $\Theta_{\mathcal{A}}$ is constructed by the bar-intrinsic construction (Theorem 13.21.69); the remaining task is to verify clutching and Verdier compatibilities in complete generality and to identify the resulting Hamiltonian modular master action. What this appendix does show is that the nonlinear layer is rigid enough to be organized theoremtically, and that it carries genuinely new modular content. The genus loop operator converts quartic contact data into genus-1 Hessian corrections that no scalar invariant can see. The quartic resonance class is not an afterthought: it is the first modular characteristic that remembers that complementarity is nonlinear.

18.12 THE GRAPH-COMPLETED FEYNMAN TRANSFORM PROGRAMME

The finite-order shadow calculus of the preceding sections captures the degree- ≤ 4 face of the universal Maurer–Cartan class $\Theta_{\mathcal{A}}$, which exists by the bar-intrinsic construction (Theorem 13.21.69). The next question is not *existence* (that is settled) but *refinement*: can one upgrade the abstract MC element to a *graph-completed Hamiltonian modular master action* that organizes the vertex-by-vertex computational content? This section constructs the natural carrier object for such a refinement, states the resulting conjecture, and introduces three new geometric avatars.

18.12.1 THE MODULAR CHIRAL FEYNMAN TRANSFORM

Definition 18.12.1 (Modular chiral Feynman transform;). Define the *modular chiral Feynman transform* of $\mathcal{A}$ by

$$\mathfrak{F}_{\text{mod}}(\mathcal{A}) := \prod_{g,n} \prod_{\Gamma \in \Gamma_{g,n}^{\text{st}}} \left(H^{\bullet}(\overline{\mathcal{M}}_{\Gamma}) \otimes \text{Or}(\Gamma) \otimes \bigotimes_{v \in V(\Gamma)} \text{CoDer}_{\text{val}(v)}^{\text{cyc}}(\widehat{B}_X(\mathcal{A})) \right)_{\text{Aut}(\Gamma)},$$

where $\Gamma_{g,n}^{\text{st}}$ is the set of stable graphs of type (g, n) , $\overline{\mathcal{M}}_{\Gamma}$ is the stratum of $\overline{\mathcal{M}}_{g,n}$ indexed by Γ , $\text{Or}(\Gamma)$ is the orientation line, and $\text{CoDer}_{\text{val}(v)}^{\text{cyc}}$ denotes cyclic coderivations of valence $\text{val}(v)$.

It carries three commuting differentials:

$$d_{\text{mod}} = d_{\text{int}} + d_{\text{split}} + d_{\text{edge}},$$

where:

- d_{int} is the internal cyclic-coderivation differential;
- d_{split} expands vertices via transferred L_{∞} -operations;
- d_{edge} inserts and contracts internal edges by the Hessian propagator.

Remark 18.12.2 (Why the Feynman transform upgrades the bar-intrinsic element). The bar-intrinsic construction produces $\Theta_{\mathcal{A}}$ as an abstract MC element. The Feynman transform upgrades this to a *Hamiltonian* MC element by resolving three structural requirements for the graph-completed refinement: (1) a cyclic structure on bar coderivations; (2) the completed tensor product with tautological coefficients; (3) a clutching-compatible graph-sum representation. In $\mathfrak{F}_{\text{mod}}(\mathcal{A})$:

- cyclicity is built into the vertex labels,
- completion is the graph-number/bar-length/weight filtration,

- clutching is the edge-insertion differential d_{edge} .

Conjecture 18.12.3 (Graph-completed Hamiltonian refinement;). The bar-intrinsic MC element $\Theta_{\mathcal{A}}$ (Theorem 13.21.69) admits a canonical *Hamiltonian* lift to a group-like element

$$\Theta_{\mathcal{A}} \in \text{MC}(\mathfrak{F}_{\text{mod}}(\mathcal{A}))$$

in the Feynman transform, whose projections recover the entire modular characteristic hierarchy:

- (i) scalar trace: $\text{tr}(\Theta_{\mathcal{A}}) = \sum_{g \geq 1} \kappa(\mathcal{A}) \lambda_g$;
- (ii) one-vertex projection: $H_{\mathcal{A}} + \mathfrak{C}_{\mathcal{A}} + \mathfrak{Q}_{\mathcal{A}} + \cdots$;
- (iii) determinant shadow: the full resonance tower $\mathfrak{R}_{r,g,n}^{\text{mod}}(\mathcal{A})$ for all $r \geq 4$;
- (iv) Legendre duality shadow: $\Theta_{\mathcal{A}^\dagger} = \Theta_{\mathcal{A}}^\vee$.

The existence of $\Theta_{\mathcal{A}}$ is a theorem; what remains conjectural is whether the abstract MC element lifts to a graph-completed Hamiltonian modular master action in $\mathfrak{F}_{\text{mod}}(\mathcal{A})$.

18.12.2 THE COMPLEMENTARITY LEGENDRIAN

Definition 18.12.4 (Complementarity Legendrian;). Given the complementarity potential $S_{\mathcal{A}}$ of Definition 18.3.7, define its 1-jet lift

$$\Lambda_{\mathcal{A}} := j^1 S_{\mathcal{A}} \subset J^1(\mathcal{M}_{\mathcal{A}}) \simeq T^*[-1]\mathcal{M}_{\mathcal{A}} \times \mathbb{A}^1.$$

This is the *complementarity Legendrian*.

Remark 18.12.5 (Three virtues of the Legendrian lift). The Legendrian $\Lambda_{\mathcal{A}}$ achieves three things simultaneously:

- (i) it removes the additive-constant ambiguity in $S_{\mathcal{A}}$;
- (ii) it turns Legendre duality into a *contact* transformation;
- (iii) it gives a geometric origin for the resonance tower: the degree- r resonance loci are the discriminants of the *front projection* of $\Lambda_{\mathcal{A}}$ restricted to the degree- r contact sector.

In this language:

- $\kappa(\mathcal{A})$ is the quadratic front curvature;
- $\Delta_{\mathcal{A}}$ is the spectral branch discriminant;
- $\mathfrak{R}_4^{\text{mod}}(\mathcal{A})$ is the first contact-front singularity divisor.

18.12.3 THE FULL RESONANCE TOWER

Definition 18.12.6 (Degree- r contact bundle and resonance class;). For every degree $r \geq 4$, define the zero-internal-edge degree- r contact bundle

$$\mathcal{C}_{g,n}^{\text{ct},(r)}(\mathcal{A}) \subset \mathcal{C}_{g,n}^{[r]}(\mathcal{A})$$

and its determinant line

$$\mathcal{L}_{r,g,n}^{\text{res}}(\mathcal{A}) := \bigotimes_d \left((\det \mathcal{C}_{g,n}^{\text{ct},(r),d}(\mathcal{A}))^{-2} \otimes (\mathcal{U}_{g,n}^{(d)})^{r_{d,r}} \right).$$

The degree- r resonance class is

$$\mathfrak{R}_{r,g,n}^{\text{mod}}(\mathcal{A}) := \text{div}(s_{r,g,n}^{\text{res}}(\mathcal{A})).$$

The quartic class of Definition 18.7.5 is the first case.

THEOREM 18.12.7 (*All-degree boundary law for the resonance tower;).* For every $r \geq 4$ and every separating clutching map ξ ,

$$\xi^* \mathfrak{R}_{r,g,n}^{\text{mod}}(\mathcal{A}) = p_1^* \mathfrak{R}_{r,g_1,n_1+1}^{\text{mod}}(\mathcal{A}) + p_2^* \mathfrak{R}_{r,g_2,n_2+1}^{\text{mod}}(\mathcal{A}) + \sum_{p+q=r+2} \mathfrak{T}_{\xi}^{(p,q)}(\mathcal{A}), \quad (18.11)$$

where $\mathfrak{T}_{\xi}^{(p,q)}(\mathcal{A})$ is the determinant divisor of one-edge sewings of degree- p and degree- q vertices. The quartic case ($r = 4$, with only the $(3, 3)$ tree term) is Theorem 18.7.II.

Proof. The argument generalises the quartic proof (Theorem 18.7.II) from degree 4 to arbitrary degree r , using the same three ingredients: Mok's degeneration formula, the internal-edge filtration, and determinant factorisation.

Step 1: Boundary filtration at degree r . Fix a separating clutching map ξ corresponding to a semistable degeneration $Y_1 \cup_D Y_2$ with r marked points distributed as $I = I_1 \sqcup I_2$. By Mok's degeneration formula [322, Theorem 5.3.4], the irreducible components of the special fibre of $\text{FM}_r(W/B)$ along ξ are indexed by rigid combinatorial types ρ [322, Definition 4.7.1]: planted forests whose associated polyhedron μ_{ρ} is a vertex. Each rigid type has a well-defined *depth* (Definition 13.22.30): the number of internal edges in the planted forest crossing the node. This induces an increasing filtration on the pulled-back degree- r contact envelope:

$$0 = F^{-1} \subset F^0 \subset F^1 \subset \dots \subset F^{\lfloor r/2 \rfloor} = \xi^* \mathcal{C}_{g,n}^{[r]}(\mathcal{A}),$$

where F^k is spanned by rigid types of depth $\leq k$.

Step 2: Identification of the associated graded. The associated graded decomposes by depth:

- (A) *Depth 0* (pure types, $r+0$ or $0+r$): all r points on one component, no edges crossing the node. These contribute the pulled-back contact sectors $p_j^* \mathcal{C}_{g_j,n_j+1}^{\text{ct},(r)}(\mathcal{A})$.
- (B) *Depth 1* (split types with a single crossing edge): points distributed as $|I_1| + |I_2|$ with $|I_1|, |I_2| \geq 1$ and no further FM bubbling. The component $\text{FM}_r(W/B)(\rho)$ is a modification of $\text{FM}_{|I_1|+1}(Y_1|D_1) \times \text{FM}_{|I_2|+1}(Y_2|D_2)$ (one extra point at the node on each side). This contributes a one-edge sewing of an degree- $(|I_1|+1)$ vertex to a degree- $(|I_2|+1)$ vertex. Summing over splits $p + q = r + 2$ yields the tree correction $\bigoplus_{p+q=r+2} \mathfrak{T}_{\xi}^{(p,q)}(\mathcal{A})$.

- (C) *Depth* ≥ 2 (nontrivial planted trees with ≥ 2 crossing edges): these rigid types have polyhedra of codimension ≥ 2 in the boundary complex, and their determinant contributions do not affect divisor classes.

Step 3: Determinant factorisation. On the associated graded gr_F , the Gram pairing of the degree- r contact envelope is block-diagonal with respect to the depth decomposition (A)–(B), since the depth-0 sector has no internal edges crossing the node while the depth-1 sector has exactly one. The determinant section of $\xi^* \mathcal{L}_{r,g,n}^{\text{res}}(\mathcal{A})$ therefore factors on gr_F as

$$\text{gr } \xi^* \mathcal{L}_{r,g,n}^{\text{res}}(\mathcal{A}) = p_1^* s_{r,g_1,n_1+1}^{\text{res}}(\mathcal{A}) \otimes p_2^* s_{r,g_2,n_2+1}^{\text{res}}(\mathcal{A}) \otimes \bigotimes_{p+q=r+2} t_{\xi}^{(p,q)}(\mathcal{A}).$$

The passage from gr_F to the original filtration does not change the divisor class, since the correction terms live in higher filtration and are nilpotent. Taking divisors yields (18.11). $\square$

18.12.4 THE COMPLEMENTARITY PHASE FUNCTION

Definition 18.12.8 (Nonlinear phase index). Define the *nonlinear phase index*

$$\nu_{\text{nl}}(\mathcal{A}, u) := \min\{r \geq 3 : \text{Sh}_r(\Theta_{\mathcal{A},u}) \neq 0\},$$

with the convention $\nu_{\text{nl}} = \infty$ when all nonlinear shadows vanish.

Conjecture 18.12.9 (Nonlinear phase of the standard families;). The nonlinear phase indices of the five model families are:

- (i) Heisenberg: $\nu_{\text{nl}} = \infty$.
- (ii) Affine $\widehat{\mathfrak{sl}}_2$ generic strict current sector: $\nu_{\text{nl}} = 3$.
- (iii) Affine critical level $k = -h^\vee$: $\nu_{\text{nl}} = 3$, but the quadratic part vanishes, so the cubic term becomes leading.
- (iv) $\beta\gamma$ weight/contact slice: $\nu_{\text{nl}} = 4$.
- (v) Virasoro and principal $\mathcal{W}_N$: $\nu_{\text{nl}} = 3$ with mixed quartic resonance.

Remark 18.12.10 (Evidence). Immediate from Theorems 18.5.1, 18.5.6, 18.5.8, 18.5.15, and 18.6.3.

Remark 18.12.11 (The phase index as a wall-crossing function). The nonlinear phase index $\nu_{\text{nl}}(\mathcal{A}, u)$ is a constructible function on parameter space, measuring the degree at which complementarity becomes genuinely nonlinear. Its jump loci are the walls of the *resonance scattering diagram* of §18.13.2.

18.12.5 THE NONLINEAR SPECTRAL-BRANCH STACK

Definition 18.12.12 (Nonlinear spectral-branch stack;). The *nonlinear spectral-branch stack* of $\mathcal{A}$ is a stack

$$\mathfrak{B}_{\mathcal{A}}^{\text{nl}}$$

whose truncations record:

- (i) branch eigenvalues at degree 2 (the spectral discriminant $\Delta_{\mathcal{A}}$);

- (ii) contact degeneracies at degree 4 (the quartic resonance class);
- (iii) higher-degree front singularities for $r \geq 5$.

$\Delta_{\mathcal{A}}$ records where quadratic transport branches collide, while $\mathfrak{R}_r^{\text{mod}}$ records where nonlinear contact sectors lose rank. Both live in a single branch-resonance geometry.

Remark 18.12.13 (Conceptual outcome: graph-completed shifted-contact geometry). The unification is

Koszul duality+Verdier duality+curvature+clutching $\implies$ graph-completed shifted-contact geometry.

The object that governs the entire nonlinear modular theory is not only $\Theta_{\mathcal{A}}$, nor only $S_{\mathcal{A}}$, but the triple

$$(\Theta_{\mathcal{A}}, \Lambda_{\mathcal{A}}, \{\mathfrak{R}_r^{\text{mod}}\}_{r \geq 4}),$$

namely: a graph-completed Hamiltonian master element, its Legendrian geometric avatar, and the full tower of Picard-valued nonlinear resonance shadows.

18.13 THE POLARIZED SCATTERING PROGRAMME

The Feynman transform carries one-color vertex labels. The next structural upgrade replaces the one-color Maurer–Cartan problem by a *polarized bipartite machine* in which complementarity becomes a graph-theoretic selection rule.

18.13.1 THE POLARIZED MODULAR GRAPH ALGEBRA

Definition 18.13.1 (Polarized modular graph algebra;). Let $\text{Def}^{\pm}(\mathcal{A})$ denote the two complementary polarized pieces of the cyclic deformation problem, corresponding to $\mathcal{A}$ and $\mathcal{A}^!$.

The *polarized modular graph algebra* is the completed vector space

$$\mathcal{G}_{\text{mod}}^{\pm}(\mathcal{A})$$

spanned by stable graphs satisfying:

- (1) every vertex is coloured by + or −,
- (2) every internal edge joins opposite colours,
- (3) a +-vertex carries a cyclic operation from $\text{Def}^+(\mathcal{A})$,
- (4) a −-vertex carries a cyclic operation from $\text{Def}^-(\mathcal{A})$,
- (5) each graph is weighted by tautological/modular coefficient data from $R\Gamma(\overline{\mathcal{M}}_{g,n})$.

The differential is

$$d = d_{\text{int}} + d_{\text{split}} + d_{\text{clutch}} + d_{\text{edge}},$$

where d_{clutch} inserts boundary degenerations and d_{edge} contracts a mixed propagator along an opposite-colour edge.

THEOREM 18.13.2 (*Bipartite complementarity principle*;). Same-colour internal-edge contractions vanish identically in $\mathcal{G}_{\text{mod}}^{\pm}(\mathcal{A})$. Equivalently, complementarity is not merely a direct-sum decomposition; it is a *selection rule*: only opposite-polarization propagators contribute to the full nonlinear theory.

Proof. This is a restatement of the bipartite vanishing theorem (Theorem 18.14.1): the Lagrangian isotropy $\langle V^+, V^+ \rangle = 0 = \langle V^-, V^- \rangle$ forces the same-colour blocks of the propagator to vanish, so every internal-edge contraction within a single colour is zero. $\square$

Conjecture 18.13.3 (*Polarized universal class*;). There exists a canonical Maurer–Cartan element

$$\Theta_{\mathcal{A}}^{\pm} \in \text{MC}(\mathcal{G}_{\text{mod}}^{\pm}(\mathcal{A}))$$

whose projections recover the entire hierarchy: scalar trace $\Rightarrow \kappa(\mathcal{A})\lambda_g$, branch determinant $\Rightarrow \Delta_{\mathcal{A}}$, one-vertex degree- r sector $\Rightarrow$ the shadow tensors $H_{\mathcal{A}}, \mathfrak{C}_{\mathcal{A}}, \mathfrak{Q}_{\mathcal{A}}, \dots$, contact determinant sector $\Rightarrow \mathfrak{R}_{r,g,n}^{\text{mod}}(\mathcal{A})$, and genus-summed semiclassical action $\Rightarrow$ the complementarity potential and its higher corrections.

18.13.2 THE RESONANCE SCATTERING DIAGRAM

Definition 18.13.4 (*Resonance wall locus*). Let

$$\mathcal{W}_{\mathcal{A}} := \{\Delta_{\mathcal{A}} = 0\} \cup \bigcup_{r \geq 4} |\mathfrak{R}_r^{\text{mod}}(\mathcal{A})|$$

be the total nonlinear wall locus in parameter space.

Definition 18.13.5 (*Resonance scattering diagram*;). The *resonance scattering diagram*

$$\mathfrak{Scat}(\mathcal{A})$$

has walls given by the irreducible components of $\mathcal{W}_{\mathcal{A}}$, and wall functions given by the gauge transport automorphisms induced by the polarized class $\Theta_{\mathcal{A}}^{\pm}$.

Interpretation:

- $\Delta_{\mathcal{A}}$ detects the quadratic spectral walls,
- $\mathfrak{R}_r^{\text{mod}}$ detect the genuinely nonlinear walls,
- chamber transport is governed by graph sums in $\mathcal{G}_{\text{mod}}^{\pm}(\mathcal{A})$.

This explains how different theories may sit on the same spectral sheet while differing nonlinearly: identical Δ , different scattering data.

18.13.3 THE COMPLEMENTARITY SCHOBERS

Definition 18.13.6 (*Complementarity schobers*;). The *complementarity schobers*

$$\mathfrak{Sch}(\mathcal{A}) \rightarrow B_{\mathcal{A}}^{\circ}$$

is the constructible sheaf of categories whose fibre over a chamber is the category of polarized quantizations of that chamber, and whose wall-crossing functors are induced by the scattering automorphisms of $\mathfrak{Scat}(\mathcal{A})$.

Remark 18.13.7 (*Why a schobers rather than a scattering diagram*). A discriminant polynomial is too coarse: it records *which* theories degenerate, but not *how* they mutate. A schobers remembers the mutation data. This is the correct categorified replacement for saying that “the same discriminant supports different chiral theories.”

18.13.4 THE MODULAR WAVEFUNCTION

Definition 18.13.8 (Modular wavefunction;). Choose one polarization, say the + -side. Quantize $\Theta_{\mathcal{A}}^{\pm}$ to an operator $\widehat{\Theta}_{\mathcal{A}}$ on the Fock space of the polarized deformation theory. The *modular wavefunction* is a section

$$\Psi_{\mathcal{A}}$$

satisfying the quantum master equation

$$\widehat{\Theta}_{\mathcal{A}} \Psi_{\mathcal{A}} = 0.$$

Semiclassically,

$$\Psi_{\mathcal{A}} \sim \exp\left(\sum_{g \geq 0} \hbar^{2g-2} F_g(\mathcal{A})\right).$$

Remark 18.13.9 (Local normal forms for the wavefunction). The nonlinear shadows now acquire microlocal meaning. Suggested local normal forms:

- Heisenberg: Gaussian,
- affine $\widehat{\mathfrak{sl}}_2$: Airy-type,
- $\beta\gamma$: Pearcey-type,
- Virasoro / principal $\mathcal{W}_N$: mixed catastrophe type.

These names are a proposal, not yet a theorem; the shadow obstruction tower determines the singularity type of the wavefunction, so the archetype trichotomy of Theorem 18.5.18 becomes a classification of local wavefunctions by catastrophe type.

18.14 THE THEOREM PROGRAMME FOR THE NONLINEAR TOWER

The constructions of §18.12–§18.13 yield a coherent programme of theorems and conjectures, ordered by structural depth.

THEOREM 18.14.1 (*Bipartite vanishing theorem;).* Same-polarization internal edges vanish identically in the polarized graph algebra $\mathcal{G}_{\text{mod}}^{\pm}(\mathcal{A})$. Thus every nontrivial nonlinear correction is represented by a bipartite stable graph.

Proof. The complementarity datum (Theorem 18.3.6) furnishes a Lagrangian decomposition $V_{\mathcal{A}} = V^{+} \oplus V^{-}$ of the cyclic slice with respect to the cyclic pairing $\langle -, - \rangle$. Isotropy of each summand means $\langle V^{+}, V^{+} \rangle = 0 = \langle V^{-}, V^{-} \rangle$, so in the adapted basis the pairing matrix has the off-diagonal block form

$$\langle -, - \rangle = \begin{pmatrix} 0 & B \\ B^{\text{t}} & 0 \end{pmatrix}, \quad B: V^{+} \xrightarrow{\sim} (V^{-})^{*}[-1].$$

The propagator $P_{\mathcal{A}} = H_{\mathcal{A}}^{-1} \in V_{\mathcal{A}} \otimes V_{\mathcal{A}}$ is the formal inverse of this pairing. Block inversion gives

$$P_{\mathcal{A}} = \begin{pmatrix} 0 & (B^{\text{t}})^{-1} \\ B^{-1} & 0 \end{pmatrix},$$

so $P^{++} = 0 = P^{--}$. Every internal edge in the graph algebra is contracted by $P_{\mathcal{A}}$. An edge joining two vertices of the same colour contributes the P^{++} or P^{--} block, which vanishes. Therefore the only graphs with nonzero weight are those whose internal edges all join opposite colours, i.e. bipartite stable graphs. $\square$

Conjecture 18.14.2 (Quartic lift theorem;). The shadow package $H_{\mathcal{A}}, \mathfrak{C}_{\mathcal{A}}, \mathfrak{Q}_{\mathcal{A}}$ is precisely the zero-internal-edge truncation of $\Theta_{\mathcal{A}}^{\pm}$ through degree 4.

Remark 18.14.3 (Computational evidence for the quartic lift). The zero-internal-edge truncation of $\Theta_{\mathcal{A}}^{\pm}$ through degree 4 has been verified to reproduce the shadow package $(\mathcal{H}_{\mathcal{A}}, \mathfrak{C}_{\mathcal{A}}, \mathfrak{Q}_{\mathcal{A}})$ for all four standard archetype families:

- (i) Heisenberg (G, depth 2, $\mathfrak{Q} = 0$): the propagator is scalar, and the graph sum terminates at the single binary graph.
- (ii) Affine (L, depth 3, $\mathfrak{Q} = 0$): the cubic shadow is the Lie bracket $\mathfrak{C} = f_c^{ab}$, and all quartic bipartite graphs cancel by the Jacobi identity.
- (iii) $\beta\gamma$ (C, depth 4, $\mathfrak{Q}$ canonical): the quartic contact invariant $\mu_{\beta\gamma} = 0$ on the weight-changing line (Corollary 18.5.16), while the quartic class on the diagonal is the canonical residue of the $\beta\gamma$ system.
- (iv) Virasoro (M, depth ∞ , $Q_{\text{Vir}}^{\text{contact}} = 10/[c(5c + 22)]$): the quartic slice matches, and the nonvanishing quintic obstruction (Theorem 18.9.6) confirms that higher-degree bipartite graphs contribute.

The bipartite vanishing theorem (Theorem 18.14.1) ensures that only mixed-polarization propagators contribute, reducing the graph enumeration from $|\text{Gr}_{0,4}^{\text{st}}|$ to $|\text{Gr}_{0,4}^{\pm, \text{conn}}|$.

Conjecture 18.14.4 (Resonance wall-crossing theorem;). The spectral discriminant $\Delta_{\mathcal{A}}$ is constant under scattering within a fixed sheet, while the resonance tower records the nonlinear wall-crossing corrections.

Conjecture 18.14.5 (Quantization theorem;). A choice of polarization produces a wavefunction $\Psi_{\mathcal{A}}$ whose semiclassical expansion recovers the genus tower and whose singular support is the complementarity Legendrian/front.

Remark 18.14.6 (Implementation path). The most direct executable route is:

- (1) extend the existing finite-dimensional cyclic L_{∞} scaffold to a two-colour model,
- (2) insert only mixed propagators,
- (3) compute the first connected graph weights for Heisenberg, affine $\widehat{\mathfrak{sl}}_2$, $\beta\gamma$, and Virasoro,
- (4) verify that the quartic resonance class is the first contact determinant in the bipartite model,
- (5) extract the first wall functions of $\mathfrak{Scat}(\mathcal{A})$.

This would turn complementarity from a theorem about decomposition into a theorem about *transport, wall-crossing, and quantization*.

Construction 18.14.7 (Bipartite graph algebra as L_{∞} truncation). The polarized graph algebra $\mathcal{G}_{\text{mod}}^{\pm}(\mathcal{A})$ admits a canonical identification with the tree-level truncation of the L_{∞} -algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$:

- (i) Each bipartite graph $\Gamma \in \text{Gr}_{0,r}^{\pm, \text{conn}}$ with zero internal edges corresponds to a tree-level r -ary L_{∞} bracket $\ell_r^{(0)}$. The correspondence sends the graph weight $W_{\Gamma}(P^{+-}, m_{\bullet})$, contracted using only the off-diagonal propagator $P^{+-} = (B^{\dagger})^{-1} \in V^{+} \otimes V^{-}$ (Theorem 18.14.1), to the r -ary homotopy transfer bracket.

- (ii) The Lagrangian decomposition $V_{\mathcal{A}} = V^+ \oplus V^-$ with off-diagonal propagator P^{+-} implements the homotopy transfer:

$$\ell_r^{\text{tr}} = \sum_{\text{binary trees } T \text{ with } r \text{ leaves}} W_T(P^{+-}, m_{\bullet}),$$

where the sum is over planar binary trees, each internal vertex carries an OPE coefficient m_k , and each internal edge is contracted by P^{+-} . This is the standard homological perturbation lemma applied to the Lagrangian splitting.

- (iii) For finite-depth algebras (classes G, L, C), the truncation $\Theta_{\leq r_{\max}}^{\pm} = \Theta^{\pm}$ is exact: no bipartite graphs with internal edges contribute beyond degree $r_{\max}$. The tree-level L_{∞} -algebra is then *formal*: it is L_{∞} -quasi-isomorphic to its cohomology with the transferred brackets $\ell_2^{\text{tr}}, \dots, \ell_{r_{\max}}^{\text{tr}}$. For class M (Virasoro, $\mathcal{W}_N$), the tower is infinite and the graph algebra receives contributions at every degree.

The shadow–formality identification (Proposition 13.22.107) is the degree-by-degree verification of this correspondence at degrees 2, 3, 4. Proposition 18.14.4 upgrades it to the full genus-0 obstruction tower; positive-genus corrections are carried separately by the quantum layer.

Construction 18.14.8 (Exchange diagram: quartic from cubic sewing). The one-edge bipartite graphs in $\text{Gr}_{0,4}^{\pm, \text{conn}}$ compute the boundary quartic class from cubic sewing:

$$[R_4^{\text{mod}}(A)]_{\text{exch}} = [C_A *_{P^{+-}} C_A]$$

where $C_A *_{P^{+-}} C_A$ denotes the cubic shadow contracted through the mixed propagator P^{+-} . For class L algebras (affine, $r_{\max} = 3$), this exchange vanishes and $R_4^{\text{mod}} = 0$. For class C algebras ($\beta\gamma$, $r_{\max} = 4$), the exchange is the *sole* source of quartic data.

Remark 18.14.9 (What shadow data is consumed by the Bridge Theorem). The Bridge Theorem programme (Remark O.13.54; Theorem O.13.55) consumes shadow data at exactly two projections of the universal MC element $\Theta_{\mathcal{A}} \in \text{MC}(\mathfrak{g}_{\mathcal{A}}^{\text{mod}})$:

- (i) *The propagator $r(z) = \tau|_{\deg 2}$ (genus-0, degree-2 MC projection).* This is the degree-2 slice of $\Theta_{\mathcal{A}}$: the degree-2, genus-0 component of the graph sum (Definition 13.22.391), with a single internal edge carrying the bar propagator. It gives $k \cdot \mathbb{1}/z$ in the Heisenberg/free case (and 0 for $\beta\gamma$, whose simple-pole OPE is absorbed by $d \log$) and $k\Omega/z$ in the affine $\widehat{\mathfrak{g}}_k$ case (Propositions O.13.129 and O.13.130): at $k = 0$ both propagators vanish, consistent. The higher-degree shadows (cubic $\mathfrak{C}$, quartic $\mathfrak{Q}$, resonance tower $\mathfrak{R}_{\bullet}^{\text{mod}}$) are degree-3, 4, $\dots$ projections of the same MC element; they do *not* enter the genus-0 bridge statement but become relevant at the modular completion level (Conjecture O.13.114).
- (ii) *The curvature $\kappa(\mathcal{A})$ (genus-1, degree-0 MC trace).* The scalar curvature is $\kappa(\mathcal{A}) = \text{tr}(\Theta_{\mathcal{A}}|_{g=1})$: the genus-1, degree-0 component of the universal MC element. It controls the genus-1 deformation of the dg-shifted Yangian and the obstructedness of the bridge at higher genus via $d^2 = \kappa \cdot \omega_1$ (Theorem 13.8.13).

CG consequence. The nonlinear shadow obstruction tower ($\kappa \rightarrow \Delta \rightarrow \mathfrak{C} \rightarrow \mathfrak{Q} \rightarrow \dots$) is the degree filtration of the single MC element $\Theta_{\mathcal{A}}$. The Bridge Theorem consumes only the degree-2 and degree-0 slices ($r(z)$ and κ). The tower is therefore a valuable parallel construction (it computes successively finer projections of the same universal object), but it is **not a prerequisite** for the bridge. The higher shadows become prerequisites only when the programme reaches the modular completion: the all-genera stable-graph Yang–Baxter equation (Conjecture O.13.114), which requires the full MC element $\Theta_{\mathcal{A}}$ at all degrees.

Remark 18.14.10 (The extended modular invariant hierarchy). The full hierarchy, extended by the constructions of this appendix, is

$$\underbrace{\kappa(\mathcal{A})}_{\text{scalar}} \longrightarrow \underbrace{\Delta_{\mathcal{A}}}_{\text{spectral}} \longrightarrow \underbrace{(H_{\mathcal{A}}, \mathfrak{C}_{\mathcal{A}}, \mathfrak{Q}_{\mathcal{A}})}_{\text{Hamiltonian jets}} \longrightarrow \underbrace{\mathfrak{R}_{\bullet}^{\text{mod}}(\mathcal{A})}_{\text{resonance tower}} \longrightarrow \underbrace{\Lambda_{\mathcal{A}}}_{\text{Legendrian}} \longrightarrow \underbrace{\Theta_{\mathcal{A}}}_{\text{master element}}.$$

Every earlier level is a shadow of every later level. The graph-completed master element is the source of all of them.

Remark 18.14.11 (The factorization envelope programme and the shadow obstruction tower). The 2025–2026 factorization envelope technology (Nishinaka [428]; Vicedo [429]) provides a functorial genus-0 machine: from a Lie conformal algebra one constructs a factorization algebra whose associated vertex algebra is the enveloping vertex algebra. The shadow obstruction tower of this appendix supplies the higher-genus completion. That is, the ideal object attached to a cyclically admissible Lie conformal algebra L (Definition ??) is not merely the genus-0 factorization algebra $\text{Fact}_X(L)$, but the full modular Koszul datum $\Pi_X(L)$ (Construction ??), in which all shadows $(\kappa, \Delta, \mathfrak{C}, \mathfrak{Q}, \Theta)$ are successive projections of a single universal Maurer–Cartan element $\Theta_L \in \text{MC}(\text{Def}_{\text{cyc}}(L) \widehat{\otimes} \mathbb{G}_{\text{mod}})$.

For the archetype families computed in this appendix:

- *Heisenberg* collapses to its scalar shadow: $\Theta_L \sim \kappa(L)\lambda + \text{exact}$, $\mathfrak{R}_4^{\text{mod}}(L) = 0$. This is the rank-one atom.
- *Affine* $\widehat{\mathfrak{g}}_k$: the first true spectral example. The branch operator T_L^{br} is nontrivial, giving a genuine discriminant.
- *Virasoro*: the first example where the scalar shadow is insufficient and the quartic resonance class $\mathfrak{R}_4^{\text{mod}}$ carries essential content.
- *Principal* $\mathcal{W}_N$: the expectation is $\Theta_{\mathcal{W}_N} = H_{Q_{\text{DS}}}^0(\Theta_{V_k(\mathfrak{g}) \otimes \mathcal{F}_{\text{gh}}})$, turning Drinfeld–Sokolov reduction into a functor on modular Koszul datums. Reduction should commute with shadow-taking: the shadow obstruction tower of $\mathcal{W}_N$ should be the BRST-reduced image of the full current-plus-ghost tower.

The abstract mechanism behind these predictions is the cubic gauge triviality theorem (Theorem 13.22.349): whenever $H^1(F^3 \mathfrak{g}_{\mathcal{A}}^{\text{mod}} / F^4 \mathfrak{g}_{\mathcal{A}}^{\text{mod}}, d_2) = 0$, the cubic shadow is gauge-trivial and the quartic resonance class is the canonical representative of the first nonlinear cohomology class. This is the abstract reason the first nonlinear shadow is quartic, and for independent sums all shadows factor (Proposition 13.22.352).

18.15 REDUCED-WEIGHT WINDOWS AND FINITE-DIMENSIONAL BAR CONTROL

The shadow obstruction tower of the preceding sections is organized by degree: the degree- r shadow jet $\text{Sh}_r(\mathcal{A})$ probes the universal MC element $\Theta_{\mathcal{A}}$ at r external legs. A complementary organizational principle is the *reduced-weight filtration* on the bar complex itself, which turns the infinite-generator completion problem into a sequence of finite-dimensional dg computations. This is the constructive backbone of the MC4 programme (Theorem 8.1.27): the coefficient-stability criterion (Theorem 8.1.48) reduces convergence to stabilization on finite windows, and the present section provides those windows explicitly.

18.15.1 REDUCED WEIGHT AND FINITE-DIMENSIONAL SLICES

Definition 18.15.1 (Reduced weight). Let $\mathcal{A} = \omega_X \oplus \bar{\mathcal{A}}$ be a conformally graded augmented chiral A_∞ -algebra with $\bar{\mathcal{A}} = \bigoplus_{h \geq 2} \mathcal{A}[h]$, each $\mathcal{A}[h]$ finite-dimensional, satisfying the *conformal estimate*

$$\text{wt}(\mu_r(a_1, \dots, a_r)) \leq \sum_{i=1}^r \text{wt}(a_i) - (r-1) \quad (18.12)$$

for all $r \geq 2$ and homogeneous elements $a_i \in \bar{\mathcal{A}}$. Define the *reduced weight* of a homogeneous element $a \in \mathcal{A}[h]$ by

$$\rho(a) := \text{wt}(a) - 1 = h - 1 \geq 1,$$

and the reduced weight of a bar monomial $sa_1 | \cdots | sa_\ell \in \bar{B}(\mathcal{A})$ by

$$\rho(sa_1 | \cdots | sa_\ell) := \sum_{i=1}^{\ell} \rho(a_i) = \sum_{i=1}^{\ell} (\text{wt}(a_i) - 1).$$

Since every letter has $\rho(a_i) \geq 1$, every bar monomial has $\rho \geq \ell$ (its bar length).

THEOREM 18.15.2 (Reduced-weight finiteness;). For every $q \geq 0$, the *exact reduced-weight slice*

$$B_{\rho(q)}(\mathcal{A}) := \text{span}\{sa_1 | \cdots | sa_\ell \mid \rho(sa_1 | \cdots | sa_\ell) = q\}$$

is finite-dimensional, and the completed bar differential is filtration-nonincreasing:

$$b(B_{\rho(\leq q)}(\mathcal{A})) \subseteq B_{\rho(\leq q)}(\mathcal{A}), \quad B_{\rho(\leq q)}(\mathcal{A}) := \bigoplus_{j=0}^q B_{\rho(j)}(\mathcal{A}).$$

Hence the *reduced-weight completed bar complex*

$$\widehat{B}_\rho(\mathcal{A}) := \prod_{q \geq 0} B_{\rho(q)}(\mathcal{A})$$

is a well-defined separated complete curved dg coalgebra with automatic continuity of the differential.

Proof. Finite-dimensionality. Every letter sa_i in a bar monomial of total reduced weight q has $\rho(a_i) \geq 1$ and $\sum_i \rho(a_i) = q$, so the bar length satisfies $\ell \leq q$ and each letter has $\text{wt}(a_i) = \rho(a_i) + 1 \leq q + 1$. Since $\mathcal{A}[h]$ is finite-dimensional for each h , the number of available letters is bounded by $\sum_{h=2}^{q+1} \dim \mathcal{A}[h]$. The number of words of length $\ell \leq q$ from this finite alphabet is finite, so $B_{\rho(q)}(\mathcal{A})$ is finite-dimensional.

Filtration compatibility. A coderivation term of the bar differential replaces r consecutive letters $a_{j_1}, \dots, a_{j_r}$ by the single letter $\mu_r(a_{j_1}, \dots, a_{j_r})$. By the conformal estimate (18.12), the reduced weight of the output is

$$\rho(\mu_r(a_{j_1}, \dots, a_{j_r})) = \text{wt}(\mu_r(a_{j_1}, \dots, a_{j_r})) - 1 \leq \sum_{k=1}^r \text{wt}(a_{j_k}) - (r-1) - 1 = \sum_{k=1}^r \rho(a_{j_k}) - (r-1).$$

Since $r \geq 2$, the change in total reduced weight is

$$\rho(\text{output letter}) - \sum_{k=1}^r \rho(a_{j_k}) \leq -(r-1) \leq -1 < 0.$$

Therefore the bar differential is strictly filtration-decreasing on each coderivation component, hence filtration-nonincreasing on the total differential. Continuity of the differential on the completed product $\widehat{B}_\rho(\mathcal{A})$ is then automatic: each projection to a finite slice factors through finitely many lower slices. $\square$

Definition 18.15.3 (Finite q -window). For each $q \geq 0$, define the *finite q -window*

$$K_q(\mathcal{A}) := B_{\rho(\leq q)}(\mathcal{A}) = \bigoplus_{j=0}^q B_{\rho(j)}(\mathcal{A}).$$

By Theorem 18.15.2, $K_q(\mathcal{A})$ is a finite-dimensional dg coalgebra (with the restricted bar differential), and the completed bar complex is the inverse limit $\widehat{B}_\rho(\mathcal{A}) = \varprojlim_q K_q(\mathcal{A})$.

THEOREM 18.15.4 (*Window locality*;). The finite q -window $K_q(\mathcal{A})$ depends only on the A_∞ operations $\{\mu_r\}$ restricted to fields of conformal weight $\leq q + 1$. No field of conformal weight $> q + 1$ can enter either the basis of $K_q(\mathcal{A})$ or its differential.

Proof. By Definition 18.15.1, every bar letter sa in $K_q(\mathcal{A})$ has $\rho(a) \leq q$, hence $\text{wt}(a) = \rho(a) + 1 \leq q + 1$. So the basis of $K_q(\mathcal{A})$ involves only fields of weight $\leq q + 1$. For the differential: the bar coderivation applies μ_r to r letters already in the window, producing a letter of weight $\text{wt}(\mu_r) \leq \sum_i \text{wt}(a_i) - (r - 1) \leq q + 1$. No field of higher weight can be produced, and no higher-weight field enters as an input (since all inputs are already in the window). $\square$

COROLLARY 18.15.5 (*Exact stabilization*;). For a genuine weight-truncation tower $\mathcal{A}_{\leq N} := \mathcal{A} / \bigoplus_{h>N} \mathcal{A}[h]$, one has a canonical isomorphism

$$K_q(\mathcal{A}_{\leq N}) \cong K_q(\mathcal{A}) \quad \text{for all } N \geq q + 1.$$

The infinite-generator problem is thereby killed exactly: a reduced-weight- q computation stabilizes at stage $N = q + 1$.

Proof. By Theorem 18.15.4, $K_q(\mathcal{A})$ depends only on fields of weight $\leq q + 1$. For $N \geq q + 1$, the truncation $\mathcal{A}_{\leq N}$ agrees with $\mathcal{A}$ on all such fields, hence the q -windows are canonically identified as dg coalgebras. $\square$

18.15.2 STABILIZATION DEFECT AND THE MC₄ OBSTRUCTION

The exact stabilization (Corollary 18.15.5) says that each finite window K_q eventually sees no new fields. The next question is finer: does the *differential* on K_q stabilize as one passes through the stage tower? The defect measures this, and its cohomology class is the first obstruction to MC₄ convergence.

Definition 18.15.6 (Stabilization defect). Fix a stage tower $\mathcal{A}_{\leq N}$ and a reduced-weight window q . For $N \geq q + 1$, the underlying vector spaces of the q -window are canonically identified: $K_q(\mathcal{A}_{\leq N}) \cong V_q$ (Corollary 18.15.5). Let $d_{q,N} \in \text{End}(V_q)$ denote the differential on the q -window at stage N . Define the *stabilization defect*

$$\delta_{q,N} := d_{q,N+1} - d_{q,N} \in \text{End}^1(V_q).$$

Since both $d_{q,N}$ and $d_{q,N+1}$ square to zero (or to the same curvature, at genus $g \geq 1$), one has

$$[d_{q,N}, \delta_{q,N}] + \delta_{q,N}^2 = 0,$$

so $\delta_{q,N}$ is a Maurer–Cartan deformation of $d_{q,N}$ in the dg Lie algebra $(\text{End}(V_q), [d_{q,N}, -])$.

Definition 18.15.7 (First stabilization obstruction). The *first stabilization obstruction* at stage N and window q is the cohomology class

$$\mathfrak{o}_{q,N} := [\delta_{q,N}] \in H^1(\text{End}(V_q), [d_{q,N}, -]).$$

If $\mathfrak{o}_{q,N} = 0$, the first-order defect is gauge-removable: there exists $\gamma \in \text{End}^0(V_q)$ such that $\delta_{q,N} = [d_{q,N}, \gamma] + O(\delta^2)$. Higher-order defects live in explicit higher cohomology groups of the same endomorphism complex.

Remark 18.15.8 (From topological convergence to finite linear algebra). Definitions 18.15.6 and 18.15.7 convert the MC4 convergence problem from “prove that the bar differential converges in a huge topological dg coalgebra” into a sequence of finite-dimensional checks: at each reduced-weight window q and each truncation stage N , *compute a finite matrix* ($\delta_{q,N}$), *compute its cohomology* (the H^1 of the endomorphism complex), and *test whether the defect class vanishes*. When $\mathfrak{o}_{q,N} = 0$ for all q and all sufficiently large N , the coefficient-stability criterion (Theorem 8.1.48) applies and the completed bar-cobar homotopy equivalence (Theorem 8.1.27) is established.

For the standard families:

- *Heisenberg and affine $\widehat{\mathfrak{g}}_k$* : finitely generated, so V_q stabilizes trivially and $\delta_{q,N} = 0$ for $N \gg 0$.
- $\beta\gamma$: one generator per conformal weight, so $\dim V_q = p(q)$ (number of partitions of q). Stabilization holds by the rank-one abelian rigidity (Theorem 18.5.19).
- *Virasoro and $\mathcal{W}_N$* : infinite towers with one primitive per weight. The stabilization defect $\delta_{q,N}$ is a finite matrix (of size $\dim V_q$) whose entries are explicit polynomial functions of c (resp. c and the central charges of the higher-spin currents). The MC4 frontier reduces to showing $[\delta_{q,N}] = 0$ for these explicit matrices.

18.15.3 MULTI-VARIABLE SHADOW OBSTRUCTION TOWER

For a chiral algebra $\mathcal{A}$ with $\dim H_{\text{cyc}}^2(\mathcal{A}) = r$ and basis $\{\eta_1, \dots, \eta_r\}$, the shadow at degree n is a degree- n polynomial $\text{Sh}_n \in \text{Sym}^n(H_{\text{cyc}}^2)$ in deformation coordinates $(x_1, \dots, x_r)$.

Definition 18.15.9 (Kappa matrix and propagator;). Define the *kappa matrix* $\kappa_{ij} = \langle \phi_i, \phi_j \rangle_{\max}$, the leading pole coefficient of the two-point function between the quasi-primary fields ϕ_i and ϕ_j dual to η_i and η_j . On the Koszul locus, κ is nondegenerate. Set $P = \kappa^{-1}$. The *multi-variable H-Poisson bracket* is

$$\{f, g\}_H = \sum_{i,j=1}^r \frac{\partial f}{\partial x_i} P_{ij} \frac{\partial g}{\partial x_j}. \quad (18.13)$$

The input shadows are:

- Sh_2 : the quadratic form κ (i.e. $\text{Sh}_2 = \sum_{i,j} \kappa_{ij} x_i x_j$);
- Sh_3 : cubic, from the OPE structure constants $C_{ijk} = \langle \phi_i, \ell_2^{\text{tr}}(\phi_j, \phi_k) \rangle$;
- Sh_4 : quartic, from quasi-primary exchange and the quartic contact invariant.

The master equation (Theorem 18.9.3) generates Sh_n for $n \geq 5$:

$$\nabla_H(\text{Sh}_n) + o^{(n)} = 0, \quad o^{(n)} = \sum_{\substack{j+k=n+2 \\ 3 \leq j \leq k}} \frac{1}{1 + \delta_{jk}} \{\text{Sh}_j, \text{Sh}_k\}_H. \quad (18.14)$$

LEMMA 18.15.10 (*Euler inversion*;). The H -covariant derivative satisfies $\nabla_H = 2E$, where $E = \sum_i x_i \partial / \partial x_i$ is the Euler operator. On homogeneous polynomials of degree n , ∇_H is invertible with $\nabla_H^{-1}(g) = g/(2n)$. In particular, each Sh_n is uniquely determined by the lower-order shadows.

Proof. The covariant derivative is $\nabla_H(f) = \{\text{Sh}_2, f\}_H$ where $\text{Sh}_2 = \sum_{i,j} \kappa_{ij} x_i x_j$. By (18.13),

$$\nabla_H(f) = \sum_{i,j,k,\ell} (\partial_{x_i} \text{Sh}_2) P_{ij} (\partial_{x_j} f) = \sum_{i,j,k} 2\kappa_{ik} x_k P_{ij} \partial_{x_j} f = 2 \sum_{j,k} \delta_{kj} x_k \partial_{x_j} f = 2 \sum_j x_j \partial_{x_j} f = 2E(f),$$

using $\sum_i \kappa_{ik} P_{ij} = \delta_{kj}$. For $f \in \text{Sym}^n$: $E(f) = n f$, so $\nabla_H^{-1}(g) = g/(2n)$. $\square$

Example 18.15.11 ($\mathcal{W}_3$ multi-variable shadow;). The algebra $\mathcal{W}_3$ has two generators: T (conformal weight 2) and W (conformal weight 3), giving deformation coordinates (x_T, x_W) with

$$\kappa = \begin{pmatrix} c/2 & 0 \\ 0 & c/3 \end{pmatrix}, \quad P = \kappa^{-1} = \begin{pmatrix} 2/c & 0 \\ 0 & 3/c \end{pmatrix}.$$

The kappa matrix is diagonal because T and W have different conformal weights, so the leading pole in $\langle T, W \rangle$ vanishes. The gravitational cubic (Theorem H.16.1) gives $\text{Sh}_3 = 2x_T^3 + 3x_T x_W^2$ (coefficient $d_W = 3$ from $T_{(1)}W = 3W$). The unique weight-4 quasi-primary $\Lambda = :TT: - \frac{3}{10} \partial^2 T$ mediates the quartic shadow through three channels:

$$Q_{TTTT} = \frac{10}{c(5c+22)}, \quad Q_{TTWW} = \frac{160}{c(5c+22)^2}, \quad Q_{WWWW} = \frac{2560}{c(5c+22)^3}. \quad (18.15)$$

The W - W - Λ coupling is $C_{WW,\Lambda} = \alpha = 16/(5c+22)$, extracted from $W_{(1)}W$ at pole order $h_W + h_W - h_\Lambda = 2$. Each pair of W -legs contributes one factor of α , yielding the *denominator filtration*: $2k$ W -legs $\Rightarrow (5c+22)^{1+k}$ in the denominator.

W -charge conservation (the $\mathbb{Z}/2$ symmetry $W \mapsto -W$) forces only even powers of x_W in every Sh_n . Consequently $\text{Sh}_n|_{x_T=0} = 0$ for odd n (Corollary 18.15.22).

The Virasoro subalgebra $\langle T \rangle$ is OPE-closed, so Theorem 18.15.20 gives $\text{Sh}_n(\mathcal{W}_3)|_{x_W=0} = \text{Sh}_n(\text{Vir})$ through all degrees (verified computationally through degree 9).

Remark 18.15.12 (*Multi-channel mixing*). The degree-6 non-autonomy of the shadow obstruction tower on the diagonal is governed by the propagator variance δ_{mix} (Proposition 13.22.180), a Cauchy-Schwarz gap that vanishes at curvature-proportionality loci where the quartic gradient is proportional to the curvature vector. For $\mathcal{W}_3$, the mixing polynomial $P(c) = 25c^2 + 100c - 428$ satisfies $\delta_{\text{mix}} = 1280 P^2 / [c^3(5c+22)^6]$.

PROPOSITION 18.15.13 (*Kac-shadow singularity principle*;). For a chiral algebra $\mathcal{A}$ in the Virasoro or $\mathcal{W}_N$ family, the denominator of $\text{Sh}_n(\mathcal{A})$, expressed as a rational function of the central charge c , divides a product of Kac determinant factors $\det M_m(c, 0)$ for $m \leq 2 \max_i (h_i)$, where h_i are the conformal weights of the generators. In particular, the singularity locus of the shadow obstruction tower is *independent of the degree n* : it is determined entirely by the quasi-primary exchange spectrum at the input degrees 2, 3, 4. For the Virasoro algebra, the exact denominator is $c^{n-2}(5c+22)^{\lfloor (n-2)/2 \rfloor}$, verified through degree 32.

Proof. The denominators of Sh_n enter through three mechanisms.

Source (i): *propagator poles*. The propagator $P = \kappa^{-1}$ has entries rational in c , with poles where $\det \kappa = 0$. For the standard families, $\kappa_{ii} = c/h_i$, so $\det \kappa$ vanishes at $c = 0$.

Source (ii): input shadow denominators. The quartic input Sh_4 involves quasi-primary exchange: $Q_{ijkl} = \sum_{\alpha} C_{ij,\alpha} N_{\alpha}^{-1} C_{kl,\alpha}$, where $N_{\alpha} = \langle \alpha | \alpha \rangle$ is the BPZ norm of the quasi-primary α . The norm N_{α} is a diagonal entry of the Gram matrix $M_h(c, 0)$ at weight $h = h_{\alpha}$, hence vanishes on the zero locus of $\det M_h(c, 0)$.

Source (iii): master-equation iteration. For $n \geq 5$, $\text{Sh}_n = -\nabla_H^{-1}(o^{(n)})$ where $o^{(n)} = \sum \{\text{Sh}_j, \text{Sh}_k\}_H$. By Lemma 18.15.10, ∇_H^{-1} introduces no new denominators (it divides by the integer $2n$). The H -Poisson bracket multiplies existing denominators and introduces the propagator entries P_{ij} . By induction, the denominators of Sh_n are products of those already present in $\text{Sh}_2, \text{Sh}_3, \text{Sh}_4$, and P .

The weight bound follows: the input quasi-primary norms N_{α} involve $\det M_m(c, 0)$ for $m \leq 2 \max_i(h_i)$ (since the exchange quasi-primaries have weight $\leq 2 \max(h_i)$). Each master-equation step preserves this bound. Hence Sh_n has denominator dividing a product of $\det M_m(c, 0)$ for $m \leq 2 \max_i(h_i)$, independent of n .

Conversely, at each Kac zero where a quasi-primary norm N_{α} vanishes, the exchange propagator N_{α}^{-1} diverges, creating a genuine pole of Sh_n . $\square$

Table 18.1: Shadow denominators and their Kac-determinant origins. Every denominator factor is a Kac zero; the converse holds at weights $\leq 2 \max(h_i)$.

Shadow	Denominator	Kac origin	Weight
Q_{TTTT}^{Vir}	$c(5c + 22)$	$\det M_4(c, 0)$	4
$Q_{TTWW}^{\mathcal{W}_3}$	$c(5c + 22)^2$	$[\det M_4(c, 0)]^2$	4
$Q_{WWWW}^{\mathcal{W}_3}$	$c(5c + 22)^3$	$[\det M_4(c, 0)]^3$	4
$Q_{T4T4}^{\mathcal{W}_4}$	c	$N_{W_4} = c/4$	4
C_{333}^2	$5c(c + 24)(5c + 22)$	$\det M_4 \cdot \det M_6$	4, 6

Remark 18.15.14 (Two-propagator quartic in $\mathcal{W}_4$). In $\mathcal{W}_4 = \mathcal{W}(\mathfrak{sl}_4, f_{\text{prin}})$, the generator W_4 has conformal weight 4, coinciding with $h_{\Lambda} = 4$. The weight-4 quasi-primary space is therefore 2-dimensional, spanned by Λ and W_4 itself. The quartic exchange formula acquires two propagator channels:

$$Q_{ijkl} = \frac{C_{ij,\Lambda} C_{kl,\Lambda}}{N_{\Lambda}} + \frac{C_{ij,W_4} C_{kl,W_4}}{N_{W_4}}.$$

The Λ -channel has denominator containing $(5c + 22)$ (the level-4 Kac factor); the W_4 -channel has denominator $c/4$ only. In the (T, W_4) -mixed channel, $Q_{T4T4} = C_{TW_4,W_4}^2 / N_{W_4} = 64/c$, which is *regular* at $c = -22/5$ (the Lee–Yang point where Λ decouples). This breaks the uniform denominator filtration of Proposition H.16.18 and shows that the singularity structure of Sh_4 depends on the *number* of quasi-primary mediators, not just their Kac factors.

THEOREM 18.15.15 (DS shadow depth increase;). Drinfeld–Sokolov reduction increases shadow depth from class L to class M . Specifically:

- (i) *Principal:* $V_k(\mathfrak{sl}_3)$ is class L ($r_{\max} = 3$) but $\mathcal{W}_3 = \text{DS}_{\text{prin}}(V_k(\mathfrak{sl}_3))$ is class M ($r_{\max} = \infty$).
- (ii) *Non-principal:* the Bershadsky–Polyakov algebra $\mathcal{BP}_k = \text{DS}_{(2,1)}(V_k(\mathfrak{sl}_3))$ is class M ($r_{\max} = \infty$): $\text{Sh}_4 = 10(k+3)^2 / [(6k+13)(10k+3)(12k^2+34k+21)]$ is nonzero at generic k (Computation 18.15.19).

Proof. The universal affine vertex algebra $V_k(\mathfrak{sl}_3)$ has quadratic OPE (the current–current OPE $J^a(z)J^b(w) \sim k\delta^{ab}/(z-w)^2 + f_c^{ab}J^c(w)/(z-w)$ is purely linear in the currents). By the PBW universality criterion (Proposition 11.1.32), $V_k(\mathfrak{sl}_3)$ is chirally Koszul, and by the shadow-formality identification (Proposition 13.22.107), the shadow obstruction tower terminates at degree 3: the cubic shadow $\mathfrak{C}$ is the Lie bracket, and all higher obstructions vanish. Thus $V_k(\mathfrak{sl}_3)$ is class L .

Principal Drinfeld–Sokolov reduction introduces the composite field $\Lambda = (TT) - \frac{3}{10}\partial^2 T$ into the W - W OPE at pole order 2: the coefficient $\alpha = 16/(5c + 22)$ is nonzero for generic c . This makes the OPE non-quadratic and produces a nonvanishing quartic shadow $Q_{TTTT} = 10/[c(5c + 22)] \neq 0$ (Theorem H.16.17). The quintic obstruction is $o^{(5)} = \{\text{Sh}_3, \text{Sh}_4\}_H$; on the T -line this reduces to the Virasoro quintic $o^{(5)}|_{x_W=0} = 480/[c^2(5c + 22)] \cdot x_T^5 \neq 0$ (Theorem 18.9.6). By shadow subalgebra autonomy (Theorem 18.15.20), the Virasoro sub-tower embeds into the $\mathcal{W}_3$ tower, so a nonvanishing Virasoro quintic implies a nonvanishing $\mathcal{W}_3$ quintic. Hence $r_{\max}(\mathcal{W}_3) = \infty$. $\square$

Remark 18.15.16. Theorem 18.15.15 shows that DS reduction does *not* preserve shadow depth class: the functor $\text{DS}: \text{class } L \rightarrow \text{class } M$ is not monotone. This is consistent with the general principle that DS reduction trades generators for relations; the output has fewer generators but more complicated OPE, and it is the OPE complexity that controls shadow depth (Definition 13.22.121).

Remark 18.15.17 (Geometric origin of shadow depth increase under DS). The depth increase $L \rightarrow M$ under DS reduction has a geometric explanation through the Slodowy-slice localization principle (Remark H.2.7).

The affine Kac–Moody algebra $\widehat{\mathfrak{g}}_k$ lives on the *linear* space $J_\infty(\mathfrak{g}^*)$: its OPE is a Lie bracket (binary), so the shadow obstruction tower terminates at degree 3 (class L). DS reduction restricts to $J_\infty(S_f)$, the arc space of the Slodowy slice $S_f = f + \mathfrak{g}^e$. As a submanifold of $\mathfrak{g}^*$, the slice S_f is an affine subspace (a translate of the linear space $\mathfrak{g}^e$), so its *extrinsic geometry is trivially flat*. The nonlinearity arises instead in the *Poisson bracket*: the Kirillov–Kostant bracket on $\mathfrak{g}^*$ is linear, but its restriction to S_f via the Dirac bracket (Hamiltonian reduction along the coadjoint orbit) acquires higher-order terms, because the constraint algebra $\mathfrak{g}/\mathfrak{g}^e$ introduces denominators and cross terms when eliminated. At the arc-space level, the Dirac bracket on $J_\infty(S_f)$ has a Taylor expansion in the $\mathcal{W}$ -algebra generators whose r -th order terms are precisely the degree- r shadow data:

- (i) The *cubic shadow* of $\mathcal{W}_N$ records the leading nonlinearity of the Dirac bracket on S_f : the binary Lie bracket on $\mathfrak{g}^*$ restricts to a bracket on S_f that has cubic corrections from the eliminated $\mathfrak{n}_+$ -directions.
- (ii) The *quartic contact coefficient* $Q_{\text{Vir}}^{\text{contact}} = 10/[c(5c + 22)]$ detects the degree-4 shadow of the Dirac bracket expansion: the iterated composition of the quadratic Virasoro OPE ($T \cdot T \sim T^2$) in the bar complex generates quartic terms at degree 4 that have no counterpart in the linear KM bracket on $\mathfrak{g}^*$. This is a bar-complex phenomenon: the quartic contact coefficient measures the obstruction to extending the degree-3 shadow to degree 4, not a direct correction to the binary bracket itself.
- (iii) Higher shadows Sh_r for $r \geq 5$ record the r -th order Dirac bracket structure on $J_\infty(S_f)$. The quintic obstruction $o_{\text{Vir}}^{(5)} \neq 0$ (Theorem 18.9.6) says the Poisson algebra on $J_\infty(S_{f_{\text{prin}}})$ for $\mathfrak{sl}_2$ has genuine fifth-order nonlinearity in its Dirac bracket, even though the slice itself is a one-dimensional affine subspace of $\mathfrak{sl}_2^*$.

Scope of the geometric explanation. The Slodowy-slice localization principle explains the depth increase $L \rightarrow M$ specifically for $\mathcal{W}$ -algebras obtained by DS reduction. It does *not* explain the shadow depth of the primitive archetypes in classes G , L , and C : Heisenberg (class G), Kac–Moody (class L), and $\beta\gamma$ (class C)

are fundamental families that do not arise from DS reduction. Their shadow depths are controlled by algebraic properties (scalar OPE (class G), the Jacobi identity (class L), and rank-one abelian rigidity (class C , Corollary 18.5.16)), not by Slodowy-slice geometry.

What the geometric principle *does* explain is the passage from class L to class M : the DS functor performs Hamiltonian reduction from $J_\infty(\mathfrak{g}^*)$ to $J_\infty(S_f)$, replacing the linear Kirillov–Kostant bracket with the nonlinear Dirac bracket on the slice. The shadow obstruction tower of the $\mathcal{W}$ -algebra is the Taylor expansion of this Dirac bracket, and DS reduction is the localization functor that creates the infinite tower from the finite one.

Remark 18.15.18 (DS ghost system and shadow consistency). The central charge formula $c_{\mathcal{W}_N}(k) = (N-1)[1 - N(N+1)(t-1)^2/t]$ (with $t = k+N$) and the Sugawara formula $c_{\hat{\mathfrak{sl}}_N}(k) = (N^2-1)k/(k+N)$ give a ghost central charge $c_{\text{ghosts}}(k) = c_{\hat{\mathfrak{sl}}_N} - c_{\mathcal{W}_N}$ that is level-dependent in general. At the shadow level, the kappa relation $\kappa(\mathcal{W}_N)(c(k)) + \kappa_{\text{ghosts}}(k) = \kappa(\hat{\mathfrak{sl}}_N)(k)$ is satisfied identically for all N ; the ghost kappa is level-dependent in general (unlike the ghost central charge for a fixed algebra). At the quartic level, $Q_{\hat{\mathfrak{sl}}_N} = 0$ (Jacobi) while $Q_{\mathcal{W}_N} \neq 0$: the quartic is *created* by the ghost sector, not transported. These are *consistency checks* between two independently computed shadow obstruction towers, not a proof that DS reduction commutes with the shadow obstruction tower as a functor. The depth-increase obstruction (Theorem 18.15.15) shows that a naive functorial statement $\text{DS}(\Theta_{\hat{\mathfrak{g}}}) = \Theta_{\mathcal{W}(\mathfrak{g})}$ cannot hold at the level of shadow obstruction towers; the correct formulation must involve the BRST cohomology of the full current-plus-ghost system.

The Feigin–Frenkel dual level for $\mathcal{W}_N$ is $k' = -k - 2N$ (i.e. $t \mapsto -t$ with $t = k+N$), satisfying $c(k) + c(k') = K_N$ where $K_N = 2(N-1)(2N^2+2N+1)$ is the Koszul conductor.

COMPUTATION 18.15.19 (Bershadsky–Polyakov shadow obstruction tower). The Bershadsky–Polyakov algebra $\mathcal{BP}_k = \mathcal{W}^k(\mathfrak{sl}_3, f_{(2,1)})$ has central charge $c(k) = -(12k^2 + 34k + 21)/(k + 3)$, Koszul conductor $K = 196$, and on the T -line:

r	$\text{Sh}_r^{T\text{-line}}(\mathcal{BP}_k)$
2	$-(12k^2 + 34k + 21)/[2(k + 3)]$
3	2
4	$10(k + 3)^2/[(6k + 13)(10k + 3)(12k^2 + 34k + 21)]$
5	$48(k + 3)^3/[(6k + 13)(10k + 3)(12k^2 + 34k + 21)^2]$

The σ -invariant: $\Delta^{(2)} = 98 = K/2$, $\Delta^{(3)} = 4$ (universal), $\Delta^{(4)}$ level-dependent with poles at $c = 0$, $c = 196$, $c = -22/5$, $c = 1002/5$. The J -line (residual $U(1)$) has class G (depth 2): the current is abelian.

THEOREM 18.15.20 (Shadow subalgebra autonomy;). Let $B \subset \mathcal{A}$ be a conformal sub-VOA satisfying:

- (i) the kappa matrix is block-diagonal between the B -generators and the complementary generators: $\kappa_{ij} = 0$ whenever ϕ_i is a B -generator and ϕ_j is not (or vice versa);
- (ii) B is *OPE-closed*: for every $n \geq 0$ and every pair of B -generators ϕ_i, ϕ_j , the quasi-primary projection of $\phi_i \phi_j$ lies in the vacuum module of B . Equivalently, $H_{\text{cyc}}^2(B)$ is a sub-dg-Lie-algebra of the modular convolution algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$.

Then

$$\text{Sh}_n(\mathcal{A})|_{x_{\mathcal{A}|B}=0} = \text{Sh}_n(B) \quad \text{for all } n \geq 2.$$

Proof. Condition (i) implies block-diagonality of the propagator $P = \kappa^{-1}$: the B -variables and complementary variables decouple in the H -Poisson bracket (18.13). Concretely,

$$\{f, g\}_H|_{x_{\mathcal{A} \setminus B}=0} = \{f|_{x_{\mathcal{A} \setminus B}=0}, g|_{x_{\mathcal{A} \setminus B}=0}\}_{H_B},$$

where $\{-, -\}_{H_B}$ is the H -Poisson bracket of B (with propagator $P_B = \kappa_B^{-1}$). The input data also restricts: $\text{Sh}_2(\mathcal{A})|_{x_{\mathcal{A} \setminus B}=0} = \text{Sh}_2(B)$ (by block-diagonality of κ), and $\text{Sh}_3(\mathcal{A})|_{x_{\mathcal{A} \setminus B}=0} = \text{Sh}_3(B)$ (the gravitational cubic tensor from Theorem H.16.1 restricts correctly, and condition (ii) ensures that any non-gravitational cubic coupling C_{ijk} with all B -indices does not receive contributions from quasi-primaries outside B).

For the quartic input Sh_4 : the quasi-primary exchange formula $Q_{ijkl} = \sum_{\alpha} C_{ij, \alpha} N_{\alpha}^{-1} C_{kl, \alpha}$ sums over *all* weight-4 quasi-primaries α of $\mathcal{A}$. Condition (ii) ensures that any $\alpha \notin B$ has $C_{ij, \alpha} = 0$ for all B -indices i, j , since the OPE $\phi_i \phi_j$ cannot produce quasi-primaries outside the B module. Hence Sh_4 restricts correctly.

Since the master equation (18.14) determines Sh_n uniquely from lower-order data (by Lemma 18.15.10), and both the bracket and the input restrict compatibly, the claim follows by induction on n . $\square$

Remark 18.15.21 (OPE-closedness is necessary). Condition (ii) cannot be dropped. In $\mathcal{W}_4 = \mathcal{W}(\mathfrak{sl}_4, f_{\text{prin}})$, the sub-VOA $B = \langle T, W_3 \rangle$ satisfies (i) but not (ii): the OPE $W_3 \cdot W_3$ produces $c_{334} W_4$ (the coupling through the weight-4 generator outside B). The W_4 -exchange contributes $4c_{334}^2/c$ to $\text{Sh}_4(\mathcal{W}_4)|_{x_4=0}$ in the pure x_3^4 channel, so the restriction exceeds $\text{Sh}_4(\mathcal{W}_3)$ by this amount. Only the Virasoro subalgebra $\langle T \rangle$ is both block-diagonal and OPE-closed in $\mathcal{W}_N$ for all N .

COROLLARY 18.15.22 (*W-line alternating vanishing*;). For $\mathcal{W}_3$, $\text{Sh}_n|_{x_T=0} = 0$ for all odd n . The pure W -sector shadow is nonzero only at even degrees.

Proof. The $\mathbb{Z}/2$ automorphism $W \mapsto -W$ of $\mathcal{W}_3$ acts on the deformation space as $x_W \mapsto -x_W, x_T \mapsto x_T$. Equivariance of the master equation forces every Sh_n to be $\mathbb{Z}/2$ -invariant: each monomial $x_T^a x_W^b$ in Sh_n has b even. Since $a + b = n$, the exponent a has the same parity as n . Restricting to $x_T = 0$ retains only the $a = 0$ term, which requires n to be even. For odd n , no $a = 0$ monomial exists, so $\text{Sh}_n|_{x_T=0} = 0$.

The even-degree restrictions are generically nonzero: $\text{Sh}_4|_{x_T=0} = Q_{WWWW} x_W^4 \neq 0$ (equation (18.15)), and similarly $\text{Sh}_6|_{x_T=0} \neq 0$ (verified computationally). $\square$

THEOREM 18.15.23 (*Shadow obstruction tower as cyclic L_{∞} MC potential*;). Let $(\ell_k^{\text{tr}})_{k \geq 1}$ denote the transferred L_{∞} operations on $H_{\text{cyc}}^2(\mathcal{A})$ (via the homotopy transfer theorem applied to the modular convolution algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$). The shadow coefficients are the cyclic invariants of the transferred operations:

$$\text{Sh}_r = \langle \eta, \ell_{r-1}^{\text{tr}}(\eta, \dots, \eta) \rangle_{\text{cyc}},$$

and the shadow potential $S_{\mathcal{A}}(x) = \sum_{r \geq 2} \text{Sh}_r x^r / r!$ is the cyclic L_{∞} Maurer–Cartan potential restricted to the primary line $\Theta = x \cdot \eta$:

$$S_{\mathcal{A}}(x) = W(x \cdot \eta), \quad W(\Theta) = \sum_{k \geq 1} \frac{1}{(k+1)!} \langle \Theta, \ell_k^{\text{tr}}(\Theta, \dots, \Theta) \rangle.$$

The critical equation $dS_{\mathcal{A}}/dx = 0$ is the Maurer–Cartan equation of the transferred L_{∞} structure, and its critical locus models the full MC moduli by the Kontsevich–Soibelman homotopy transfer equivalence $\text{MC}(\mathfrak{g}_{\mathcal{A}}^{\text{mod}}) \simeq \text{MC}(H^*(\mathfrak{g}_{\mathcal{A}}^{\text{mod}}))$.

This potential coincides with the complementarity action of Definition 13.22.92 restricted to the primary line and genus 0. At genus 0, the MC equation on H_{cyc}^2 implies associativity of the shadow quantum product, recovering the WDVV equation of the shadow CohFT.

Proof. Expand $W(x\eta) = \sum_{k \geq 1} \frac{x^{k+1}}{(k+1)!} \langle \eta, \ell_k^{\text{tr}}(\eta, \dots, \eta) \rangle = \sum_{r \geq 2} \frac{x^r}{r!} \text{Sh}_r$, identifying $\text{Sh}_r = \langle \eta, \ell_{r-1}^{\text{tr}}(\eta, \dots, \eta) \rangle$. The curvature $\text{Sh}_2 = \langle \eta, \ell_1^{\text{tr}}(\eta) \rangle = \langle \eta, d^{\text{tr}}\eta \rangle = \kappa$ recovers the Hessian; the cubic $\text{Sh}_3 = \langle \eta, \ell_2^{\text{tr}}(\eta, \eta) \rangle$ recovers the Lie bracket contribution; the quartic $\text{Sh}_4 = \langle \eta, \ell_3^{\text{tr}}(\eta, \eta, \eta) \rangle$ recovers the Λ -exchange (the homotopy-transferred ternary operation). The identification with the complementarity action follows from the genus-0 specialization: the complementarity action $\mathfrak{S}_{\mathcal{A}}$ (Definition 13.22.92) evaluates the modular MC element $\Theta_{\mathcal{A}}$ on the cyclic deformation complex; at genus 0 and on the primary line, this reduces to $W(x \cdot \eta)$ by the bar-intrinsic construction (Theorem 13.21.69). $\square$

PROPOSITION 18.15.24 (*Shadow potential convergence*;). For the Virasoro algebra at central charge $c \notin \{0, -22/5\}$:

- (i) The shadow obstruction tower $\sum_{r \geq 2} \text{Sh}_r t^r$ has finite convergence radius. By the closed form $H(t) = t^2 \sqrt{Q_L(t)}$ (Theorem 13.22.137), the radius equals the distance from the origin to the nearest zero of $Q_L(t)$.
- (ii) The shadow potential $S_{\text{Vir}}(x) = \sum_{r \geq 2} \text{Sh}_r x^r / r!$ is an entire function of x : since $H(t) = t^2 \sqrt{Q_L(t)}$ is algebraic with convergence radius $R > 0$, the Cauchy estimate gives $|\text{Sh}_r| \leq M/R^r$ for constants $M, R > 0$ depending on c . Then $|\text{Sh}_r / r!| \leq M/(R^r \cdot r!)$ decays super-exponentially, giving infinite convergence radius by the ratio test.
- (iii) At the Kac zeros $c = 0$ and $c = -22/5$, the convergence radii collapse: $P = \kappa^{-1}$ diverges at $c = 0$, and Sh_4 has a pole at $c = -22/5$.

Proof. Part (i): by Theorem 13.22.137, the shadow generating function satisfies the algebraic relation $H(t)^2 = t^4 Q_L(t)$, so $H(t) = t^2 \sqrt{Q_L(t)}$ is an algebraic function of t . Its singularities are precisely the zeros of $Q_L(t)$ (branch points of the square root). The convergence radius of the Taylor series of H equals the distance to the nearest singularity. Each shadow coefficient is a rational function of c with denominator $c^{ar} (5c + 22)^{br}$ (Proposition 18.15.13); for fixed $c \notin \{0, -22/5\}$ the zeros of Q_L are at finite nonzero distance from the origin, giving $R > 0$.

Part (ii): by the Cauchy integral formula for Taylor coefficients of a function analytic on a disk of radius R , $|\text{Sh}_r| \leq \sup_{|t|=R'} |H(t)| / (R')^r$ for any $R' < R$. This is a geometric bound $|\text{Sh}_r| \leq M \cdot (1/R')^r$. The factorial in the potential kills this geometric growth: $|\text{Sh}_r / r!| \leq M / (R'^r \cdot r!) \rightarrow 0$ super-exponentially.

Part (iii): at $c = 0$, $\kappa = 0$ and Q_L degenerates (its leading coefficient vanishes); at $c = -22/5$, the Kac determinant vanishes at level 4 and Sh_4 has a pole. $\square$

Remark 18.15.25 (*Shadow discriminant instability*). The discriminant of the truncated critical equation (the locus in c where critical points of $S_{\mathcal{A}}^{\leq N}$ collide) changes at every truncation order N . At degree 4 the discriminant numerator is $(15c + 56)$; at degree 5 it becomes $(30c + 133)(90c + 271)$; at degrees 6 and 7 it is an irreducible polynomial of degree 4 and 7 respectively. The zeros of the truncated discriminant *cluster toward the Kac zeros* $c = 0$ and $c = -22/5$ as $N \rightarrow \infty$, consistent with the shadow potential being entire: the full discriminant of an entire function is an infinite product whose Taylor approximants have migrating roots.

The *denominators* of the shadow discriminant (the pole locus) are stable: always $c^{N(N-1)/2} (5c + 22)^{f(N)}$, in agreement with Proposition 18.15.13: the shadow pole structure is a genuine invariant controlled by the Kac determinant.

18.15.4 THE MC MODULI CURVE

The shadow potential $S_{\mathcal{A}}(x; c)$ (Theorem 18.15.23) is entire in x for generic c (Proposition 18.15.24). Its critical locus is the *MC moduli curve*.

Definition 18.15.26 (MC moduli curve;). For a chiral algebra $\mathcal{A}$ of shadow class M with $\dim H_{\text{cyc}}^2 = 1$, the *MC moduli curve* is the analytic subset

$$\mathcal{M}_{\mathcal{A}} := \{(x, c) \in \mathbb{C} \times \mathbb{C}^* : (\partial S_{\mathcal{A}}/\partial x)(x; c) = 0, x \neq 0\},$$

equipped with the projection $\pi: \mathcal{M}_{\mathcal{A}} \rightarrow \mathbb{C}_c^*$ to the central-charge line (punctured at the Kac locus $K = \{c \in \mathbb{C} : \det \kappa(c) = 0\}$). The fiber $\pi^{-1}(c)$ is the set of nontrivial Maurer–Cartan solutions at central charge c .

THEOREM 18.15.27 (MC moduli curve structure;). Let $\mathcal{A}$ be a chiral algebra of shadow class M with $\dim H_{\text{cyc}}^2 = 1$. The MC moduli curve satisfies:

- (a) *Discrete fibers.* For each $c \notin K$, the fiber $\pi^{-1}(c)$ is a discrete (countable) subset of $\mathbb{C}_x^*$.
- (b) *Branch point accumulation.* The branch locus $B \subset \mathbb{C}_c^*$ of π accumulates at each point of the Kac locus K . In the degree- N truncation, the number of branch points grows linearly with N .
- (c) *Kac locus = essential singularity.* At each Kac zero $c_0 \in K$, the MC moduli curve has an essential singularity: the shadow coefficients $\text{Sh}_n(c)$ have poles at c_0 of order growing with n , and the monodromy of π around c_0 involves infinitely many Picard–Lefschetz transpositions (one per accumulating branch point).
- (d) *Stable pole structure.* The shadow coefficients $\text{Sh}_n(c)$ are rational functions of c with poles only at the Kac locus K . The pole orders at each $c_0 \in K$ grow linearly in n (Proposition 18.15.13).
- (e) *Unstable discriminant.* The discriminant $\Delta_N(c) = c^{a(N)}(5c + 22)^{b(N)}P_N(c)$ of the degree- N critical equation has stable factors $\{c, 5c + 22\}$ (Kac determinant factors) and an unstable factor P_N whose roots cluster toward the Kac zeros as $N \rightarrow \infty$.

Proof. Part (a) follows from the entirety of $S_{\mathcal{A}}$ in x : the derivative $\partial S/\partial x$ is a nonconstant entire function, hence has discrete zero set.

Part (b): the degree- N truncation replaces $\partial S/\partial x$ by a polynomial of degree $N-1$ in x . The discriminant of this polynomial, computed explicitly for $N = 4, 5, 6, 7$, has the stated factorization with $\deg P_N$ growing linearly. The roots of P_N cluster toward $c = -22/5$ (the weight-4 Kac zero), as verified numerically.

Part (c): at a Kac zero c_0 , the shadow coefficient $\text{Sh}_n(c_0)$ has a pole of order linear in n (from the iterated propagator $P = \kappa^{-1}$). The shadow potential $S(x; c_0)$ is therefore a formal (not convergent) power series, and the MC moduli curve has no well-defined fiber over c_0 . The infinitely many branch points accumulating at c_0 (from part (b)) generate infinitely many Picard–Lefschetz transpositions in the monodromy group.

Part (d) is Proposition 18.15.13.

Part (e): direct computation at $N = 4, 5, 6, 7$. □

THEOREM 18.15.28 (Hadamard factorization of the MC potential;). For a class M algebra $\mathcal{A}$ with $\dim H_{\text{cyc}}^2 = 1$ and central charge $c \notin K$, the derivative of the shadow potential has the Hadamard product representation

$$\frac{\partial S_{\mathcal{A}}}{\partial x}(x; c) = e^{ax+b} \cdot x \cdot \prod_{k=1}^{\infty} \left(1 - \frac{x}{x_k(c)}\right) e^{x/x_k(c)},$$

where $\{x_k(c)\}_{k \geq 1}$ are the nontrivial MC solutions, $b = \log(\kappa/2)$, and $a = -\sum_k 1/x_k(c)$. The product converges absolutely and uniformly on compact subsets of $\mathbb{C}_x$. The shadow potential has order $\rho = 1$ (the shadow coefficients grow geometrically as $|\text{Sh}_r| \sim (6/|c|)^r/r$, and the factorial in $r!$ reduces this to order 1). The Hadamard genus is therefore at most 1, and Weierstrass primary factors $E_1(u) = (1-u)e^u$ ensure convergence.

Proof. The shadow potential $S_{\mathcal{A}}(x; c)$ is entire of order 1. The raw shadow coefficients satisfy $|\text{Sh}_r| \sim (2/r)(6/|c|)^{r-2}$ (Proposition 18.15.24), so $|\text{Sh}_r/r!| \sim (6e/|c|r)^r/r^{3/2}$ by Stirling, giving $\rho = \limsup_{r \rightarrow \infty} r \log r / (-\log |\text{Sh}_r/r!|) = 1$. By the Hadamard factorization theorem for entire functions of order 1, $\partial S/\partial x = e^{ax+b} x \prod_k E_1(x/x_k)$ where $E_1(u) = (1-u)e^u$ is the Weierstrass primary factor of genus 1 and a, b are constants. The leading coefficient $e^b = \kappa/2$ is determined by $\partial^2 S/\partial x^2|_{x=0} = \kappa$ (Lemma 18.15.10), and $a = -\sum_k 1/x_k(c)$ by the standard Hadamard normalization. $\square$

COROLLARY 18.15.29 (*MC solution counting*;). The number $N(R; c)$ of nontrivial MC solutions with $|x_k(c)| \leq R$ satisfies the Jensen estimate

$$N(R; c) \leq \frac{1}{\log 2} \log \frac{\max_{|x|=2R} |\partial S/\partial x|}{|\kappa/2| \cdot R}.$$

Since $\partial S/\partial x$ has order 1, $N(R; c) = O(R)$ for fixed $c \notin K$: the MC solutions have at most linear density. They accumulate only at $x = \infty$, not at any finite point.

REMARK 18.15.30 (*Trivial isomonodromy at rank 1*). The logarithmic derivative $(\partial^2 S/\partial x^2)/(\partial S/\partial x) = 1/x + \sum_k 1/(x - x_k(c))$ defines a meromorphic connection on $\mathbb{C}_x$ with simple poles at $x = 0$ and $x = x_k(c)$, all with residue 1. Since the residues are *scalar* (rank 1: the deformation space is one-dimensional), the commutators $[A_i, A_j] = 0$ vanish, and the Schlesinger system reduces to $dA_k/dc = 0$ (trivially satisfied). The connection is therefore *trivially isomonodromic* as c varies: the monodromy is the identity at each pole, independent of the positions $x_k(c)$.

At rank ≥ 2 (e.g., $\mathcal{W}_3$ with $\dim H_{\text{cyc}}^2 = 2$), the residues are matrices and the Schlesinger equations give nontrivial constraints on the variation of MC solutions with c . The isomonodromic structure at rank 2 is the subject of Conjecture 18.15.31.

CONJECTURE 18.15.31 (*Rank-2 isomonodromic structure*). For $\mathcal{W}_3$ with $\dim H_{\text{cyc}}^2 = 2$, the MC moduli (the critical locus of $S_{\mathcal{W}_3}$ on the two-dimensional deformation space (x_T, x_W) , viewed as a family of point configurations in $\mathbb{C}^2$ parameterized by c) satisfies the Schlesinger system for the KZ connection with 2×2 Casimir $\Omega = \text{diag}(\kappa_T, \kappa_W) = \text{diag}(c/2, c/3)$ (whose trace is $\kappa(\mathcal{W}_3) = 5c/6$).

Chapter 19

Branch-line reductions, primitive modular characteristics, and the intrinsic invariant ladder

The full modular Maurer–Cartan element $\Theta_{\mathcal{A}}$ lives in an infinite-dimensional convolution algebra. A *branch-line reduction* restricts $\Theta_{\mathcal{A}}$ to a configuration of minimal complexity (two-point branch lines, rank-one spectral sectors, genus-2 transparency windows) and proves structural theorems inside the resulting finite-dimensional quotient.

The *primitive modular characteristics* are the irreducible components of $\Theta_{\mathcal{A}}$ under the clutching maps of $\overline{\mathcal{M}}_{g,n}$: they are to the shadow obstruction tower what primitive elements are to a Hopf algebra. The intrinsic invariant ladder

$$\kappa(\mathcal{A}) \rightsquigarrow \Delta_{\mathcal{A}}(x) \rightsquigarrow \Theta_{\mathcal{A}}.$$

The load-bearing theorems are the scalar modular characteristic (Theorem 13.21.44), the spectral characteristic (Theorem 13.21.63), and the universal modular Maurer–Cartan theorem (Theorems 13.21.66 and 13.21.117). The purpose of the appendix is not to replace the full MC2 package by a smaller surrogate. It is to extract exact finite-dimensional quotients of that package and prove structural theorems inside those quotients. Those quotient theorems clarify which parts of the higher-genus story are already forced by the scalar and spectral shadows, and which parts still belong to the genuinely infinite cyclic L_{∞} geometry.

Two corrections organize the whole discussion. First, the natural intrinsic ladder is κ, Δ, Θ , not a comparison theorem such as Drinfeld–Kohno. The spectral discriminant is the first non-scalar invariant built purely from the modular Koszul package, whereas DK-type comparison theorems sit later in the theorem graph. Second, the universal class $\Theta_{\mathcal{A}}$ is available by Theorems 13.21.66 and 13.21.117. For one-channel families, the minimal class lies on a single line $\eta \otimes \Gamma_{\mathcal{A}}$; on the proved uniform-weight lane (Definition 13.21.41) this further specializes to $\kappa(\mathcal{A})\eta \otimes \Lambda$. The non-scalar content is organized by the shadow obstruction tower (Definition 13.22.46), with finite-order shadows proved through degree 4. The new constructions below therefore have a precise role: they are shadow and quotient theorems *inside* the proved finite-order modular package.

What is new here. The appendix proves five families of results.

1. It constructs the scalar Maurer–Cartan skeleton and the spectral cumulant hierarchy as canonical logarithmic shadows of $\Theta_{\mathcal{A}}$.

2. It proves an abstract filtered obstruction theorem showing that the first nontrivial correction to a scalar shadow is necessarily traceless and quadratic.
3. It proves that the positive-weight Virasoro sector is contractible in the effective L_0 -model, so the first non-scalar content is forced into finite reduced spectral sectors.
4. It proves a genus-2 transparency theorem for every rank-two branch-line quotient with scalar square.
5. It computes the first primitive traceless coefficients in the pure branch and top-Hodge primitive quotients, including the universal genus-3 constant 7 on the shared $\widehat{\mathfrak{sl}}_2/\text{Virasoro}/\beta\gamma$ spectral sheet.

Construction 19.0.1 (Branch lines as shadow depth loci). Branch-line reductions are the geometric loci where the shadow depth $r_{\max}(\mathcal{A})$ transitions between archetype classes. The weight-changing line in the $\beta\gamma$ system (class C, $r_{\max} = 4$) degenerates to the Heisenberg line (class G, $r_{\max} = 2$) when the quartic contact invariant $\mu_{\beta\gamma}$ vanishes (Corollary 18.5.16). The general mechanism has three layers.

- (i) The shadow depth $r_{\max}(\mathcal{A})$ is the smallest integer r such that the obstruction class $o_{r+1}(\mathcal{A}) \in H^2(F^{r+1}\mathfrak{g}/F^{r+2}\mathfrak{g}, d_2)$ vanishes identically, or ∞ if no such r exists (Definition 13.22.46). It classifies chiral algebras into four archetype classes: G ($r_{\max} = 2$, Gaussian), L ($r_{\max} = 3$, Lie/tree), C ($r_{\max} = 4$, contact/quartic), M ($r_{\max} = \infty$, mixed).
- (ii) A branch line is a one-parameter family in which the shadow depth drops: there exists a critical value of the spectral parameter at which $o_{r_{\max}}(\mathcal{A})$ becomes cohomologous to zero, reducing the effective shadow depth by at least one. The primitive modular characteristics are the irreducible components of $\Theta_{\mathcal{A}}$ that survive on the branch line; those that vanish are precisely the obstructions that the branch-line reduction removes.
- (iii) For the $\beta\gamma$ system, the weight-changing branch line is the locus where the quartic contact invariant $\mu_{\beta\gamma} = \langle \eta, m_3(\eta, \eta, \eta) \rangle$ vanishes. At this locus the shadow obstruction tower truncates from degree 4 to degree 2, and the residual modular characteristic is the scalar $\kappa(\beta\gamma) = 1$, matching the Heisenberg value at rank 1. This is the content of the rank-one abelian rigidity argument of Corollary 18.5.16.

19.1 THE INVARIANT LADDER FROM FIRST PRINCIPLES

The modular characteristic hierarchy has three logarithmic levels and three different kinds of geometry.

- (i) The scalar level is governed by the single number $\kappa(\mathcal{A})$ and the tautological line $\kappa(\mathcal{A})\lambda_g$ on $\overline{\mathcal{M}}_g$ (Theorem 13.21.44).
- (ii) The spectral level is governed by the spectral discriminant $\Delta_{\mathcal{A}}(x)$, equivalently by the branch transport operator in the finite-rank spectral model (Theorem 13.21.63).
- (iii) The full level is governed by the cyclic deformation complex $\text{Def}_{\text{cyc}}(\mathcal{A})$ and the universal Maurer–Cartan class $\Theta_{\mathcal{A}}$ (Theorems 13.21.66 and 13.21.117).

The point of view of this appendix is that the scalar and spectral levels are not secondary bookkeeping devices. They are exact quotient faces of $\Theta_{\mathcal{A}}$, and they can therefore be studied as mathematical objects in their own right.

Definition 19.1.1 (Scalar Maurer–Cartan skeleton). Let $\mathcal{A}$ be a modular Koszul chiral algebra. Define the abelian dg Lie algebra

$$\mathfrak{s}_{\mathcal{A}} := \prod_{g \geq 1} \mathbf{Q} u_g, \quad |u_g| = 1 - 2g, \quad d = 0, \quad [-, -] = 0.$$

The *scalar Maurer–Cartan skeleton* of $\mathcal{A}$ is the element

$$\Theta_{\mathcal{A}}^{\text{sc}} := \sum_{g \geq 1} \kappa(\mathcal{A}) u_g \otimes \lambda_g \in \mathfrak{s}_{\mathcal{A}} \widehat{\otimes} \prod_{g \geq 1} H^{2g}(\overline{\mathcal{M}}_g, \mathbf{Q}). \quad (19.1)$$

PROPOSITION 19.1.2 (*The scalar shadow is an abelian MC element;*). For every modular Koszul chiral algebra $\mathcal{A}$, the class $\Theta_{\mathcal{A}}^{\text{sc}}$ of (19.1) is a Maurer–Cartan element of the abelian dg Lie algebra $\mathfrak{s}_{\mathcal{A}}$. It is exactly the image of $\Theta_{\mathcal{A}}$ under the scalar trace map of Theorem 13.21.66.

Proof. Each summand $u_g \otimes \lambda_g$ has total degree $(1 - 2g) + 2g = 1$, so $\Theta_{\mathcal{A}}^{\text{sc}}$ has Maurer–Cartan degree 1. Since $\mathfrak{s}_{\mathcal{A}}$ is abelian and has zero differential, the MC equation reduces to closedness, which is immediate because the classes λ_g are closed. The trace identity is precisely clause (i) of Theorem 13.21.66. $\square$

Remark 19.1.3 (The scalar ladder is a quotient, not a replacement). The existence of $\Theta_{\mathcal{A}}^{\text{sc}}$ does not compete with the full theorem. It identifies the maximal abelian quotient of the full modular deformation problem. Every finite or filtered approximation to $\Theta_{\mathcal{A}}$ that respects the scalar trace must reduce to $\Theta_{\mathcal{A}}^{\text{sc}}$ after projecting away all brackets and all non-scalar channels.

19.2 SPECTRAL CUMULANTS AND THE CONNECTED POTENTIAL

Theorem 13.21.63 isolates the first intrinsic non-scalar invariant: the spectral discriminant. The next step is to extract from it a canonical infinite hierarchy of characteristic numbers.

Definition 19.2.1 (Spectral cumulants and connected potential). Let $\mathcal{A}$ be a modular Koszul chiral algebra for which the spectral characteristic is realized by a finite-rank branch transport operator T_{br} with

$$\Delta_{\mathcal{A}}(x) = \det(1 - xT_{\text{br}}).$$

Define the *spectral cumulants*

$$\mathfrak{c}_m(\mathcal{A}) := \text{Tr}(T_{\text{br}}^m), \quad m \geq 1,$$

and the *connected spectral potential*

$$\Psi_{\mathcal{A}}(x) := -\log \Delta_{\mathcal{A}}(x).$$

THEOREM 19.2.2 (*Spectral cumulant hierarchy;*). The connected potential satisfies

$$\Psi_{\mathcal{A}}(x) = \sum_{m \geq 1} \frac{\mathfrak{c}_m(\mathcal{A})}{m} x^m. \quad (19.2)$$

Consequently:

- (i) each $\mathfrak{c}_m(\mathcal{A})$ is a canonical spectral invariant;
- (ii) the discriminant $\Delta_{\mathcal{A}}(x)$ is determined by finitely many cumulants once its degree is fixed;

(iii) in the shared rank-two spectral sheet $\Delta(x) = (1 - 3x)(1 + x)$ of Theorem K.7.1, one has

$$\mathfrak{c}_m = 3^m + (-1)^m. \quad (19.3)$$

Proof. Using $\Delta_{\mathcal{A}}(x) = \det(1 - xT_{\text{br}})$, one computes

$$-\log \Delta_{\mathcal{A}}(x) = -\log \det(1 - xT_{\text{br}}) = -\text{Tr} \log(1 - xT_{\text{br}}) = \sum_{m \geq 1} \frac{\text{Tr}(T_{\text{br}}^m)}{m} x^m,$$

which is (19.2). This proves (i). For (ii), write $\Delta_{\mathcal{A}}(x) = 1 - e_1x + e_2x^2 - \cdots + (-1)^d e_dx^d$. The Newton identities recover the elementary symmetric polynomials e_i from the power sums $\mathfrak{c}_1, \dots, \mathfrak{c}_d$, so those first d cumulants determine $\Delta_{\mathcal{A}}$. Finally, in the shared sheet, T_{br} has eigenvalues 3 and -1 , hence (19.3). $\square$

Remark 19.2.3 (Connected cycle interpretation). Formula (19.2) is the connected-cycle expansion of the spectral transport. The coefficient $\mathfrak{c}_m(\mathcal{A})/m$ is the cyclic trace of length- m branch transport, divided by the number of cyclic choices of basepoint. In particular, $\Psi_{\mathcal{A}}(x)$ is the connected one-loop spectral shadow of the full modular Maurer–Cartan class.

19.3 AN ABSTRACT FILTERED OBSTRUCTION THEOREM

The full MC2 theorem resolves the existence of $\Theta_{\mathcal{A}}$. The next theorem clarifies a different question: where can a first nontrivial correction appear in a trace-compatible quotient or truncation of a Maurer–Cartan problem?

Definition 19.3.1 (Trace-compatible filtered dg Lie algebra). A trace-compatible filtered dg Lie algebra consists of:

- (i) a complete descending filtration $L = F^1L \supseteq F^2L \supseteq \cdots$ by dg Lie ideals;
- (ii) an abelian dg Lie algebra S ;
- (iii) a morphism of filtered dg Lie algebras $\text{tr}: L \rightarrow S$ such that $\text{tr}[x, y] = 0$ for all $x, y \in L$.

Write $L^\circ := \ker(\text{tr})$ for the traceless sector.

THEOREM 19.3.2 (*First obstruction is traceless and quadratic*). Let $(L, F^\bullet, \text{tr})$ be a trace-compatible filtered dg Lie algebra, and let $\theta_{\text{sc}} \in S^1$ be a closed degree-1 element. Suppose that $\vartheta^{(1)} \in F^1L/F^2L$ is a first-order lift of θ_{sc} . For any representative $\tilde{\vartheta}_1 \in F^1L$, define the curvature modulo F^3L by

$$\Omega_2(\tilde{\vartheta}_1) := d\tilde{\vartheta}_1 + \frac{1}{2}[\tilde{\vartheta}_1, \tilde{\vartheta}_1] \mod F^3L.$$

Then:

- (i) $\Omega_2(\tilde{\vartheta}_1)$ defines a class

$$o_2 \in H^2(F^2L/F^3L)$$

independent of the representative;

- (ii) $o_2 = 0$ if and only if $\vartheta^{(1)}$ lifts to a Maurer–Cartan solution modulo F^3L ;

(iii) the class o_2 lies in the traceless sector $H^2(F^2L^\circ/F^3L^\circ)$.

Proof. Because $\vartheta^{(1)}$ is closed modulo F^2L , the curvature of $\tilde{\vartheta}_1$ lies in F^2L . A standard graded Jacobi identity computation gives

$$d\Omega_2(\tilde{\vartheta}_1) \equiv 0 \pmod{F^3L},$$

so Ω_2 is a cocycle modulo F^3L . If one changes the representative by an element $\alpha \in F^2L$, then

$$\Omega_2(\tilde{\vartheta}_1 + \alpha) - \Omega_2(\tilde{\vartheta}_1) \equiv d\alpha \pmod{F^3L},$$

because every bracket involving α lands in F^3L . This proves (i).

For (ii), a correction $\vartheta_2 \in F^2L/F^3L$ produces a Maurer–Cartan solution modulo F^3L exactly when

$$d\vartheta_2 = -\Omega_2(\tilde{\vartheta}_1) \quad \text{in } F^2L/F^3L.$$

So the obstruction vanishes precisely when the class o_2 vanishes.

Finally,

$$\text{tr}(\Omega_2(\tilde{\vartheta}_1)) = d \text{tr}(\tilde{\vartheta}_1) + \frac{1}{2} \text{tr}[\tilde{\vartheta}_1, \tilde{\vartheta}_1] = d\theta_{\text{sc}} + 0 = 0.$$

Hence the obstruction class lies in the kernel of the trace map. This is (iii). $\square$

COROLLARY 19.3.3 (*Vanishing criterion for filtered lifts;*). In the situation of Theorem 19.3.2, assume in addition that

$$H^2(F^nL^\circ/F^{n+1}L^\circ) = 0 \quad \text{for all } n \geq 2.$$

Then every scalar Maurer–Cartan skeleton admits a lift to an honest Maurer–Cartan element of L . If in addition

$$H^1(F^nL^\circ/F^{n+1}L^\circ) = 0 \quad \text{for all } n \geq 2,$$

then the lift is unique up to gauge equivalence among all lifts with the same scalar trace.

Proof. The proof is the standard inductive extension argument. At stage n , the failure of a lift modulo $F^{n+2}L$ defines a class in $H^2(F^{n+1}L/F^{n+2}L)$. Repeating the trace computation from the proof of Theorem 19.3.2, one sees that this class lies in the traceless sector. The vanishing of H^2 kills the obstruction and produces a lift at the next stage. Completeness of the filtration yields a limit Maurer–Cartan element. The vanishing of H^1 gives uniqueness by the usual gauge-induction argument. $\square$

Remark 19.3.4 (*Use after MC2*). In the present repository the full lift already exists, so Corollary 19.3.3 is not needed to prove $\Theta_{\mathcal{A}}$. Its role is diagnostic: any finite or spectral approximation to $\Theta_{\mathcal{A}}$ begins to fail, if it fails at all, in the traceless quadratic sector.

19.4 VIRASORO POSITIVE-WEIGHT ACYCLICITY AND REDUCED SPECTRAL LOCALIZATION

This section isolates the first genuinely finite obstruction sector in the Virasoro family. The mechanism is the same one that already drives the PBW calculations: positive conformal weight is invertible under the L_0 -action.

Definition 19.4.1 (Effective positive-weight functor). Let $\bar{V}_{\text{Vir}_c} = \bigoplus_{h \geq 2} M_h$ be the augmentation ideal of the Virasoro vacuum algebra, graded by conformal weight. An *effective positive-weight functor* on $\bar{V}_{\text{Vir}_c}$ is a finite polynomial Schur functor built from tensors, symmetric powers, exterior powers, and finite-dimensional auxiliary spaces, with the condition that every homogeneous monomial has strictly positive total conformal weight.

If $\mathcal{F}(\bar{V}_{\text{Vir}_c})$ is such a functor, define the *effective differential*

$$d_{\text{eff}} := \mathcal{F}(L_0),$$

where L_0 acts diagonally by conformal weight.

LEMMA 19.4.2 (Positive-weight contraction;). Let $W = \bigoplus_{m > 0} W_m$ be a positively graded vector space, and let D act on W_m by $m \text{ id}$. Then the complex (W, D) is contractible.

Proof. Define $h: W \rightarrow W$ by $h|_{W_m} = m^{-1} \text{id}$. Then on W_m one has

$$Dh + hD = \text{id}_{W_m}.$$

Hence id_W is null-homotopic. □

THEOREM 19.4.3 (Positive-weight Virasoro sectors are acyclic;). For every effective positive-weight functor $\mathcal{F}(\bar{V}_{\text{Vir}_c})$, the complex $(\mathcal{F}(\bar{V}_{\text{Vir}_c}), d_{\text{eff}})$ is contractible. In particular,

$$H^\bullet(\mathcal{F}(\bar{V}_{\text{Vir}_c}), d_{\text{eff}}) = 0.$$

Proof. Every homogeneous monomial of $\mathcal{F}(\bar{V}_{\text{Vir}_c})$ has total conformal weight $m > 0$. On the weight- m subspace, d_{eff} acts by $m \text{ id}$. Apply Lemma 19.4.2 weight by weight. □

COROLLARY 19.4.4 (Localization to reduced spectral sectors;). In every quotient of the Virasoro modular deformation problem whose associated graded is built from effective positive-weight functors and a finite-dimensional reduced spectral sector, the positive-weight part is acyclic. Consequently the first non-scalar quotient data are forced into finite reduced spectral sectors.

Proof. The associated graded of the positive-weight part is acyclic by Theorem 19.4.3. Hence every spectral sequence argument collapses there, leaving only the reduced finite-rank sector. □

Remark 19.4.5 (The reduced line on the shared sheet). On the shared sheet $\Delta(x) = (1 - 3x)(1 + x)$ of Theorem K.7.1, the reduced spectral algebra is two-dimensional. Its traceless part is therefore one-dimensional. Any reduced traceless coefficient in a one-channel quotient must lie on a single line. The genus-2 coefficient in the branch-line quotient is therefore forced, a priori, to have the form $\mu_2(c) \tau \otimes \lambda_2$.

PROPOSITION 19.4.6 (Odd-sheet rigidity for one-line reductions;). Let $t = k + 2$ and write

$$c = 1 - \frac{6(k+1)^2}{k+2} = 13 - 6(t + t^{-1}).$$

Suppose that a reduced traceless Virasoro coefficient is represented on the shared spectral line by $m(t)\tau$, where:

- (i) $m(t) = m(t^{-1})$ (sheet descent);

- (ii) the same-family involution $k \mapsto -k - 4$, equivalently $t \mapsto -t$, acts by $\tau \mapsto -\tau$ (*odd spectral normalization*).

Then

$$m(t) = (t + t^{-1})Q\left((t + t^{-1})^2\right) \quad (19.4)$$

for a unique function Q . Equivalently, the descended coefficient is of the form

$$\mu(c) = (c - 13)P((c - 13)^2) \quad (19.5)$$

for a unique function P .

Proof. Set $u = t + t^{-1}$, so $c = 13 - 6u$. The sheet-descent assumption says that m depends only on u . Under the same-family involution, $t \mapsto -t$, hence $u \mapsto -u$. Because the spectral line is odd, the transformed coefficient must satisfy $m(-t) = -m(t)$, so the descended function of u is odd. Every odd function of u has the form $uQ(u^2)$, proving (19.4). Substituting $u = (13 - c)/6$ yields (19.5). $\square$

COROLLARY 19.4.7 (*The genus-2 one-line coefficient is centered at 13;*). Every genus-2 reduced traceless coefficient on the shared spectral line that obeys the hypotheses of Proposition 19.4.6 satisfies

$$\mu_2(26 - c) = -\mu_2(c), \quad \mu_2(13) = 0.$$

19.5 RANK-TWO BRANCH-LINE REDUCTIONS

The previous sections motivate a general finite-dimensional quotient. The right level of generality is a rank-two spectral sheet.

Construction 19.5.1 (*Rank-two branch algebra*). Fix distinct scalars $\lambda_+, \lambda_- \in \mathbf{C}$, and define

$$R_{\lambda_+, \lambda_-} := \mathbf{C}[K] / ((K - \lambda_+)(K - \lambda_-)).$$

Set

$$c := \frac{\lambda_+ + \lambda_-}{2}, \quad \delta := \frac{\lambda_+ - \lambda_-}{2}, \quad \tau := K - c.$$

Then

$$R_{\lambda_+, \lambda_-} = \mathbf{C} \cdot 1 \oplus \mathbf{C} \cdot \tau, \quad \tau^2 = \delta^2.$$

The line $\mathbf{C}\tau$ is the *branch line*.

Proof. Expanding the quadratic relation for K gives $K^2 - (\lambda_+ + \lambda_-)K + \lambda_+\lambda_- = 0$. Hence

$$(K - c)^2 = K^2 - 2cK + c^2 = ((\lambda_+ + \lambda_-)K - \lambda_+\lambda_-) - 2cK + c^2 = c^2 - \lambda_+\lambda_- = \delta^2.$$

So every polynomial in K reduces uniquely to a scalar plus a multiple of τ . $\square$

LEMMA 19.5.2 (*Universal branch moments;*). In the rank-two branch algebra one has

$$K^m = a_m + b_m \tau, \quad b_m = \frac{\lambda_+^m - \lambda_-^m}{\lambda_+ - \lambda_-}, \quad (19.6)$$

for every $m \geq 1$. Equivalently,

$$\text{pr}_\tau(K^m) = \frac{\lambda_+^m - \lambda_-^m}{\lambda_+ - \lambda_-} \tau.$$

Proof. Write $K^m = a_m + b_m \tau$. Evaluating on the two eigenspaces of K yields

$$\lambda_+^m = a_m + b_m \delta, \quad \lambda_-^m = a_m - b_m \delta.$$

Subtracting gives

$$2\delta b_m = \lambda_+^m - \lambda_-^m.$$

Since $2\delta = \lambda_+ - \lambda_-$, one obtains (19.6). □

Definition 19.5.3 (Branch-line and primitive quotients). Let $\mathcal{A}$ be a modular Koszul chiral algebra whose spectral characteristic factors through a rank-two sheet.

- (i) The *branch-line quotient* keeps only the scalar vertex data $\kappa(\mathcal{A})\lambda_h$, the branch transport along edges, and the projection to the branch line $\mathbf{C}\tau$.
- (ii) The *pure-branch primitive quotient* further discards every positive-genus vertex decoration and every separating edge.
- (iii) The *top-Hodge primitive quotient* keeps the top Hodge line $\mathbf{Q}\lambda_{g(v)}$ on each vertex, retains only connected nonseparating graphs, and projects the spectral factor to the branch line.

Definition 19.5.4 (Hodge depth). For a connected stable graph Γ , define its *Hodge depth* by

$$\delta(\Gamma) := |E(\Gamma)| + \sum_{v \in V(\Gamma)} g(v).$$

THEOREM 19.5.5 (Depth formula;). For every connected stable graph Γ of total genus g ,

$$\delta(\Gamma) = g + |V(\Gamma)| - 1. \tag{19.7}$$

Consequently:

- (i) $\delta(\Gamma) \geq g$;
- (ii) equality holds if and only if $|V(\Gamma)| = 1$.

Thus the first primitive depth in genus g is exactly the one-vertex sector.

Proof. The genus formula for a connected stable graph is

$$g = b_1(\Gamma) + \sum_v g(v) = |E(\Gamma)| - |V(\Gamma)| + 1 + \sum_v g(v).$$

Rearranging gives (19.7). The corollaries are immediate. □

19.6 GENUS-2 TRANSPARENCY

The one-dimensional branch line forces a strong vanishing statement in genus 2. The proof is entirely geometric: separating clutching sees λ_2 , and nonseparating clutching kills it.

LEMMA 19.6.1 (*Separating Hodge splitting*;). For the separating clutching map

$$\xi_{\text{sep}}: \overline{\mathcal{M}}_{1,1} \times \overline{\mathcal{M}}_{1,1} \longrightarrow \overline{\mathcal{M}}_2,$$

one has a canonical isomorphism of Hodge bundles

$$\xi_{\text{sep}}^* \mathbb{E}_2 \cong \text{pr}_1^* \mathbb{E}_1 \oplus \text{pr}_2^* \mathbb{E}_1.$$

Hence

$$\xi_{\text{sep}}^* \lambda_2 = \lambda_1 \boxtimes \lambda_1. \quad (19.8)$$

Proof. Let $C = C_1 \cup_q C_2$ be a separating nodal genus-2 curve with elliptic components C_1 and C_2 . The normalization description of the dualizing sheaf identifies sections of ω_C with pairs of sections of $\omega_{C_1}(q)$ and $\omega_{C_2}(q)$ whose residues at q add to zero. On an elliptic curve every section of $\omega_{C_i}(q)$ is already holomorphic, so the residue condition is automatic. Therefore

$$H^0(C, \omega_C) \cong H^0(C_1, \omega_{C_1}) \oplus H^0(C_2, \omega_{C_2}),$$

and this identification globalizes over the separating boundary family. Taking top Chern classes gives (19.8). $\square$

LEMMA 19.6.2 (*Nonseparating Hodge extension*;). For the nonseparating clutching map

$$\xi_{\text{ns}}: \overline{\mathcal{M}}_{1,2} \longrightarrow \overline{\mathcal{M}}_2,$$

one has an exact sequence

$$0 \longrightarrow \mathbb{E}_1 \longrightarrow \xi_{\text{ns}}^* \mathbb{E}_2 \longrightarrow \mathcal{O} \longrightarrow 0.$$

Consequently,

$$\xi_{\text{ns}}^* \lambda_2 = 0.$$

Proof. A point of the nonseparating boundary is an elliptic curve E with two marked points p, q identified. Sections of the dualizing sheaf of the nodal curve correspond to meromorphic differentials on E with at most simple poles at p and q and opposite residues. Such a space is generated by the holomorphic differential on E together with a normalized differential of the third kind having residues $+1$ and -1 at p and q . The quotient line is therefore trivial, which gives the exact sequence above. Since the quotient has vanishing first Chern class, one gets

$$\xi_{\text{ns}}^* \lambda_2 = c_2(\xi_{\text{ns}}^* \mathbb{E}_2) = 0.$$

$\square$

THEOREM 19.6.3 (*Genus-2 transparency on a one-line branch quotient*;). Let $R = S \oplus T$ be a commutative algebra such that T is one-dimensional and $T^2 \subseteq S$. Let $\Xi_g \in H^\bullet(\overline{\mathcal{M}}_g, \mathbb{Q}) \otimes R$ be a clutching-compatible tower,

$$\xi_{g_1, g_2}^* \Xi_{g_1+g_2} = \Xi_{g_1} \boxtimes \Xi_{g_2}.$$

Assume that:

- (i) the genus-1 traceless part vanishes;
- (ii) the genus-2 traceless part lies on the top Hodge line:

$$\mathrm{pr}_T(\Xi_2) = \nu_2 \tau \otimes \lambda_2 \quad (19.9)$$

for some nonzero generator τ of T .

Then $\nu_2 = 0$.

Proof. Restrict to the separating boundary. By clutching,

$$\xi_{\mathrm{sep}}^* \Xi_2 = \Xi_1 \boxtimes \Xi_1.$$

Because the genus-1 traceless part vanishes, the traceless part of $\Xi_1 \boxtimes \Xi_1$ vanishes as well. On the other hand, (19.9) and Lemma 19.6.1 give

$$\mathrm{pr}_T(\xi_{\mathrm{sep}}^* \Xi_2) = \nu_2 \tau \otimes \lambda_1 \boxtimes \lambda_1.$$

Now $\tau \neq 0$, and $\lambda_1 \boxtimes \lambda_1 \neq 0$ on $\overline{\mathcal{M}}_{1,1} \times \overline{\mathcal{M}}_{1,1}$, so $\nu_2 = 0$. Lemma 19.6.2 shows that there is no nonseparating contribution on the top Hodge line, because $\xi_{\mathrm{ns}}^* \lambda_2 = 0$. $\square$

COROLLARY 19.6.4 (*Virasoro genus-2 coefficient vanishes in the one-line quotient*;). In every Virasoro branch-line quotient whose genus-2 traceless part lies on λ_2 , the coefficient $\mu_2(c)$ vanishes identically.

Proof. Apply Theorem 19.6.3 to the one-dimensional branch line of the shared rank-two sheet. $\square$

COROLLARY 19.6.5 (*The first primitive traceless coefficient begins in genus 3*;). In the top-Hodge branch-line quotient, the first possible nonzero primitive traceless contribution occurs in genus 3.

Proof. Genus 1 is scalar by hypothesis, and genus 2 is annihilated by Theorem 19.6.3. $\square$

19.7 THE PURE-BRANCH PRIMITIVE GENUS-3 COEFFICIENT

The pure-branch quotient keeps only genus-zero vertices and nonseparating edges. In genus 3 there is only one primitive graph: the three-loop rose.

LEMMA 19.7.1 (*Uniqueness of the primitive rose in genus 3*;). In the pure-branch primitive quotient, the connected genus-3 sector is one-dimensional, generated by the one-vertex three-loop rose. If

$$\xi_{\mathrm{rose}}^{(3)} : \overline{\mathcal{M}}_{0,6} \longrightarrow \overline{\mathcal{M}}_3$$

glues the ordered pairs (1, 2), (3, 4), and (5, 6), then the corresponding class is

$$\rho_3 := (\xi_{\mathrm{rose}}^{(3)})_*(1).$$

Proof. In the pure-branch primitive quotient every vertex has genus 0, so the total genus is the first Betti number:

$$3 = b_1(\Gamma) = |E(\Gamma)| - |V(\Gamma)| + 1.$$

The primitive sector at minimal depth has $|V(\Gamma)| = 1$ by Theorem 19.5.5, hence $|E(\Gamma)| = 3$. The unique connected one-vertex graph with three edges is the rose. $\square$

THEOREM 19.7.2 (*Pure-branch primitive coefficient on a rank-two sheet;*). Let $\mathcal{A}$ be a modular Koszul chiral algebra whose spectral characteristic factors through the rank-two sheet R_{λ_+, λ_-} . In the pure-branch primitive quotient, the first primitive traceless coefficient is

$$\Theta_{3, \text{prim}}^{\text{pb}}(\mathcal{A}) = \frac{\lambda_+^3 - \lambda_-^3}{\lambda_+ - \lambda_-} \tau \otimes \rho_3. \quad (19.10)$$

For the shared sheet $\Delta(x) = (1 - 3x)(1 + x)$, this becomes

$$\Theta_{3, \text{prim}}^{\text{pb}} = 7 \tau \otimes \rho_3.$$

Proof. By Lemma 19.7.1, the primitive quotient is one-dimensional on the graph side, so the only possible coefficient is a scalar multiple of $\tau \otimes \rho_3$. Each loop contributes one copy of the branch transport operator K , so the total transport is K^3 . Projecting to the branch line and applying Lemma 19.5.2 gives (19.10). On the shared sheet, $(\lambda_+, \lambda_-) = (3, -1)$, hence the coefficient is $(27 - (-1))/4 = 7$. $\square$

Remark 19.7.3 (*Rose coefficients in all genera*). The same proof gives the entire pure rose tower. If ρ_g^{rose} denotes the class of the g -loop rose, then

$$\Theta_{g, \text{rose}}^{\text{pb}}(\mathcal{A}) = \frac{\lambda_+^g - \lambda_-^g}{\lambda_+ - \lambda_-} \tau \otimes \rho_g^{\text{rose}}.$$

For the shared sheet this coefficient is $d_g = (3^g - (-1)^g)/4$.

19.8 THE TOP-HODGE PRIMITIVE QUOTIENT

The pure-branch quotient isolates the universal constant 7, but it forgets the scalar vertex data. The next exact quotient restores the top Hodge line on each vertex.

Definition 19.8.1 (*Graph-normalized primitive classes*). For $0 \leq h \leq g$, let

$$\xi_h^{(g-h)} : \overline{\mathcal{M}}_{h, 2(g-h)} \longrightarrow \overline{\mathcal{M}}_g$$

be the map that glues the ordered pairs $(1, 2), \dots, (2(g-h)-1, 2(g-h))$. Define

$$\bar{\eta}_{g,h} := \frac{1}{2^{g-h}(g-h)!} (\xi_h^{(g-h)})_*(\lambda_h), \quad \lambda_0 := 1.$$

The prefactor is the standard reciprocal automorphism factor for the one-vertex $(g-h)$ -loop graph.

Remark 19.8.2 (*The genus-3 basis*). For genus 3, the classes of Definition 19.8.1 are

$$\bar{\rho}_3 := \bar{\eta}_{3,0}, \quad \bar{\epsilon}_3 := \bar{\eta}_{3,1}, \quad \bar{\gamma}_3 := \bar{\eta}_{3,2}.$$

These are respectively the three-loop rational rose, the elliptic bi-rose with a λ_1 -insertion, and the genus-2 monorose with a λ_2 -insertion.

THEOREM 19.8.3 (*First primitive top-Hodge layer;*). Let $\mathcal{A}$ be a modular Koszul chiral algebra whose spectral characteristic factors through the rank-two sheet R_{λ_+, λ_-} . In the top-Hodge primitive quotient, the first primitive layer in genus $g \geq 2$ is

$$\Sigma_g(\mathcal{A}) = \tau \otimes \left(\frac{\lambda_+^g - \lambda_-^g}{\lambda_+ - \lambda_-} \bar{\eta}_{g,0} + \kappa(\mathcal{A}) \sum_{h=1}^{g-1} \frac{\lambda_+^{g-h} - \lambda_-^{g-h}}{\lambda_+ - \lambda_-} \bar{\eta}_{g,h} \right). \quad (19.11)$$

Proof. By Theorem 19.5.5, the first primitive depth in genus g is the one-vertex sector. A one-vertex primitive graph is therefore determined by its vertex genus h and its loop number $g - h$. On the graph side this contributes the class $\bar{\eta}_{g,h}$. On the scalar side, a genus- h vertex contributes $\kappa(\mathcal{A})\lambda_h$ for $h \geq 1$, whereas the genus-zero vertex is the undeformed tree-level base and contributes only the unit. On the spectral side, each loop contributes one factor of K , so the total branch transport is K^{g-h} . Projecting to the branch line and using Lemma 19.5.2 gives exactly (19.11). $\square$

COROLLARY 19.8.4 (*The genus-3 primitive coefficient;*). For genus 3 one has

$$\Sigma_3(\mathcal{A}) = \tau \otimes \left(\frac{\lambda_+^3 - \lambda_-^3}{\lambda_+ - \lambda_-} \bar{\rho}_3 + \kappa(\mathcal{A}) \frac{\lambda_+^2 - \lambda_-^2}{\lambda_+ - \lambda_-} \bar{\epsilon}_3 + \kappa(\mathcal{A}) \bar{\gamma}_3 \right).$$

On the shared sheet $(\lambda_+, \lambda_-) = (3, -1)$, this becomes

$$\Sigma_3(\mathcal{A}) = \tau \otimes (7\bar{\rho}_3 + 2\kappa(\mathcal{A})\bar{\epsilon}_3 + \kappa(\mathcal{A})\bar{\gamma}_3). \quad (19.12)$$

For Virasoro, where $\kappa(\text{Vir}_c) = c/2$ by Theorem 13.21.44, one gets

$$\Sigma_3(\text{Vir}_c) = \tau \otimes \left(7\bar{\rho}_3 + c\bar{\epsilon}_3 + \frac{c}{2}\bar{\gamma}_3 \right).$$

Proof. Substitute $g = 3$ into Theorem 19.8.3. For the shared sheet,

$$\frac{3^3 - (-1)^3}{3 - (-1)} = 7, \quad \frac{3^2 - (-1)^2}{3 - (-1)} = 2, \quad \frac{3 - (-1)}{3 - (-1)} = 1.$$

The Virasoro specialization follows from the scalar identity $\kappa(\text{Vir}_c) = c/2$. $\square$

REMARK 19.8.5 (*What genus 3 remembers*). Equation (19.12) separates the first primitive traceless coefficient into three distinct sources:

- (i) the universal pure-branch constant 7, already visible on the three-loop rational rose;
- (ii) the genus-1 scalar shadow transported through two loops;
- (iii) the genus-2 scalar shadow transported through one loop.

The quotient therefore exhibits a clean operator-level decomposition of what the first primitive non-scalar correction can see.

19.9 SHARED-SHEET SPECIALIZATIONS AND CONTROL CASES

COROLLARY 19.9.1 (*Universal coefficients on the shared sheet;*). On the shared sheet of Theorem K.7.1, the branch-line moments are

$$d_m := \frac{3^m - (-1)^m}{4},$$

so that

$$d_1 = 1, \quad d_2 = 2, \quad d_3 = 7, \quad d_{m+2} = 2d_{m+1} + 3d_m.$$

Accordingly,

$$\Sigma_g(\mathcal{A}) = \tau \otimes \left(d_g \bar{\eta}_{g,0} + \kappa(\mathcal{A}) \sum_{h=1}^{g-1} d_{g-h} \bar{\eta}_{g,h} \right)$$

for every algebra on the shared sheet.

Proof. This is the specialization of Lemma 19.5.2 and Theorem 19.8.3 to $(\lambda_+, \lambda_-) = (3, -1)$. The recurrence follows from the minimal polynomial $K^2 - 2K - 3 = 0$. $\square$

Example 19.9.2 (The scalar-only Heisenberg frame). The Heisenberg frame example in Part I shows the opposite extreme from the shared interacting sheet. Its higher-genus package is already controlled by the scalar invariant κ , so there is no nontrivial rank-two branch-line quotient to extract. In that sense the Heisenberg example is the scalar atom, whereas the shared $\widehat{\mathfrak{sl}}_2/\text{Virasoro}/\beta\gamma$ sheet is the first genuine spectral atom.

19.10 WHAT REMAINS OPEN ABOVE THE QUOTIENT

The quotients constructed here are exact, but they are not the whole story. They record only what is forced by the scalar shadow, the rank-two spectral sheet, and the stable-graph clutching algebra. The full modular deformation complex contains strictly more information.

Problem 19.10.1 (Branch realization of the full cyclic complex). Construct a natural morphism from the full cyclic deformation complex

$$\mathcal{R}_{\text{br}}: \text{Def}_{\text{cyc}}(\mathcal{A}) \longrightarrow \text{End}(V_{\text{br}}) \widehat{\otimes} C^*(\text{stable graphs})$$

whose logarithmic connected trace recovers the spectral potential $\Psi_{\mathcal{A}}(x)$.

Conjecture 19.10.2 (Spectral shadow principle;). For every modular Koszul chiral algebra $\mathcal{A}$, the full universal class $\Theta_{\mathcal{A}}$ admits a natural branch realization

$$\mathcal{R}_{\text{br}}: L_{\mathcal{A}}^{\circ} \longrightarrow \text{End}(V_{\text{br}, \mathcal{A}})[[x]]$$

whose connected one-loop image is exactly

$$-\log \Delta_{\mathcal{A}}(x) = \Psi_{\mathcal{A}}(x).$$

The proved spectral potential is the one-loop connected shadow of the full graph-valued Maurer–Cartan element.

Remark 19.10.3 (Why the logarithm is canonical). The conjecture is structurally forced: a Maurer–Cartan element in a completed dg Lie algebra decomposes into connected graph contributions by the standard exponential/logarithm correspondence. The determinant $\Delta_{\mathcal{A}}$ is the partition function (disconnected sum), and $\Psi_{\mathcal{A}} = -\log \Delta_{\mathcal{A}}$ is the connected potential. The identification would say that the spectral connected potential is exact at the one-loop level, with all higher-loop connected contributions lying in the traceless sector.

Problem 19.10.4 (Renormalization of primitive quotient coefficients). Determine whether the coefficients in the primitive quotients are exact images of the full Maurer–Cartan class or receive corrections from non-top-Hodge vertex decorations and genuinely higher cyclic L_{∞} -operations. In particular, decide whether the quotient formula

$$\Sigma_3(\text{Vir}_c) = \tau \otimes \left(7\bar{\rho}_3 + c\bar{\epsilon}_3 + \frac{c}{2}\bar{\gamma}_3 \right)$$

is already the exact genus-3 traceless image of Θ_{Vir_c} under a canonical branch realization.

Problem 19.10.5 (Beyond top Hodge). Describe the first quotient above the top-Hodge primitive layer. A natural candidate is the quotient that keeps one additional tautological vertex decoration, for example a ψ -class or a boundary divisor class, together with the same branch-line projection. Theorem 19.5.5 suggests that the first new terms should appear either at the same depth with richer vertex decorations or one depth higher with multi-vertex primitive graphs.

Remark 19.10.6 (The structural picture). The quotient theory established here has a clean shape.

- (i) The scalar Maurer–Cartan skeleton is the abelian shadow of the full universal class.
- (ii) The spectral discriminant produces a connected cumulant tower.
- (iii) The first nontrivial correction to a scalar shadow is forced into a traceless quadratic sector.
- (iv) In the Virasoro family, the positive-weight sector is contractible, so the first finite obstruction is spectral.
- (v) On every one-line branch quotient with scalar square, genus 2 is transparent.
- (vi) The first primitive top-Hodge coefficient therefore occurs in genus 3, and on the shared sheet its universal pure-branch part is the constant 7.

This is the exact content of the branch-line and primitive quotient programme extracted from the thread.

Chapter 20

Computational methods

The shadow obstruction tower of a chirally Koszul algebra is a square root.

The Maurer–Cartan element $\Theta_{\mathcal{A}}$ of a chirally Koszul algebra $\mathcal{A}$, restricted to a primary line L of the cyclic deformation complex, is the Taylor expansion of one algebraic function of degree 2. The function is $\sqrt{Q_L(t)}$, where Q_L is a quadratic polynomial determined by three invariants: the modular characteristic κ , the cubic shadow α , and the critical discriminant $\Delta = 8\kappa S_4$. The Taylor coefficients are the shadow tower. The branch points of $\sqrt{Q_L}$ are the singularities. The monodromy is -1 : the Koszul sign.

The structure is not three independent methods that happen to agree, but four languages for a single object:

Algebra	Taylor coefficients of $\sqrt{Q_L}$
Deformation theory	MC recursion as fixed-point equation
Analysis	Darboux asymptotics, Borel summability
Geometry	flat section of a logarithmic connection

These are not alternatives. They are the same object described in four ways. The cross-consistencies are tautologies, once one sees that the object is one.

20.1 THE SQUARE ROOT

Fix a chirally Koszul algebra $\mathcal{A}$ with $\kappa = \kappa(\mathcal{A}) \neq 0$. Let L be a one-dimensional primary slice of $\text{Def}_{\text{cyc}}^{\text{mod}}(\mathcal{A})$. The shadow tower on L is the sequence $\{S_r\}_{r \geq 2}$ of exact rational numbers defined by the degree- r projection of $\Theta_{\mathcal{A}}$ along L .

Definition 20.1.1 (Shadow metric). The *shadow metric* on L is the quadratic polynomial

$$Q_L(t) = 4\kappa^2 + 12\kappa\alpha t + (9\alpha^2 + 2\Delta)t^2, \quad \Delta = 8\kappa S_4.$$

The *shadow generating function* is $H(t) = t^2 \sqrt{Q_L(t)}$.

Three coefficients. A quadratic. An algebraic function of degree 2. The Taylor coefficients of $\sqrt{Q_L}$ are determined by (κ, α, S_4) through the convolution recursion: write $\sqrt{Q_L(t)} = \sum_{n \geq 0} a_n t^n$. Then

$$a_0 = 2\kappa, \quad a_1 = 3\alpha, \quad a_2 = 4S_4,$$

and for $n \geq 3$,

$$a_n = -\frac{1}{2a_0} \sum_{j=1}^{n-1} a_j a_{n-j}. \quad (20.1)$$

No square roots are extracted. Every a_n is a rational function of (κ, α, S_4) with rational coefficients.

THEOREM 20.1.2 (*Riccati algebraicity*). The shadow coefficients satisfy

$$S_r = \frac{a_{r-2}}{r}, \quad r \geq 2.$$

Proof. The weighted generating function $H(t) = \sum_{r \geq 2} r S_r t^r$ satisfies the algebraic identity

$$H(t)^2 = t^4 Q_L(t),$$

which is the content of Theorem 13.22.137. Both sides equal the bilinear form $\langle \Theta_L, \Theta_L \rangle$ evaluated on the cyclic pairing: the left side uses the generating function squared, the right uses the Gaussian decomposition $Q_L = (2\kappa + 3\alpha t)^2 + 2\Delta t^2$. Choosing the branch with $H(t) \sim 2\kappa t^2$ as $t \rightarrow 0$ gives $H = t^2 \sqrt{Q_L}$. The coefficient of t^r in H is $r S_r$. $\square$

Example 20.1.3 (*The first ten Virasoro shadows*). For the Virasoro algebra at central charge c : $\kappa = c/2$, $\alpha = 2$, $S_4 = 10/[c(5c + 22)]$. The convolution recursion gives

$$\begin{aligned} S_2 &= \frac{c}{2}, \\ S_3 &= 2, \\ S_4 &= \frac{10}{c(5c + 22)}, \\ S_5 &= \frac{-48}{c^2(5c + 22)}, \\ S_6 &= \frac{80(45c + 193)}{3c^3(5c + 22)^2}, \\ S_7 &= \frac{-2880(15c + 61)}{7c^4(5c + 22)^2}, \\ S_8 &= \frac{80(2025c^2 + 16470c + 33314)}{c^5(5c + 22)^3}, \\ S_9 &= \frac{-1280(2025c^2 + 15570c + 29554)}{3c^6(5c + 22)^3}, \\ S_{10} &= \frac{256(91125c^3 + 1050975c^2 + 3989790c + 4969967)}{c^7(5c + 22)^4}. \end{aligned}$$

Every number is a rational function of c . The denominators encode a single Gram determinant. The numerators encode the shadow radius. The signs encode the argument of the nearest branch point. Ten invariants from one quadratic form.

Example 20.1.4 (*Virasoro at $c = 1/2$*). At the Ising point $c = 1/2$: $\kappa = 1/4$, $\alpha = 2$, $S_4 = 10/[(1/2)(49/2)] = 40/49$. The shadow metric is $Q_L(t) = 1/4 + 6t + (36 + 640/49)t^2 = 1/4 + 6t + (2404/49)t^2$. The convolution recursion (20.1) produces $S_5, S_6, \dots$ as explicit fractions with denominators $c^{r-3}(5c + 22)^{\lfloor (r-2)/2 \rfloor} = (1/2)^{r-3}(49/2)^{\lfloor (r-2)/2 \rfloor}$, all exact. The growth rate $\rho \approx 12.5$: the tower diverges rapidly and requires Borel resummation.

Remark 20.1.5 (The cubic shadow $\alpha = 2$ is determined). The value $\alpha = 2$ for the Virasoro algebra is not assumed. It is *determined* by three independent routes: (i) the Sugawara self-coupling $C_{TT}^T = 2$ in the OPE $T(z)T(w) \sim \dots + 2T(w)/(z-w)^2 + \dots$; (ii) back-derivation from S_5 , via the identity $\alpha = -5\kappa S_5/(6S_4)$; (iii) the critical cubic (20.2): matching $45\alpha^2 = 180$ gives $\alpha^2 = 4$.

THEOREM 20.1.6 (Denominator theorem). For all $r \geq 4$:

$$\text{denom}(S_r) = (\text{const}) \cdot c^{r-3} (5c + 22)^{\lfloor (r-2)/2 \rfloor}.$$

No Kac determinant zeros beyond weight 4 appear.

Proof. Induction on n in the recursion (20.1). Base: $a_2 = 40/[c(5c+22)]$. Step: the product $a_j a_{n-j}$ contributes c^{n-2} and $(5c+22)^{\lfloor j/2 \rfloor + \lfloor (n-j)/2 \rfloor}$ in the denominator; the inequality $\lfloor j/2 \rfloor + \lfloor (n-j)/2 \rfloor \leq \lfloor n/2 \rfloor$ is saturated by $j = 2$ (for n even) or $j = 1$ (for n odd), making the bound exact. Division by $2c$ raises the c -power to $n - 1$. $\square$

The shadow obstruction tower sees only the first Gram determinant. The quartic contact invariant $Q_{\text{Vir}}^{\text{ct}} = 10/[c(5c + 22)]$ has poles at $c = 0$ and $c = -22/5$; the zeros of $\det G_4 = c^2(5c + 22)/2$. The shadow obstruction tower's poles are the representation theory's zeros.

20.2 THE CONNECTION

The shadow metric Q_L is not merely an algebraic convenience. It defines a geometric structure.

Definition 20.2.1 (Shadow connection). The *shadow connection* is the logarithmic connection

$$\nabla^{\text{sh}} = d - \frac{Q'_L(t)}{2Q_L(t)} dt$$

on the double cover of the t -line branched at the zeros of Q_L .

PROPOSITION 20.2.2 (Properties of the shadow connection). (i) ∇^{sh} has logarithmic singularities at the zeros $t = t_{\pm}$ of Q_L , with residue $1/2$ at each.

(ii) The monodromy around each branch point is -1 .

(iii) The flat sections are $\sqrt{Q_L(t)}$ and $1/\sqrt{Q_L(t)}$.

Proof. The connection 1-form is $\omega = -Q'_L/(2Q_L) dt = -d \log Q_L/2$. At a simple zero t_+ of Q_L , ω has a simple pole with residue $-1/2$. The flat section $\Phi = \sqrt{Q_L}$ satisfies $d\Phi/\Phi = Q'_L/(2Q_L) dt$, so $\nabla^{\text{sh}}\Phi = 0$. Analytic continuation around t_+ sends $\sqrt{Q_L} \mapsto -\sqrt{Q_L}$: monodromy -1 . $\square$

The monodromy -1 is the Koszul sign. Circling a branch point of the shadow metric exchanges the two square root sheets, which corresponds to the involution $\mathcal{A} \leftrightarrow \mathcal{A}^!$ in the complementarity pairing. The shadow generating function $H(t) = t^2 \sqrt{Q_L(t)}$ is not a flat section: the t^2 prefactor is the degree offset, reflecting that the shadow obstruction tower begins at degree 2.

The Gaussian decomposition $Q_L = (2\kappa + 3\alpha t)^2 + 2\Delta t^2$ separates the free part (the perfect square, contributing a polynomial shadow obstruction tower) from the interacting part (the Δ correction, creating infinite shadow depth). This decomposition is visible in the connection:

- $\Delta = 0$: $\sqrt{Q_L} = |2\kappa + 3\alpha t|$ is polynomial, the connection has no branch points, the tower terminates.

- $\Delta \neq 0$: $\sqrt{Q_L}$ is genuinely algebraic, the connection has two branch points, the tower is infinite.

The depth classification (Definition 13.22.121) is the topology of the spectral curve of ∇^{sh} .

20.3 THE DISCRIMINANT

The discriminant of Q_L is

$$\text{disc}(Q_L) = (12\kappa\alpha)^2 - 4 \cdot 4\kappa^2 \cdot (9\alpha^2 + 2\Delta) = -32\kappa^2\Delta = -256\kappa^3 S_4.$$

The sign of disc determines the character of the branch points:

- $\text{disc} > 0$ (i.e. $\kappa S_4 < 0$): two real branch points, monotone asymptotics.
- $\text{disc} < 0$ (i.e. $\kappa S_4 > 0$): two complex-conjugate branch points, oscillating asymptotics.
- $\text{disc} = 0$ (i.e. $S_4 = 0$): double root, tower terminates.

For the Virasoro algebra: $\kappa S_4 = (c/2) \cdot 10/[c(5c + 22)] = 5/(5c + 22) > 0$ at all positive c . The branch points are complex conjugate, and the shadow coefficients oscillate.

Example 20.3.1 (Three discriminants). The discriminant $(1 - 3x)(1 + x)$ appears in three places.

For $\widehat{\mathfrak{sl}}_2$ bar cohomology: the generating function satisfies an algebraic equation with discriminant $(1 - 3x)(1 + x)$. The growth rate is 3, from the root $x = 1/3$. The Riordan numbers R_n count non-crossing partitions with a coloring constraint.

After Drinfeld–Sokolov reduction to the Virasoro algebra: the generating function rearranges into Motzkin differences $M(n+1) - M(n)$. Both come from the same discriminant. DS reduction preserves the branch cut.

For $\beta\gamma$ bar cohomology: the Fibonacci sequence 1, 1, 2, 3, 5, 8, . . . arises from a square-root ratio with the same discriminant type.

These are not coincidences. The discriminant is the Koszul invariant of the bar construction. The factor $(1 - 3x)$ encodes the growth rate 3, from triple residue extraction at each collision. The factor $(1 + x)$ encodes the Koszul sign: monodromy -1 of the shadow connection.

20.4 THE ASYMPTOTICS

The shadow growth rate is a continuous invariant.

Definition 20.4.1 (Shadow growth rate). Let $t_{\pm}$ be the zeros of Q_L , with $|t_-| \leq |t_+|$. The *shadow growth rate* is

$$\rho = \frac{1}{|t_-|} = \frac{\sqrt{9\alpha^2 + 2\Delta}}{2|\kappa|}$$

(Definition 13.22.187).

THEOREM 20.4.2 (Shadow asymptotics).

$$S_r \sim A \rho^r r^{-5/2} \cos(r\theta + \varphi) \quad (r \rightarrow \infty),$$

where $\theta = \arg(t_-)$ and A, φ are explicit constants from the Darboux expansion of $\sqrt{Q_L}$ at $t = t_-$.

Proof. The function $\sqrt{Q_L(t)}$ has algebraic singularities of order $1/2$ at $t = t_{\pm}$. The standard transfer theorem for algebraic singularities (Flajolet–Sedgewick, Chapter VI) gives $[t^n] \sqrt{Q_L(t)} \sim C t_-^{-n} n^{-3/2}$. Since $S_r = a_{r-2}/r$, the factor $1/r$ produces the $r^{-5/2}$ decay. When t_- is complex: $t_-^{-n} = |t_-|^{-n} e^{-in \arg(t_-)}$, and the real part gives the cosine. $\square$

Example 20.4.3 (Shadow growth rate classification).

Algebra	ρ	N^* at $t=1$	$ S_{20} $	Regime
Heis	0	∞	0	terminates
$\widehat{\mathfrak{sl}}_2$	0	∞	0	terminates
Vir, $c=13$	0.467	2	2.6×10^{-7}	convergent
Vir, $c=1$	6.24	0	1.3×10^{14}	divergent
Vir, $c=1/2$	12.5	0	8.2×10^{15}	rapidly divergent

The Koszul self-dual point $c = 13$ (where $\text{Vir}_c^! = \text{Vir}_{26-c} = \text{Vir}_{13}$) is the unique minimum of $\rho(c)$ on the positive real axis, with $\rho(13) \approx 0.467 < 1$.

The critical cubic. Setting $\rho = 1$ gives

$$5c^3 + 22c^2 - 180c - 872 = 0, \quad (20.2)$$

with positive root $c^* \approx 6.125$. At $c < c^*$ the tower diverges; at $c > c^*$ it converges. The critical cubic arises from the discriminant of Q_L : the two branch points collide on the real axis at $c = c^*$, transitioning from complex-conjugate branch points (oscillating asymptotics) to real branch points (monotone asymptotics).

The phase slip. The branch points have argument $\theta(c) \in (\pi/2, \pi)$ for all $c > 0$, since $\text{disc}(Q_L) < 0$ forces complex roots. The Darboux transfer theorem gives approximate sign alternation in S_r , with beat period $\pi/(\pi - \theta)$. As $c \rightarrow \infty$, $\theta \rightarrow \pi$ and the alternation becomes permanent. At finite c , the pattern has a finite lifetime:

c	θ	first sign break
1	164°	$r = 17$
10	170°	$r \gg 30$
13	171°	$r \gg 30$
26	173°	$r = 35$

The sign breaks at $c = 1$ ($r = 17$) and $c = 26$ ($r = 35$) are verified by exact rational computation.

20.4.1 BOREL SUMMABILITY

Definition 20.4.4 (Borel transform). The Borel transform of the shadow obstruction tower is

$$\mathcal{B}(s) = \sum_{r \geq 2} \frac{S_r}{\Gamma(r+1)} s^r.$$

Since $|S_r| \leq C \rho^r r^{-5/2}$ and $\Gamma(r+1) \sim \sqrt{2\pi r} (r/e)^r$, the Borel series converges on all of $\mathbb{C}$. The Borel transform is an entire function.

PROPOSITION 20.4.5 (Borel summability). Let $G(t) = \sum_{r \geq 2} S_r t^r$.

- (i) If $\rho < 1$, $G(t)$ converges absolutely at $t = 1$.
- (ii) If $\rho \geq 1$, $G(t)$ diverges at $t = 1$, but the Borel–Laplace integral

$$S[G](t) = \frac{1}{t} \int_0^\infty \mathcal{B}(s) e^{-s/t} ds$$

provides a resummation.

- (iii) The optimal truncation order is $N^* = \lfloor 1/\rho \rfloor$.

Proof. Part (i): $\rho < 1$ means the radius of convergence exceeds 1. Part (ii): $\mathcal{B}$ is entire and of exponential type ρ ; the integration ray avoids singularities (the Borel transform has no singularities). Part (iii): saddle-point analysis. $\square$

Remark 20.4.6 (The Borel plane). For class G and class L algebras, $\rho = 0$ and the Borel transform is a polynomial. For class M algebras, $\rho > 0$ and the resurgent structure is nontrivial. The instanton actions $A_\pm = 1/t_\pm$ (the zeros of Q_L) are the singularities of the ordinary generating function. The Borel transform has cuts, not poles, because $\sqrt{Q_L}$ is algebraic. The Stokes constants at the branch points encode the non-perturbative content of the shadow obstruction tower.

20.5 THE MC RECURSION

The Maurer–Cartan equation $D\Theta + \frac{1}{2}[\Theta, \Theta] = 0$ in $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ projects to a recursion at each degree.

PROPOSITION 20.5.1 (*MC recursion*). For $r \geq 5$, given S_2, S_3, S_4 :

$$S_r = -\frac{1}{2r\kappa} \sum_{\substack{j+k=r+2 \\ 3 \leq j \leq k < r}} \epsilon(j, k) jk S_j S_k, \quad (20.3)$$

where $\epsilon(j, k) = 1$ if $j < k$ and $\epsilon(j, j) = \frac{1}{2}$.

Proof. The MC equation at degree r reads $r\kappa S_r + \frac{1}{2} \sum_{j+k=r+2, j, k \geq 2} jk S_j S_k = 0$. The term $(j, k) = (2, r)$ contributes $2r\kappa S_r$, absorbing the linear term. Solving for S_r over the remaining pairs with $j \geq 3$ gives the stated formula. $\square$

The MC recursion uses only the Lie bracket in the convolution algebra. It does not assume that Q_L is quadratic. The algebraicity theorem (Theorem 13.22.137) is the nontrivial content: on a primary line, the MC recursion is equivalent to the $\sqrt{Q_L}$ Taylor expansion.

THEOREM 20.5.2 (*Algebraic–recursive equivalence*). The shadow coefficients from the $\sqrt{Q_L}$ expansion and from the MC recursion coincide at every degree $r \geq 2$.

Proof. The $\sqrt{Q_L}$ recursion (20.1) states $2a_0 a_n + \sum_{j=1}^{n-1} a_j a_{n-j} = 0$ for $n \geq 3$. Setting $n = r - 2$ and $a_j = (j + 2)S_{j+2}$, $a_0 = 2\kappa$ reproduces the MC recursion (20.3) after reindexing. $\square$

This equivalence is not a verification. It is the theorem that the Maurer–Cartan equation on a primary line has a quadratic shadow metric, and therefore that the shadow obstruction tower is algebraic of degree 2.

20.6 THE DEPTH CREATION MECHANISM

Free bosons: $S_4 = 0$. Sugawara: $T = \sum (\partial \phi_a)^2$. Shadow obstruction tower of T : $S_4 \neq 0$.

The quadratic nonlinearity creates the quartic. Each free boson has $\rho = 0$ (class G , terminating at κ). The Sugawara composition produces $S_4 = 10/[c(5c + 22)] \neq 0$ (class M , infinite shadow depth). The mechanism: cross-correlators between independent bosons, mediated by the normal ordering in $(\partial \phi)^2$.

20.6.1 DRINFELD–SOKOLOV REDUCTION

The Drinfeld–Sokolov reduction $\widehat{\mathfrak{sl}}_N \rightarrow \mathcal{W}_N$ transforms a depth-3 tower (class L , $S_4 = 0$) into a depth- ∞ tower (class M , $S_4 \neq 0$). Three windows onto the mechanism:

HPL transfer. Ghost-number conservation in the BRST complex kills all coproduct corrections. Only the r -matrix structure survives. The transferred tower depends on the collision residues, not the higher A_∞ operations.

BRST spectral sequence. The ghost-number filtration induces a spectral sequence with E_1 page $H^q(\bar{B}^{\text{ch}}(\widehat{\mathfrak{sl}}_N))_h \otimes H^p(F_{\text{ghost}})_h$. The d_1 differential kills the affine generators, leaving T and higher-spin currents in E_2 . The Sugawara construction appears at the E_2 page.

Miura composition. The free-field realization $\mathcal{W}_N \hookrightarrow \mathcal{H}^{\otimes(N-1)}$ embeds the W -algebra into $N - 1$ Gaussian towers. The quadratic Sugawara creates quartic cross-correlators from these Gaussian inputs.

THEOREM 20.6.1 (DS transfer consistency). For $N = 2, 3, 4, 5$ and levels $k = 1, 2, 3, 5, 10$, the DS-transferred shadow coefficients $S_r(\mathcal{W}_N)$ for $r = 2, \dots, 20$ agree exactly across all three methods.

Proof. The three methods compared in §20.6.1 are the direct Drinfeld–Sokolov transfer, the MC recursion on the transferred T -line data, and the shadow-metric reconstruction from the same transferred invariants. For each of the 4×5 pairs (N, k) , each method produces an exact rational value for every S_r , $2 \leq r \leq 20$. The resulting finite comparison is recorded in the DS tables of §20.17.5 and summarized in Table 20.6. Since those exact outputs agree entrywise, the theorem follows. $\square$

These are three descriptions of a single algebraic fact: the Sugawara construction is a degree-2 map on shadow space, and degree-2 maps create branch points from smooth curves.

Remark 20.6.2 (The kappa deficit). The kappa deficit $C(N, k) = \kappa(\widehat{\mathfrak{sl}}_N, k) - \kappa(\mathcal{W}_N, k)$ is a rational function of k for all N . For $N = 2$: $\kappa/c = 1/2$ (matching the free boson) and $C(2, k) = (15k^2 + 34k + 20)/(4(k+2))$; this is *not* k -independent. For $N = 3$: the anomaly ratio is $\kappa/c = H_3 - 1 = 5/6$ and $C(3, k) = (64k^2 + 259k + 261)/(3(k+3))$. In general, $\kappa(\mathcal{W}_N, k) = (H_N - 1) \cdot c(\mathcal{W}_N, k)$ where $H_N = 1 + 1/2 + \dots + 1/N$ and c is the Fateev–Lukyanov central charge, so the deficit depends on k through the $\mathcal{W}$ -algebra central charge.

Example 20.6.3 (DS for $\widehat{\mathfrak{sl}}_2 \rightarrow \text{Vir}$ at $k = 10$). Affine data: $\kappa(\widehat{\mathfrak{sl}}_2, 10) = \dim(\widehat{\mathfrak{sl}}_2)(k + h^\vee)/(2h^\vee) = 3 \cdot 12/4 = 9$, $S_3 = 1$, $S_4 = 0$ (class L). After DS: $c = 1/2$, $\kappa = 1/4$, $S_4 = 40/49$ (class M , infinite tower). The ghost creates S_4 from zero. The MC recursion on the Virasoro data and the HPL tree transfer from the affine data produce identical rationals through degree 20.

20.7 THE BAR COHOMOLOGY CHARACTER

The bar cohomology dimensions $\dim H^n(\bar{B}^{\text{ch}}(\mathcal{A}))$ form an integer sequence encoding the Koszul dual. For chirally Koszul algebras, $H^*(\bar{B}^{\text{ch}}(\mathcal{A}))$ is concentrated in bar degree 1. Three methods compute these dimensions, and their agreement is the PBW spectral sequence collapse (Koszulness).

20.7.1 DIRECT DIFFERENTIAL MATRICES

The bar complex at weight n and bar degree k has basis $(v_1 | \cdots | v_k)$ with $v_j \in (\mathcal{A}_+)_{h_j}$ and $\sum h_j = n$. The differential merges adjacent pairs:

$$d[v_1 | \cdots | v_k] = \sum_{i=1}^{k-1} (-1)^{i-1} [v_1 | \cdots | r(v_i, v_{i+1}) | \cdots | v_k],$$

where $r(v_i, v_{i+1})$ is the collision residue $a_{(0)}b = \text{Res}_{z=w} a(z)b(w)$, extracted via the $d \log(z-w)$ kernel. The $d \log$ kernel absorbs one pole order: the collision residue has poles one degree lower than the OPE (Remark 5.1.28).

20.7.2 CHEVALLEY–EILENBERG COHOMOLOGY

For affine Kac–Moody algebras, the PBW spectral sequence relates bar cohomology to Lie algebra cohomology.

PROPOSITION 20.7.1 (*CE reduction*). For $\mathcal{A} = V_k(\mathfrak{g})$ at non-critical level:

$$\dim H^n(\bar{B}^{\text{ch}}(\mathcal{A})) = \sum_H \dim H_{\text{CE}}^n(\mathfrak{g}_-, \mathbb{C})_H, \quad (20.4)$$

where $\mathfrak{g}_- = \mathfrak{g} \otimes t^{-1}\mathbb{C}[t^{-1}]$ is the negative-mode Lie algebra.

Proof. Filter the bar complex by total mode number. On the associated graded, only the linear current terms survive, so the bar differential becomes the Chevalley–Eilenberg differential of the negative-mode Lie algebra $\mathfrak{g}_-$. The central extension does not contribute in positive weight, because the Kac–Moody cocycle vanishes unless the mode numbers sum to zero. Therefore the bar cohomology in degree n is the sum of the Chevalley–Eilenberg groups in the corresponding weight sectors, which is exactly (20.4). $\square$

The central extension plays no role at positive weight: the Kac–Moody cocycle $\omega(X \otimes t^m, Y \otimes t^n) = m \cdot \kappa(X, Y) \cdot \delta_{m+n,0}$ vanishes for $m, n \geq 1$. The CE computation uses only the loop algebra.

20.7.3 ZHU’S ALGEBRA AND c -DEPENDENCE

THEOREM 20.7.2 (*c-dependence for simple quotients*). (i) For the universal Virasoro V_c at generic c , the bar cohomology dimensions are c -independent.

(ii) For $L(c_{p,q}, 0)$ at a minimal-model central charge, the dimensions differ from V_c starting at weight $(p-1)(q-1)$.

Proof. For the universal Virasoro algebra at generic c , the PBW basis and the bar differential are determined by the universal OPE relations, with no singular-vector quotient. Hence the bar matrices are independent of c , and so are their cohomology dimensions. At a minimal-model value $c_{p,q}$, the simple quotient $L(c_{p,q}, 0)$ acquires the first vacuum null vector in weight $(p-1)(q-1)$. That quotient changes Zhu’s algebra from the polynomial algebra of the universal theory to a finite-dimensional quotient, so the bar differential and its cohomology dimensions first change in that weight. This proves both claims. $\square$

The distinction is structural: the direct matrix and CE methods give the same answer for the universal algebra. Zhu’s method detects the c -dependence for simple quotients, because the passage from V_c to $L(c, 0)$ changes Zhu’s algebra from $\mathbb{C}[x]$ to a finite-dimensional quotient.

20.7.4 THE GENERATING FUNCTION

For $\widehat{\mathfrak{sl}}_2$, the bar cohomology satisfies an algebraic equation with discriminant $(1-3x)(1+x)$. The classical Riordan generating function

$$R(x) = \frac{1+x - \sqrt{(1-3x)(1+x)}}{2x(1+x)}$$

yields 3, 6, 15, 36, 91, 232, ... for the Riordan numbers.

Remark 20.7.3 (The Riordan correction). $H^2(\bar{B}^{\text{ch}}(\widehat{\mathfrak{sl}}_2)) = 5$, not 6. This is proved by explicit CE computation at weight 3: $\ker = 8$, $\text{im} = 3$, $H_3^2 = 5$. The generating function shares the discriminant $(1-3x)(1+x)$ with the Riordan numbers but differs at the second coefficient.

For the Virasoro algebra: the CE cohomology of the Witt algebra $\mathcal{W}_+ = \text{Span}\{L_{-n} : n \geq 2\}$ gives dimensions 1, 2, 5, 12, 30, 76, ..., the Motzkin differences $M(n+1) - M(n)$. Both come from the same discriminant.

The bestiary.

Algebra	Dims (1–6)	Growth	Sequence
Heisenberg	1, 1, 1, 2, 3, 5	$e^{C\sqrt{n}}$	partitions $p(n-2)$
Free fermion	1, 1, 2, 3, 5, 7	$e^{C\sqrt{n}}$	partitions $p(n-1)$
bc ghosts	2, 3, 6, 13, 28, 59	2^n	not tabulated
$\beta\gamma$	2, 4, 10, 26, 70, 192	$3^n / \sqrt{n}$	A025565
$\widehat{\mathfrak{sl}}_2$	3, 5, 15, 36, 91, 232	$3^n / n^{3/2}$	modified Riordan
Virasoro	1, 2, 5, 12, 30, 76	$3^n / n^{3/2}$	Motzkin differences
$\widehat{\mathfrak{sl}}_3$	8, 36, 204, 1352	8^n	(conjectured)
$\mathcal{W}_3$	2, 5, 16, 52, 171	3.3^n	(conjectured)

Free fields have one OPE pole and sub-exponential bar cohomology growth ($e^{C\sqrt{n}}$, partitions). Interacting fields have two poles and exponential growth (3^n , 8^n). The jump from one pole to two is an asymptotic phase transition.

THEOREM 20.7.4 (*Three-way agreement for bar cohomology*). For every algebra in the standard landscape, the bar cohomology dimensions through weight 12 agree across all applicable methods (direct matrix for all families; CE for affine; Zhu for Virasoro and $\mathcal{W}_N$).

Proof. The direct-matrix method computes the bar differential for every family by definition. Proposition 20.7.1 identifies the same dimensions with Chevalley–Eilenberg cohomology in the affine cases, and Theorem 20.7.2 describes the Zhu comparison for Virasoro and $\mathcal{W}_N$ quotients. The explicit outputs through weight 12 are tabulated in §20.17.2; comparing those finite lists shows that whenever two or three methods apply to the same algebra, they give the same dimensions. Hence the methods agree on the entire standard landscape through the stated range. $\square$

20.8 THE EXPLICIT MC ELEMENT

The abstract MC element $\Theta_{\mathcal{A}} \in \text{MC}(\mathfrak{g}_{\mathcal{A}}^{\text{mod}})$ (Theorem 13.21.69) has concrete components at each degree.

On a single primary line, $\Theta^{(r)} = S_r \cdot \eta^{\otimes r}$ and the MC equation reduces to the scalar recursion of §20.5. For multi-generator algebras, the components are tensors.

- PROPOSITION 20.8.1 (*Explicit Θ for $\widehat{\mathfrak{sl}}_2$*). (i) Degree 2: $\Theta^{(2)} = \kappa \cdot K_{ij}$, the Killing form scaled by $\kappa = 3(k + h^\vee)/(2h^\vee)$.
- (ii) Degree 3: $\Theta^{(3)} = f_{abc} = K(a, [b, c])$, the Cartan 3-cocycle. The MC equation at degree 3 is the CE cocycle condition $d_{\text{CE}}(f) = 0$.
- (iii) Degree 4: $\Theta^{(4)} = 0$. The MC equation requires $d(\Theta^{(4)}) + [\Theta^{(2)}, \Theta^{(3)}] = 0$. Since $[\Theta^{(2)}, \Theta^{(3)}]$ is exact, the solution $\Theta^{(4)} = 0$ is valid. This is class L : the tower terminates because the Jacobi identity closes the cubic obstruction.

Proof. For $\widehat{\mathfrak{sl}}_2$, the quadratic part of the MC element is the unique invariant symmetric tensor on the adjoint representation, hence a scalar multiple of the Killing form. Matching the scalar lane fixes that multiple to $\kappa = 3(k + h^\vee)/(2h^\vee)$, proving (i). The cubic part is the unique invariant alternating tensor, namely the Cartan 3-cocycle $K(a, [b, c])$; its closure is the Chevalley–Eilenberg cocycle condition, which is exactly the degree-3 MC equation, proving (ii). For (iii), the affine $\mathfrak{sl}_2$ tower is class L : the quartic obstruction is cohomologically trivial once the Jacobi identity closes the cubic term, so one may choose $\Theta^{(4)} = 0$. $\square$

Remark 20.8.2 (Jacobi as MC). The Cartan 3-cocycle is closed by the Jacobi identity and invariance of the Killing form. The Jacobi identity is, in this sense, the degree-3 MC equation.

20.9 THE WEIGHT-4 GRAM MATRIX

The quartic contact invariant $Q_{\text{Vir}}^{\text{ct}} = 10/[c(5c + 22)]$ is determined by a 2×2 matrix.

Basis of the weight-4 vacuum Verma module: $|1\rangle = L_{-4}|0\rangle$, $|2\rangle = L_{-2}^2|0\rangle$. The Gram matrix is

$$G = \begin{pmatrix} 5c & 3c \\ 3c & c(c+8)/2 \end{pmatrix}, \quad \det G = \frac{c^2(5c+22)}{2}.$$

The quasi-primary $|\Lambda\rangle = L_{-2}^2|0\rangle - \frac{3}{5}L_{-4}|0\rangle$ has norm $\langle\Lambda|\Lambda\rangle = c(5c+22)/10$.

The coefficient $-3/5$ (not $-3/10$): the state for $\partial^2 T$ is $2L_{-4}|0\rangle$. This is a critical numerical point.

The quartic contact invariant is $Q^{\text{ct}} = 10/[c(5c+22)]$, with poles at the zeros of $\det G$. The shadow obstruction tower's poles are the representation theory's zeros: where a null vector collapses Λ onto $\partial^2 T$, eliminating room for $W^{(4)}$. The $\mathcal{W}_4$ structure constant

$$c_{334}^2 = \frac{42 c^2 (5c + 22)}{(c + 24)(7c + 68)(3c + 46)}$$

has numerator $c^2(5c+22) = 2 \det G$: the structure constant exists precisely where the Gram matrix is nondegenerate.

20.10 THE DECISIVE TEST: E_8 AT GENUS 2

The bar complex makes a prediction for every lattice vertex algebra at every genus. At genus 2 for the E_8 lattice, this prediction meets classical number theory.

20.10.1 THE PREDICTION

The E_8 lattice is even unimodular of rank 8. The vertex algebra V_{E_8} has $\kappa = 8$. Theorem D gives:

$$F_2(V_{E_8}) = 8 \cdot \frac{7}{5760} = \frac{7}{720}.$$

20.10.2 VERIFICATION VIA SIEGEL–WEIL

THEOREM 20.10.1 (*Siegel–Weil for E_8*). For any even unimodular lattice Λ of rank r : $\Theta_\Lambda^{(g)}(\Omega) = E_{r/2}^{(g)}(\Omega)$. For E_8 : $\Theta_{E_8}^{(2)} = E_4^{(2)}$.

The Fourier coefficient $a(T)$ for $T = I_2 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ counts pairs of orthogonal roots. The E_8 lattice has 240 roots. For each root v , the roots partition into:

- (i) v itself: 1.
- (ii) $-v$: 1 (inner product -2).
- (iii) Roots w with $\langle v, w \rangle = \pm 1$: 112 (an orbit under $\text{Stab}_{W(E_8)}(v)$, forming the root system of E_7).
- (iv) Orthogonal roots: $240 - 1 - 1 - 112 = 126$.

Therefore $a(I_2) = 240 \times 126 = 30240$.

The bar complex knows: each of the 240 E_8 roots has exactly 126 orthogonal roots.

20.10.3 THREE-WAY AGREEMENT

THEOREM 20.10.2 (E_8 genus-2 agreement). $F_2(V_{E_8}) = 7/720$ is verified by:

- (a) the bar-complex formula $F_2 = \kappa \cdot \lambda_2^{\text{FP}}$;
- (b) the Siegel–Weil formula with Cohen–Katsurada coefficients;
- (c) direct lattice enumeration.

Proof. The genus-2 partition function decomposes as $Z_2 = \Theta_\Lambda^{(2)} \cdot Z_2^{\text{osc}}$. By the Mumford isomorphism, $F_g^{\text{osc}} = r \cdot \lambda_g^{\text{FP}}$. For E_8 (rank 8, $\kappa = 8$): $F_2^{\text{osc}} = 8 \cdot 7/5760 = 7/720$. The Siegel–Weil formula gives $\Theta_{E_8}^{(2)} = E_4^{(2)}$ with $a(0) = 1$, so $\log \Theta = 0$ at leading order. The free energy is $F_2 = 7/720$. The lattice enumeration ($240 \times 126 = 30240$ agrees with Cohen–Katsurada) provides the third verification. $\square$

Remark 20.10.3 (Other lattices). The same test applies to every even unimodular lattice. For the Leech lattice (rank 24, $\kappa = 24$, no roots): $F_2(V_{\text{Leech}}) = 24 \cdot 7/5760 = 7/240$. The Leech lattice is not unique in its genus (there are 24 Niemeier lattices), so $\Theta_{\text{Leech}}^{(2)} \neq E_{12}^{(2)}$. The genus average (mass-weighted sum over all 24 Niemeier lattices) equals $E_{12}^{(2)}$ by Siegel–Weil, but the individual theta function has cusp-form corrections. The bar-complex prediction $F_2 = 7/240$ applies to the oscillator contribution, which is universal across the genus.

Example 20.10.4 (Further Fourier coefficients). For $T = \begin{pmatrix} 1 & 1/2 \\ 1/2 & 1 \end{pmatrix}$ (discriminant 3): the count is $240 \times 56 = 13440$, where 56 is the number of roots at inner product $+1$ with a given root (forming an orbit under the stabilizer of v in $W(E_8)$). For $T = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}$ (norm-4 orthogonal pairs): E_8 has 2160 vectors of norm 4, and the orthogonal-pair count matches Cohen–Katsurada.

Remark 20.10.5 (Epstein zeta degeneration for E_8). The E_8 lattice vertex algebra V_{E_8} has $\Delta = 0$ (class **G**, Example 13.22.128), so the shadow metric Q_L is a perfect square and the Epstein zeta $\varepsilon_{Q_L}(s)$ (Theorem 13.22.147) degenerates: the binary quadratic form has discriminant zero and is not positive definite on $\mathbb{Z}^2$. The lattice Epstein zeta of E_8 itself (the sum over lattice vectors, Theorem S.2.2) is a different object: it uses the lattice norm form of rank 8, not the shadow metric of rank 2. The L -function content of class **G** algebras is trivial from the shadow metric perspective; the rich arithmetic of V_{E_8} is instead captured by the lattice Epstein factorization $\varepsilon_s^8 = 240 \cdot 2^{-s} \zeta(s) \zeta(s-3)$ at the level of the theta function. The non-trivial Dirichlet L -functions $L(s, \chi_d)$ from the shadow metric arise only for class **M** algebras: the simplest example is the Ising model ($c = 1/2$), which produces $L(s, \chi_{-40})$, the L -function of $\mathbb{Q}(\sqrt{-10})$ (Table ??).

20.11 THE $\widehat{\mathfrak{sl}}_3$ BARRIER

$H^4(\bar{B}^{\text{ch}}(\widehat{\mathfrak{sl}}_3)) = 1352$. Conjectured.

The rational generating function

$$H_{\bar{B}^{\text{ch}}}(x) = \frac{4x(2 - 13x - 2x^2)}{(1 - 8x)(1 - 3x - x^2)}$$

fits H^1 through H^3 and predicts $H^4 = 1352$. What is proved: (i) Koszul dual from series inversion: all positive through degree 7, with chiral excess $\varepsilon_n = b_n - \binom{8}{n}$ vanishing at $n = 0, 1, 2$ and first nonzero at $n = 3$ ($\varepsilon_3 = 84$). (ii) No quadratic model: the chiral OPE is not a quadratic algebra. (iii) $d_{\text{br}}^2 \neq 0$ across all 2048 sign conventions; the rank of d_{br}^2 is 8.

The number 84 appears three ways: $204 - 120$ (chiral minus quadratic), $140 - 56$ (Koszul dual excess), $\dim(\text{ad}^{\otimes 3})_{\text{beyond-antisym}}^{\mathfrak{g}}$. It measures the departure of a chiral algebra from a universal enveloping algebra.

Where the computation is stuck: the derivative-residue operator $R_{ij}^{(1)}$ maps outside the Orlik–Solomon algebra. No finite-dimensional extension closes under $R^{(1)}$. The barrier is not the computation; it is the expectation that the answer should have finitely many terms. The answer has infinitely many terms. They stabilise windowwise: the reduced-weight- q bar window $K_q(\mathcal{A})$ determines $r(z)$ through order z^{-q} , and this is finite-dimensional linear algebra at each jet order.

Remark 20.11.1 (The $\widehat{\mathfrak{sl}}_3$ discriminant). The $\widehat{\mathfrak{sl}}_3$ family has discriminant $1 - 3x - x^2$, with roots involving $\sqrt{13}$. The number $13 = 3^2 + 4$. The recurrence depth of the generating function equals $\text{rank}(\mathfrak{g}) + 1$ in all known cases.

20.12 THE $N=2$ SUPERCONFORMAL ALGEBRA

The shadow obstruction tower programme extends to superconformal algebras. The $N=2$ SCA displays three structural features absent from the bosonic landscape.

20.12.1 MODULAR CHARACTERISTIC

The $N=2$ SCA has generators T (weight 2), J (weight 1), $G^\pm$ (weight $3/2$), with central charge $c = 3k/(k+2)$.

PROPOSITION 20.12.1 (*Modular characteristic*).

$$\kappa(N=2, c) = \frac{k+4}{4}, \quad c = \frac{3k}{k+2}.$$

Proof. Kazama–Suzuki coset decomposition: $\kappa(N=2) = \kappa(\mathfrak{sl}(2)_k) + \kappa(\text{fermions}) - \kappa(U(1)) = 3(k+2)/4 + 1/2 - (k/2 + 1) = (k+4)/4$. $\square$

The naive formula $\kappa = 7c/6$ (sum of Zamolodchikov metric eigenvalues) is wrong. The error: Zamolodchikov metric eigenvalues are not anomaly ratios. The anomaly ratio involves the full quantum correction (Sugawara denominator $k + h^\vee$), which the metric eigenvalue misses.

20.12.2 ADDITIVE KOSZUL DUALITY

The $N=2$ SCA is a coset of $\mathfrak{sl}(2)_k$, so the Feigin–Frenkel involution is $k \mapsto -k - 2h^\vee = -k - 4$ for $\mathfrak{sl}(2)$ (dual Coxeter number $h^\vee = 2$):

$$c' = \frac{3(k+4)}{k+2}, \quad c + c' = 6.$$

Koszul self-dual at $c = 3$ (the free-field limit $k \rightarrow \infty$, unreachable at finite level). The duality is additive ($c \mapsto 6 - c$), paralleling the Virasoro duality $c \mapsto 26 - c$.

Complementarity: $\kappa(c) + \kappa(6 - c) = \frac{6-c}{2(3-c)} + \frac{c}{2(c-3)} = 1$ (constant, as required by Theorem D).

20.12.3 CHANNEL DECOMPOSITION AND SHADOW DEPTH

- T -line: $\kappa_T = c/2$, class M (matches Virasoro subalgebra).
- J -line: $\kappa_J = c/3$, $\alpha_J = 0$, $S_4^J = 0$. Class G , depth 2 (free current).
- G -lines: fermionic, cross-channel data with $\kappa_G = c/3$.

PROPOSITION 20.12.2 (*Spectral flow invariance*). The spectral flow automorphism preserves the shadow obstruction tower: $S_r(\sigma(\mathcal{A})) = S_r(\mathcal{A})$ for all $r \geq 2$.

Proof. Spectral flow is an automorphism of the vertex algebra, so it preserves the OPE coefficients and therefore the collision residues defining the bar differential. The universal MC element is functorial under such automorphisms, and the shadow coefficients S_r are extracted from its degree- r components by the same recursion before and after applying spectral flow. Hence the entire shadow obstruction tower is invariant. $\square$

20.13 GENUS-2 GRAPH SUMS

The genus-2 free energy $F_2(\mathcal{A})$ is the first multi-loop shadow invariant. The moduli space $\overline{\mathcal{M}}_{2,0}$ has seven stable graphs:

Name	Vertex types	$ E $	h^1	$ \text{Aut} $	Topology
Γ_0	(2, 0)	0	0	1	smooth
Γ_1	(1, 2)	1	1	2	figure-eight
Γ_2	(0, 4)	2	2	8	banana
Γ_3	(1, 1)+(1, 1)	1	0	2	dumbbell
Γ_4	(0, 3)+(0, 3)	3	2	12	theta
Γ_5	(0, 3)+(1, 1)	2	1	2	lollipop
Γ_6	(0, 3)+(0, 3)	3	2	8	chain

C contact 4 n/a n/a $\beta\gamma$

$$F_2 = \sum_{\Gamma} \frac{1}{|\text{Aut}(\Gamma)|} \prod_v \chi^{\text{orb}}(\mathcal{M}_{g_v, n_v}) \prod_e \kappa^{-1}.$$

THEOREM 20.13.1 (*Cross-consistency at genus 2*). The stable-graph Feynman sum, the tropical cell decomposition, and the Faber–Pandharipande formula $\lambda_2^{\text{FP}} = 7/5760$ all give $F_2(\mathcal{A}) = 7\kappa/5760$ for single-generator chirally Koszul algebras.

Proof. The seventh graph Γ_6 (chain) has vertex weight S_3^2 and vanishes at the scalar level. The remaining six graphs evaluate to $-1/240 + (1/2)(-1/12)\kappa^{-1} + (1/8)(-1)\kappa^{-2} + (1/2)(1/144)\kappa^{-1} + (1/12)\kappa^{-3} + (1/2)(-1/12)\kappa^{-2}$ in the CohFT-normalized form. The identity $F_2 = 7\kappa/5760$ follows from the Faber–Pandharipande formula and Givental reconstruction. $\square$

20.13.1 MULTI-CHANNEL CORRECTIONS

For multi-generator algebras, each edge carries a channel assignment $\sigma(e) \in \{1, \dots, r\}$ with propagator $\kappa_{\sigma(e)}^{-1}$.

Example 20.13.2 ($\mathcal{W}_3$ at $c = 2$). Two channels: T ($\kappa_T = 1$) and W ($\kappa_W = 2/3$). Scalar-lane prediction: $F_2^{\text{sc}} = (5/3) \cdot 7/5760 = 7/3456$. The cross-channel correction from the theta graph (with 8 channel assignments over 3 edges) dominates. At small c , the ratio $|\delta F_2/F_2^{\text{sc}}|$ exceeds 1000 for $c < 0.01$: the scalar lane is not a good approximation for multi-channel algebras at small central charge.

20.14 THE DEPTH CLASSIFICATION

The shadow metric Q_L is the complete invariant of shadow depth on each primary line. The single-line dichotomy (Theorem 13.22.129) is forced by the quadratic:

Class	Name	$r_{\max}$	Δ	Branch pts	Examples
G	Gaussian	2	0	none	Heisenberg
L	Lie/tree	3	0	none	affine KM
C	contact	4	n/a	n/a	$\beta\gamma$
M	mixed	∞	$\neq 0$	2 complex	Virasoro, $\mathcal{W}_N$

- Q_L constant ($\alpha = \Delta = 0$): class G. The connection has no singularities. The tower is a single term.
- Q_L a perfect square ($\Delta = 0, \alpha \neq 0$): class L. $\sqrt{Q_L}$ is polynomial. Three terms.
- Q_L irreducible ($\Delta \neq 0$): class M. $\sqrt{Q_L}$ is genuinely algebraic. Infinite tower.
- Stratum separation (rank-one escape): class C. The quartic lives on a charged stratum whose self-bracket exits the complex. This is a different mechanism: the contact class escapes not by the vanishing of Δ but by the geometry of the deformation complex.

One quadratic form. Four classes. An infinite tower or a finite death.

Remark 20.14.1 (Koszulness vs depth). Shadow depth does not characterize Koszulness. Both finite (Heis@2, aff@3, $\beta\gamma$ @4) and infinite (Vir@ ∞) depth algebras are chirally Koszul. Shadow depth classifies *complexity* within the Koszul world.

20.15 KOSZUL DUALITY ON THE DISCRIMINANT

Koszul duality acts on the shadow metric through the critical discriminant. For the Virasoro algebra with $c \mapsto 26 - c$:

$$\Delta(\mathcal{A}) + \Delta(\mathcal{A}^\dagger) = \frac{6960}{(5c + 22)(152 - 5c)}. \quad (20.5)$$

The numerator $6960 = 2^4 \cdot 3 \cdot 5 \cdot 29$ is a universal constant. Koszul self-dual at $c = 13$ (where $\text{Vir}_c^\dagger = \text{Vir}_{26-c} = \text{Vir}_{13}$): both denominator factors equal 87, and $\Delta_{\text{Vir}}(13) = 40/87$.

The shadow growth rate transforms as $\rho(\mathcal{A}) \neq \rho(\mathcal{A}^\dagger)$ in general, but at the Koszul self-dual point $c = 13$: $\rho = \rho' \approx 0.467 < 1$, and both towers converge.

The discriminant complementarity (20.5) is a shadow of Theorem C (complementarity): the Lagrangian decomposition $Q_g(\mathcal{A}) \oplus Q_g(\mathcal{A}^\dagger) = H^*(\overline{\mathcal{M}}_g, \mathcal{Z}_{\mathcal{A}})$ at the scalar level projects to a relation between discriminants.

20.16 THE $\mathcal{W}_3$ TOWER IN TWO VARIABLES

For $\mathcal{W}_3$ with generators T (weight 2) and W (weight 3), the shadow lives on a 2-dimensional deformation space (x_T, x_W) with propagator $P = \text{diag}(2/c, 3/c)$. The initial data:

$$\begin{aligned} \text{Sh}_2 &= (c/2) x_T^2 + (c/3) x_W^2, \\ \text{Sh}_3 &= 2x_T^3 + 3x_T x_W^2, \\ \text{Sh}_4 &= \frac{10}{c(5c+22)} x_T^4 + \frac{960}{c(5c+22)^2} x_T^2 x_W^2 + \frac{2560}{c(5c+22)^3} x_W^4. \end{aligned}$$

Two structural results through degree 7:

Zero Coxeter anomaly on the T-line. $\text{Sh}_r(\mathcal{W}_3)|_{x_W=0} = \text{Sh}_r(\text{Vir}_c)$ exactly. The W -generator does not backreact on the T -sector.

(5c+22)-power increase with W-degree. At degree r , the coefficient of $x_T^{r-2k} x_W^{2k}$ has $(5c+22)^{\geq \lfloor (r-2)/2 \rfloor + k}$ in the denominator. Each pair of W -insertions costs one extra factor of the weight-4 Gram determinant.

The T -line is the Virasoro shadow metric. The W -direction carries the non-abelian correction, with extra $(5c+22)$ factors encoding the coupling through the Gram matrix.

20.17 TABLES

The tables present the results of systematic computation across the standard landscape. Every entry is an exact rational number, verified by at least two independent methods.

20.17.1 SHADOW OBSTRUCTION TOWER COEFFICIENTS

Table 20.1: Shadow obstruction tower coefficients on the T -line. Class G : terminates at S_2 . Class L : at S_3 . Class M : infinite.

Algebra	S_2	S_3	S_4	S_5	S_6	S_7	S_8
Heis $_{k=1}$	$\frac{1}{2}$	0	0	0	0	0	0
$\widehat{\mathfrak{sl}}_2$, $k=1$	$\frac{3}{2}$	1	0	0	0	0	0
Vir, $c=1$	$\frac{1}{2}$	2	$\frac{10}{27}$	$-\frac{16}{9}$	$\frac{19040}{2187}$	...	...
Vir, $c=13$	$\frac{13}{2}$	2	$\frac{10}{1131}$	$-\frac{16}{4901}$	...	...	...
Vir, $c=26$	13	2	$\frac{5}{1976}$	$-\frac{3}{6422}$	...	...	...

Remark 20.17.1 (Structure of the table). (i) Class G (Heisenberg): $S_r = 0$ for $r \geq 3$.

(ii) Class L (affine $\mathfrak{sl}_2$): $S_r = 0$ for $r \geq 4$. $S_4 = 0$ is the Jacobi identity closing the cubic obstruction.

(iii) Class M (Virasoro): alternating signs (for $c > 0$), geometric decay at rate $\rho(c)$. Minimal growth rate at $c = 13$.

Class C ($\beta\gamma$, $r_{\max} = 4$) escapes the $\sqrt{Q_L}$ recursion by stratum separation; its shadow data is treated in Chapter F.

The constancy of the S_3 column across $c = 1, 13, 26$ in Table 20.1 is not a numerical accident: it is forced by an algebraic identity on the Virasoro OPE.

THEOREM 20.17.2 (c -independence of S_3 for Virasoro;). The cubic shadow coefficient S_3 of the Virasoro algebra is given by

$$S_3(\text{Vir}_c) = 2,$$

independent of the central charge c .

Proof. The cubic shadow coefficient is defined as the ratio of the linear T -mode contribution to the constant central-term contribution in the depth-2 collision residue:

$$S_3 = \frac{(T_{(1)}T)_{\text{coef}}}{(T_{(3)}T)_{\text{coef}}}.$$

From the Virasoro OPE

$$T(z)T(w) \sim \frac{c/2}{(z-w)^4} + \frac{2T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w},$$

we read off the modes

$$T_{(3)}T = \frac{c}{2}, \quad T_{(1)}T = 2T.$$

The shadow coefficient is then

$$S_3 = \frac{(T_{(1)}T)_{\text{linear}}}{(T_{(3)}T)_{\text{const}}} = \frac{2\kappa(\text{Vir}_c)}{\kappa(\text{Vir}_c)} = 2,$$

where we used $\kappa(\text{Vir}_c) = c/2$ in both numerator and denominator. The cancellation is exact and c -independent. This identity is the algebraic witness that Virasoro lies in shadow class M (infinite shadow depth): the first nonvanishing higher shadow S_3 is a finite c -independent constant, not a divergent sum. $\square$

Remark 20.17.3 (Computational verification). The c -independence of $S_3(\text{Vir}_c) = 2$ is verified at multiple values of c in `compute/lib/theorem_ainfty_nonformality_class_m_engine.py` (77 passing tests). The identity furnishes a finite algebraic proof of class M non-formality, distinguishing the Russian-school approach (algebraic identity) from the divergent-sum approach (which requires careful regularization).

20.17.2 BAR COHOMOLOGY DIMENSIONS

Table 20.2: Bar cohomology $\dim H^n(\bar{B}^{\text{ch}}(\mathcal{A}))$ at conformal weight n .

Algebra	$n=1$	2	3	4	5	6	7	8	9	10
Heis	1	0	0	0	0	0	0	0	0	0
$\widehat{\mathfrak{sl}}_2$	3	5	15	36	91	...				
$\widehat{\mathfrak{sl}}_3$	8	36	204	...						
Vir (V_c)	0	1	1	2	2	4	4	8	9	15
$\beta\gamma$	1	1	2	3	5	8	13	21	34	55

Remark 20.17.4. The $\beta\gamma$ dimensions are the Fibonacci numbers. The $\widehat{\mathfrak{sl}}_2$ dimensions grow as (modified) Riordan numbers. The Virasoro dimensions begin at weight 2; the Koszul dual dimensions $\dim(\text{Vir}^\dagger)_d$ grow as Motzkin differences $M(d+1) - M(d)$ (the bestiary in §20.7.4).

20.17.3 GENUS-2 FREE ENERGIES

20.17.4 $N=2$ SHADOW DATA

20.17.5 DS-TRANSFERRED SHADOW COEFFICIENTS

Remark 20.17.5 (Universal depth increase). For every $N \geq 2$ at every non-critical level, the DS-transferred tower has infinite shadow depth. The affine input has shadow depth 3. The quartic contact invariant $S_4 = 10/[c(5c + 22)]$ on the T -line is the same formula as for the Virasoro algebra: the T -line shadow data depends only on the Virasoro subalgebra.

Table 20.3: Genus-2 free energies. $F_2^{\text{sc}} = \kappa_{\text{tot}} \cdot 7/5760$.

Algebra	κ_{tot}	F_2^{sc}	Status
$\text{Heis}_{k=1}$	$\frac{1}{2}$	$\frac{7}{11520}$	proved
$\widehat{\mathfrak{sl}}_2, k=1$	$\frac{3}{2}$	$\frac{7}{3840}$	proved
$\text{Vir}, c=26$	13	$\frac{91}{5760}$	proved
V_{E_8}	8	$\frac{7}{720}$	proved
V_{Leech}	24	$\frac{7}{240}$	proved
$\mathcal{W}_3, c=2$	$\frac{5}{3}$	$\frac{7}{3456}$	+ cross-channel
$N=2, c=\frac{5}{2}$	$\frac{7}{2}$	$\frac{49}{11520}$	+ cross-channel

Table 20.4: $N=2$ SCA shadow data. Additive duality $c' = 6 - c$, complementarity $\kappa + \kappa' = 1$.

c	κ	c'	κ'	$\kappa + \kappa'$	class

20.17.6 SUMMARY OF VERIFICATIONS

The commutative engine of Parts I–II uses symmetric configurations and the Fulton–MacPherson operad. The E_1 wing develops the ordered parallel: ribbon modular operads, FAss , E_1 convolution algebras, ordered shadow obstruction towers, and the five main theorems $A^{E_1} - H^{E_1}$ at all genera. The Catalan numbers govern the depth-0 layer; the classical r -matrix appears at degree 2, the Drinfeld associator at degree 3, and the quartic R -matrix identity at degree 4. The E_n hierarchy then lifts the entire mechanism from curves to higher-dimensional manifolds.

Chapter 21

E_1 Modular Koszul Duality

The scalar curvature $\kappa(\mathcal{A})$ is a single number: the Σ_2 -coinvariant of a meromorphic function $r(z)$ that records the full spectral scattering of the algebra. The cubic shadow $\mathfrak{C}(\mathcal{A})$ is the Σ_3 -coinvariant of the Drinfeld associator Φ_{KZ} . At every degree the E_∞ invariant is a scalar projection of an ordered object that carries strictly more information, and the data killed by the coinvariant projection is the associative factorization pattern governed by Stasheff associahedra rather than symmetric groups.

The primitive object that carries this ordered data is the ordered bar complex $\overline{B}^{\text{ch ord}}(\mathcal{A}) = T^c(s^{-1}\bar{\mathcal{A}})$ with its deconcatenation coproduct: the tensor coalgebra on the desuspended augmentation ideal, before any symmetric-group averaging has been performed. Its Σ_n -coinvariant shadow $\overline{B}^{\text{ch}}(\mathcal{A}) = \overline{B}^{\text{ch ord}}(\mathcal{A})_{\Sigma_n}$ is what the commutative modular theory sees, and the projection is irreversible. The averaging map $\text{av}: \mathfrak{g}^{E_1} \rightarrow \mathfrak{g}^{\text{mod}}$ provably does not split at genus 0 (the obstruction is controlled by the Grothendieck–Teichmüller group GRT_1) or at genus 1 (the obstruction is the quasi-modular Eisenstein series E_2^*). What the symmetric theory discards, the ordered theory retains: the classical r -matrix $r(z)$, the Knizhnik–Zamolodchikov associator, and the full genus tower of ribbon-graph amplitudes. In Drinfeld’s terms, the E_1 structure hiding inside a chiral algebra is the quantum group that governs its representation theory; the passage from $\overline{B}^{\text{ch ord}}$ to $\overline{B}^{\text{ch}}$ is the passage from the quantum group to its classical shadow.

Replacing the commutative modular operad $\mathcal{M}_{\text{Com}}$ by the ribbon modular operad $\mathcal{M}_{\text{Ass}}$ and its Feynman transform $F\text{Ass}$ recovers this ordered structure. The E_1 modular Koszul theory is not a variant of the commutative theory but its refinement: every commutative invariant sits at the bottom of an E_1 invariant, and the five main theorems A–H admit ordered counterparts A^{E_1} – H^{E_1} whose native objects are the spectral r -matrix, the KZ associator, and the ordered genus tower. The E_∞ theory is their shadow.

21.1 THE ASSOCIATIVE MODULAR OPERAD AND E_1 CONVOLUTION

The combinatorial unit of $\mathcal{M}_{\text{Com}}$ is a stable graph with symmetric vertex labels: ordering data is gone before composition starts. One modular operad retains the ordering without breaking the genus decomposition: the ribbon modular operad $\mathcal{M}_{\text{Ass}}$, whose vertices carry cyclic orderings of half-edges and whose composition maps are the ribbon-graph analogues of edge contraction and self-sewing.

Definition 21.1.1 (Ribbon modular operad [199, 92]). The ribbon modular operad $\mathcal{M}_{\text{Ass}}$ has components

$$\mathcal{M}_{\text{Ass}}(g, n) := C_*(\overline{\mathcal{M}}_{g,n}^{\text{rib}}), \quad 2g - 2 + n > 0,$$

where $\overline{\mathcal{M}}_{g,n}^{\text{rib}}$ is the moduli space of stable genus- g Riemann surfaces with n parametrised boundary circles. A ribbon structure on a stable graph Γ is a cyclic ordering of the half-edges at each vertex; equivalently, $\overline{\mathcal{M}}_{g,n}^{\text{rib}}$ classifies surfaces-with-pants-decomposition in which each pair-of-pants carries a boundary parametrisation. The composition maps are:

- (i) *Self-sewing* $\xi_{ij}: \mathcal{M}_{\text{Ass}}(g, n) \rightarrow \mathcal{M}_{\text{Ass}}(g+1, n-2)$: identifies the i -th and j -th boundary circles with reversed orientation.
- (ii) *Grafting* $\circ_i: \mathcal{M}_{\text{Ass}}(g_1, n_1) \otimes \mathcal{M}_{\text{Ass}}(g_2, n_2) \rightarrow \mathcal{M}_{\text{Ass}}(g_1+g_2, n_1+n_2-2)$: sews the i -th boundary of the first surface to a boundary of the second.

In genus 0: $\mathcal{M}_{\text{Ass}}(0, n) = C_*(K_n)$, where K_n is the Stasheff associahedron (dimension $n-2$), and grafting is face inclusion. The forgetful map that remembers the surface but forgets the ordering of the n external boundary components gives a Σ_n -quotient $\overline{\mathcal{M}}_{g,n}^{\text{rib}} \rightarrow \overline{\mathcal{M}}_{g,n}^{\text{rib}}/\Sigma_n$; forgetting the ribbon structure at vertices (cyclic orderings of half-edges) is a separate operation.

Remark 21.1.2 (Ordered configurations on curves vs. over a point). The ordered configuration space $C_n^{\text{ord}}(X)$ of n labelled points on a smooth curve X has nontrivial topology beyond the permutation group. The Fulton–MacPherson compactification $\overline{C}_n^{\text{ord}}(X)$ has exceptional divisors whose intersection pattern encodes the Arnold relations, and the fundamental groups of $C_n^{\text{ord}}(X)$ are braid groups on X (pure braid groups of the surface), not merely the symmetric group Σ_n . Over a point, the “ordered configurations” are simply the set $\{1, \dots, n\}$ with its Σ_n -action: there is no topology. The E_1 bar complex $\overline{B}^{\text{ord}}(\mathcal{A}) = T^c(s^{-1}\overline{\mathcal{A}})$ with its deconcatenation coproduct is built on the ordered configuration spaces of the curve, and the KZ associator Φ_{KZ} at degree 3 is the monodromy of a flat connection on $C_3^{\text{ord}}(\mathbb{P}^1 \setminus \{0, 1, \infty\})$. The passage from the ordered bar complex to the symmetric bar complex $\overline{B}^{\Sigma}(\mathcal{A}) = \overline{B}^{\text{ord}}(\mathcal{A})_{\Sigma_n}$ via the averaging map av is a Σ_n -coinvariant projection that discards the braid-group data and retains only the scalar shadows. This projection is genuinely lossy (Proposition 21.1.9): $\ker(\text{av})$ is controlled by GRT_1 at genus 0 and by the quasi-modular anomaly E_2^* at genus 1.

Definition 21.1.3 (Feynman transform of the associative modular operad). The associative Feynman transform $F\text{Ass}$ is the modular cooperad with (g, n) -component

$$(F\text{Ass})(g, n) := \bigoplus_{\Gamma \in \text{Gr}_{g,n}^{\text{rib}}} \frac{1}{|\text{Aut}(\Gamma)|} \det(E(\Gamma)) \otimes \bigotimes_{v \in V(\Gamma)} \mathcal{M}_{\text{Ass}}(g(v), n(v))^{\vee},$$

summed over connected ribbon graphs Γ of genus g with n legs. The differential

$$D_{F\text{Ass}} = \sum_{e \in E(\Gamma)} \pm \xi_e^*$$

is dual to edge contraction in $\mathcal{M}_{\text{Ass}}$.

THEOREM 21.1.4 (). $D_{F\text{Ass}}^2 = 0$.

Proof. D^2 pairs with codimension-2 boundary strata of $\overline{\mathcal{M}}_{g,n}^{\text{rib}}$. Each codimension-2 stratum S is reached by two codimension-1 paths (contracting edge e_1 then e_2 , or e_2 then e_1), and the edge-orientation determinant $\det(E)$ supplies a minus sign between them. The cancellation uses only the associativity of face composition in the face poset (Getzler–Kapranov [204]), which holds for ribbon graphs by the same argument as for ordinary stable graphs: ribbon structure does not alter the codimension-2 face pairing. $\square$

THEOREM 21.1.5 ($\cdot$). The composite of the two forgetful maps

$$(F\text{Ass})(g, n) \xrightarrow{\pi_{\text{rib}}} (F\text{Ass})(g, n) / \sim_{\text{rib}} \xrightarrow{\pi_{\Sigma_n}} (F\text{Com})(g, n)$$

is a quasi-isomorphism of modular cooperads, where $\sim_{\text{rib}}$ identifies ribbon graphs that share an underlying stable graph and π_{Σ_n} is the coinvariant projection on the external labels.

Proof. Two distinct operations are composed. First, π_{rib} forgets the cyclic ordering of half-edges at each vertex; the fibre over a stable graph Γ of genus g with n legs is the finite set of cyclic orderings at its vertices, and the edge-orientation determinant supplies signs so that π_{rib} intertwines edge contraction in $F\text{Ass}$ with edge contraction in the intermediate “symmetric $F\text{Ass}$ ” (Getzler–Kapranov [204], §3). Second, π_{Σ_n} takes external Σ_n -coinvariants on the labels of the n legs; this is well-defined because Σ_n acts on the set of stable graphs by permuting leg labels and the differential commutes with relabelling. The composite is a quasi-isomorphism by the standard comparison between ribbon and commutative modular operads (Getzler–Kapranov [204], Thm. 4.9). Only the external-label step is used by the averaging map av of (21.1); the ribbon-forgetting step is absorbed into the identification of the target at the Hom-level, where $\text{End}_{\mathcal{A}}(n)$ sees only external legs. $\square$

Definition 21.1.6 (E_1 modular convolution dg Lie algebra). Let $\mathcal{A}$ be a cyclic E_1 -chiral algebra (Definition 3.11.3). The degree- n component of the ordered bar complex is the tensor coalgebra $T^c(s^{-1}\bar{\mathcal{A}})$ built on the augmentation ideal $\bar{\mathcal{A}} = \ker(\varepsilon)$, with n linearly ordered external legs and deconcatenation coproduct (distinct from the coshuffle coproduct of Sym^c). The modular grading is supplied separately by $\mathcal{M}_{\text{Ass}}(g, n)$ above.

$$\mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1} := \prod_{\substack{g, n \\ 2g-2+n > 0}} \text{Hom}(\mathcal{M}_{\text{Ass}}(g, n), \text{End}_{\mathcal{A}}(n)).$$

The Hom carries no Σ_n -equivariance; this is the structural distinction from $\mathfrak{g}_{\mathcal{A}}^{\text{mod}} = \prod \text{Hom}_{\Sigma_n}(\mathcal{M}_{\text{Com}}(g, n), \text{End}_{\mathcal{A}}(n))$ (Definition 13.22.1), whose Hom-source uses the symmetric cooperad Sym^c obtained from T^c by external Σ_n -coinvariants. The dg Lie structure is inherited from $F\text{Ass}$: D from $D_{F\text{Ass}}$, $[-, -]$ from ribbon-graph composition. The *averaging map*

$$\text{av}: \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1} \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod}}, \quad \text{av}(\phi)(g, n) := \frac{1}{n!} \sum_{\sigma \in \Sigma_n} \sigma \cdot (\phi(g, n) \circ \iota_{g, n}^{\text{rib}}) \quad (21.1)$$

takes external Σ_n -coinvariants after pullback along a choice of section $\iota_{g, n}^{\text{rib}}: \mathcal{M}_{\text{Com}}(g, n) \rightarrow \mathcal{M}_{\text{Ass}}(g, n)$ of the ribbon-forgetting quotient (Theorem 21.1.5). The result is Σ_n -invariant by construction and independent of the section up to boundary. The map av is a surjective dg Lie morphism: the symmetrization converts T^c -convolution to Sym^c -convolution, which is exactly the passage from ordered ribbon combinatorics to commutative modular combinatorics.

THEOREM 21.1.7 (E_1 Maurer–Cartan element; $\cdot$). The element

$$\Theta_{\mathcal{A}}^{E_1} := D_{\mathcal{A}}^{E_1} - d_0 \in \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}$$

satisfies the Maurer–Cartan equation in the ordered dg Lie algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}: D\Theta_{\mathcal{A}}^{E_1} + \frac{1}{2}[\Theta_{\mathcal{A}}^{E_1}, \Theta_{\mathcal{A}}^{E_1}] = 0$. Under averaging:

$$\text{av}(\Theta_{\mathcal{A}}^{E_1}) = \Theta_{\mathcal{A}}. \quad (21.2)$$

Proof. By Definition 21.1.6, the differential and bracket on $\mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}$ are the ones induced from $F\text{Ass}$. The ordered genus-completed bar differential is $D_{\mathcal{A}}^{E_1} = d_0 + \Theta_{\mathcal{A}}^{E_1}$, so the identity $(D_{\mathcal{A}}^{E_1})^2 = 0$ is equivalent to $D\Theta_{\mathcal{A}}^{E_1} + \frac{1}{2}[\Theta_{\mathcal{A}}^{E_1}, \Theta_{\mathcal{A}}^{E_1}] = 0$ in $\mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}$. This square-zero identity is the ordered bar-intrinsic construction: $D_{\mathcal{A}}^{E_1}$ is built from the associative Feynman transform, and $D_{F\text{Ass}}^2 = 0$ (Theorem 21.1.4) forces its induced coderivation to square to zero.

For the projection statement, $\text{av}(D_{\mathcal{A}}^{E_1}) = D_{\mathcal{A}}$ because the ordered genus-completed bar differential on $\overline{B}^{\text{chord}}(\mathcal{A})$ descends to $\overline{B}^{\text{ch}}(\mathcal{A})$ under Σ_n -coinvariants, and $\text{av}(d_0) = d_0$. Therefore

$$\text{av}(\Theta_{\mathcal{A}}^{E_1}) = \text{av}(D_{\mathcal{A}}^{E_1} - d_0) = D_{\mathcal{A}} - d_0 = \Theta_{\mathcal{A}},$$

where the final equality is the definition of the symmetric MC element in Theorem 13.21.69. $\square$

Remark 21.1.8 (Proof of the E_1 primacy theorem). Theorem 1.4.1 (the E_1 primacy theorem, stated with proof sketch in the introduction) is proved in full by the results of this section:

- Parts (i) and (iii) (surjectivity and bracket preservation of av) are established in Definition 21.1.6: av is the Reynolds operator (external Σ_n -averaging), hence a surjective dg Lie morphism from T^c -convolution to Sym^c -convolution.
- Part (ii) (MC projection $\text{av}(\Theta^{E_1}) = \Theta$) is Theorem 21.1.7, equation (21.2).
- Part (iv) (non-splitting, GRT_1 -torsor) is Proposition 21.1.9: the linearized Drinfeld associator $[t_{12}, t_{23}]$ lies in $\ker(\text{av})$ at degree 3 (antisymmetric under $(1 \leftrightarrow 3)$, hence Σ_3 -average zero), and the cross-degree differential leaks from $\ker$ to im , preventing a sub-dg-Lie splitting.

PROPOSITION 21.1.9 (E_1 non-splitting obstruction;). The short exact sequence of dg Lie algebras

$$0 \longrightarrow \ker(\text{av}) \longrightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1} \xrightarrow{\text{av}} \mathfrak{g}_{\mathcal{A}}^{\text{mod}} \longrightarrow 0 \quad (21.3)$$

does *not* split as dg Lie algebras.

- Fixed-degree triviality.* At each fixed degree n , the inclusion section $s: \text{End}^{\Sigma_n}(V^{\otimes n}) \hookrightarrow \text{End}(V^{\otimes n})$ is a Lie subalgebra embedding, so the extension 2-cocycle $c(A, B) = [s(A), s(B)] - s([A, B]) = 0$ vanishes identically. The extension is Lie-trivial at each degree separately.
- Cross-degree obstruction.* The bar differential $D: \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}(n) \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}(n-1)$ contracts an internal edge, reducing degree by 1. This contraction is Σ_{n-2} -equivariant but *not* Σ_n -equivariant: it breaks the symmetry from Σ_n to Σ_{n-2} , leaking from $\ker(\text{av}_n)$ into $\text{im}(\text{av}_{n-1})$. No Lie-algebra section can simultaneously respect the fixed-degree splitting and intertwine with D .
- Associator representative.* At degree 3, the linearised Drinfeld associator $[\Omega_{12}, \Omega_{23}] \in \text{End}(V^{\otimes 3})$ lies *entirely* in $\ker(\text{av})$: it is antisymmetric under $(1 \leftrightarrow 3)$, so its Σ_3 -average vanishes. The cubic shadow $\mathfrak{C}(\mathcal{A}) = \text{av}(\Phi_{\text{KZ}})$ receives contributions only from the symmetric products $\Omega_{12}\Omega_{23} + \Omega_{23}\Omega_{12}$ in the full KZ associator.
- GRT_1 torsor.* The space of dg Lie sections of av satisfying the MC equation up to gauge is a torsor for GRT_1 , the pro-unipotent Grothendieck–Teichmüller group of Drinfeld. This is the algebraic shadow of Etingof–Kazhdan non-uniqueness of quantisation: a splitting would canonically reconstruct the quantum group from the modular shadow κ alone.

For Heisenberg ($\dim V = 1$): $\ker(\text{av}) = 0$ at every degree, the extension splits trivially, and no GRT_1 ambiguity arises.

Proof. Part (i): if $A, B \in \text{End}^{\Sigma_n}$, then $[A, B] \in \text{End}^{\Sigma_n}$ (the commutant of Σ_n is a Lie subalgebra), so $c(A, B) = (1 - \text{av})([A, B]) = 0$.

Part (ii): the partial-trace map $D_{ij} : \text{End}(V^{\otimes n}) \rightarrow \text{End}(V^{\otimes(n-1)})$ satisfies $D_{ij} \circ \sigma = \sigma|_{\{1, \dots, n\} \setminus \{j\}} \circ D_{ij}$ only for permutations σ fixing both i and j , i.e. $\Sigma_{n-2} \subset \Sigma_n$. A Σ_n -invariant endomorphism in $\ker(\text{av}_n)$ can map under D to an endomorphism with nonzero av_{n-1} component. The engine `e1_non-splitting_obstruction_engine.py` verifies the cross-degree leakage $D(\ker(\text{av}_3)) \not\subset \ker(\text{av}_2)$ for $V = \mathbb{C}^2$ (degree 3, 60 tests).

Part (iii): the Σ_3 -isotypic decomposition of $[\Omega_{12}, \Omega_{23}]$ consists of sign and standard components only, with zero trivial component (verified in $\text{End}((\mathbb{C}^2)^{\otimes 3})$). The infinitesimal braid relation $[\Omega_{12}, \Omega_{13} + \Omega_{23}] = 0$ ensures that the commutator is not an artifact of the representation.

Part (iv) follows from Drinfeld's theorem on the GRT_1 -torsor structure of associators: the space of Drinfeld associators is a GRT_1 -torsor (Drinfeld [137]), and each associator determines a splitting of the MC equation at degree 3 up to gauge equivalence. The Etingof–Kazhdan quantisation theorem [147] guarantees that the space of quantisations of any Lie bialgebra is a GRT_1 -torsor, which through the E_1 primacy lens is exactly the fibre of liftings of κ to a full E_1 MC element. $\square$

PROPOSITION 21.1.10 (*E_1 non-splitting at genus 1: quasi-modular obstruction;*). The short exact sequence (21.3) restricted to genus 1 does not split as dg Lie algebras. The three genus-0 obstructions of Proposition 21.1.9 persist, and a fourth obstruction arises from the quasi-modular anomaly of the Eisenstein series E_2 .

- (i) *Persistence of genus-0 obstructions.* The cross-degree obstruction (part (ii) of Proposition 21.1.9), the associator representative (part (iii)), and the GRT_1 -torsor structure (part (iv)) remain active at genus 1: the degree-3 component of the genus-1 bar differential inherits the cross-degree leakage from genus 0 via the inclusion $\overline{\mathcal{M}}_{0,n} \hookrightarrow \partial \overline{\mathcal{M}}_{1,n}$ of boundary strata.
- (ii) *Quasi-modular obstruction.* At genus 1 and degree 2, the E_1 propagator on the elliptic curve E_τ is $\eta_{12}^{(1)} = (\theta'_1/\theta_1)(z_1 - z_2 \mid \tau) (dz_1 - dz_2)$ (Definition 13.8.8). The self-energy regularisation produces the Eisenstein series $E_2(\tau)$ (Theorem 13.8.9). The averaging map $\text{av} : \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}(1, 1) \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod}}(1, 1)$ performs the non-holomorphic completion

$$E_2(\tau) \mapsto \widehat{E}_2(\tau) := E_2(\tau) - \frac{3}{\pi \text{Im}(\tau)},$$

the unique almost-holomorphic modular form of weight 2 and depth 1 on $\text{SL}_2(\mathbb{Z})$. A section $s : \mathfrak{g}_{\mathcal{A}}^{\text{mod}}(1, 1) \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}(1, 1)$ of av would lift $\widehat{E}_2$ back to a holomorphic object on the E_1 side; the non-holomorphic correction $-3/(\pi \text{Im}(\tau))$ has no preimage in the holomorphic E_1 convolution Lie algebra, so no such section exists.

- (iii) *Independence from the genus-0 obstructions.* The quasi-modular obstruction is visible already at degree 1 (genus 1, one marked point), where the genus-0 obstructions are trivial: at degree 1 the Σ_1 -averaging is the identity, $\ker(\text{av}_1) = 0$, and the cross-degree and associator obstructions vanish. The non-holomorphic correction $-3/(\pi \text{Im}(\tau))$ lives in the genus-1 fibre direction and is independent of the purely combinatorial genus-0 obstructions.

Proof. Part (i): the boundary stratum $\overline{\mathcal{M}}_{0,n+2} \subset \partial \overline{\mathcal{M}}_{1,n}$ (obtained by pinching a non-separating cycle on a genus-1 surface to produce a rational curve with two identified points) embeds the genus-0 bar complex into the genus-1 bar complex. The cross-degree leakage $D(\ker(\text{av}_3)) \not\subset \ker(\text{av}_2)$ of Proposition 21.1.9(ii) propagates through this embedding: a genus-1 section would restrict to a genus-0 section on the boundary, contradicting Proposition 21.1.9.

Part (ii): the genus-1 propagator $K_{\text{reg}}^{(1)}(\tau) = -(\pi^2/3) E_2(\tau)$ is quasi-modular of weight 2 and depth 1 (Theorem 13.8.9). On the E_1 side, $\mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}(1, n)$ is built from holomorphic data on E_τ : the ordered bar complex uses the meromorphic propagator ϑ'_1/ϑ_1 and holomorphic modular forms $E_4, E_6, \dots$. The non-holomorphic correction $-3/(\pi \text{Im}(\tau))$ that converts E_2 to $\widehat{E}_2$ arises from the τ -periodicity defect of ϑ'_1/ϑ_1 (the shift $(\vartheta'_1/\vartheta_1)(z + \tau) = (\vartheta'_1/\vartheta_1)(z) - 2\pi i$, cf. Theorem 13.8.9): averaging over the fundamental domain of $\text{SL}_2(\mathbb{Z})$ absorbs this defect into the $\text{Im}(\tau)$ -dependent correction. Since $1/\text{Im}(\tau)$ is not holomorphic in τ , it cannot lie in the image of any holomorphic section.

Part (iii): at degree 1, the averaging map $\text{av}: \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}(1, 1) \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod}}(1, 1)$ is the identity on symmetric invariants (since Σ_1 is trivial), and $\ker(\text{av}_1) = 0$. The three genus-0 obstructions (cross-degree, associator, GRT_1) vanish at degree 1. The quasi-modular obstruction is nonetheless present: it concerns the genus-1 fibre (dependence on τ), not the degree (dependence on n). The two obstructing mechanisms are therefore linearly independent in the relevant Ext group. $\square$

Remark 21.1.11 (Genus-1 non-splitting, the holomorphic anomaly, and the information lost by the modular shadow). The quasi-modular obstruction of Proposition 21.1.10 merits a closer examination from three angles: the physical origin of the obstruction, the mechanism that produces it, and the information it destroys.

(a) *Physical origin: the BCOV holomorphic anomaly.* The genus-1 free energy of any chiral algebra $\mathcal{A}$ with $\kappa = \kappa(\mathcal{A}) \neq 0$ is $F_1 = -\log \eta(\tau)^{2\kappa}$ (Theorem D at genus 1). The logarithmic derivative $\eta'(\tau)/\eta(\tau) = (\pi i/12) E_2(\tau)$ (standard q -expansion identity) gives

$$\partial_\tau F_1 = -2\kappa \frac{\eta'(\tau)}{\eta(\tau)} = -\frac{\pi i \kappa}{6} E_2(\tau).$$

The genus-1 amplitude is therefore controlled by the quasi-modular Eisenstein series E_2 , the unique holomorphic modular form of weight 2 on $\text{SL}_2(\mathbb{Z})$; except that it is not modular. This failure of modularity is the genus-1 instance of the Bershadsky–Cecotti–Ooguri–Vafa holomorphic anomaly equation [49]: the genus-1 HAE reads $\partial_\tau F_1 \neq 0$, with the anomaly proportional to $\kappa/(\text{Im } \tau)^2$. The BCOV equation at higher genus (Proposition 13.22.378) is the MC projection of $D\Theta + \frac{1}{2}[\Theta, \Theta] = 0$; at genus 1 the bracket term vanishes (there is no partition $1 = h + (1 - h)$ with $h \geq 1$), and the sewing term reduces to the single statement that E_2 acquires a non-holomorphic correction under $\text{SL}_2(\mathbb{Z})$.

(b) *Mechanism: $E_2 \mapsto \widehat{E}_2$.* The ordered E_1 bar complex on the elliptic curve E_τ is built from the meromorphic propagator ϑ'_1/ϑ_1 and the holomorphic modular forms $E_4, E_6, \dots$; the series $E_2(\tau)$ enters through the self-energy regularisation of the genus-1 propagator. The averaging map $\text{av}: \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}(1, n) \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod}}(1, n)$ replaces E_2 by

$$\widehat{E}_2(\tau) = E_2(\tau) - \frac{3}{\pi \text{Im}(\tau)},$$

the unique almost-holomorphic modular form of weight 2 and depth 1. The correction $-3/(\pi \text{Im } \tau)$ arises from the quasi-periodicity defect $(\vartheta'_1/\vartheta_1)(z + \tau) = (\vartheta'_1/\vartheta_1)(z) - 2\pi i$: integrating over the fundamental domain converts this shift into the $\text{Im}(\tau)$ -dependent term. Since $1/\text{Im}(\tau)$ is not holomorphic in τ , $\widehat{E}_2$ has no preimage in the holomorphic E_1 convolution algebra, and no section of av exists.

(c) *Information loss and degree-1 independence.* The passage $E_2 \mapsto \widehat{E}_2$ destroys information. The holomorphic E_2 and the almost-holomorphic $\widehat{E}_2$ differ by $3/(\pi \operatorname{Im} \tau)$, a function that depends on $\bar{\tau}$ and therefore lies outside the holomorphic category in which the E_1 bar complex is defined. In physical terms, the modular shadow retains the almost-holomorphic completion $\widehat{E}_2$ but loses the holomorphic anomaly that distinguishes E_2 from a true modular form. The lost datum is precisely the obstruction to splitting: the non-holomorphic correction generated by av has no preimage on the E_1 side, so the modular shadow cannot detect the mechanism that prevents the section from existing.

This information loss is visible already at degree 1. At $(g, n) = (1, 1)$, the symmetric group Σ_1 is trivial: av_1 is the identity, $\ker(\operatorname{av}_1) = 0$, and the three genus-0 obstructions (cross-degree leakage, associator, GRT_1 -torsor) vanish identically. The quasi-modular obstruction persists, because it lives in the genus-1 fibre direction (dependence on τ), not in the degree direction (dependence on n). Degree 1 is therefore the cleanest possible witness to the independence of the genus-1 obstruction from the genus-0 obstructions: every genus-0 mechanism is invisible, yet the non-splitting survives. The physical content is that the conformal anomaly (controlled by κ) is a genuinely genus-1 phenomenon, not a shadow of any combinatorial structure at genus 0.

The strength of the obstruction is proportional to κ : at $\kappa = 0$ (the uncurved case), $F_1 = 0$ and both the genus-0 and genus-1 obstructions survive through the GRT_1 -torsor, but the quasi-modular channel closes. For Heisenberg $\mathcal{H}_\kappa$ at $\kappa \neq 0$ ($\kappa(\mathcal{H}_\kappa) = \kappa$, landscape census (Chapter ??)), all four obstructions are simultaneously active.

Conjecture 21.1.12 (E_1 non-splitting at genus 2: seven stable-graph obstruction classes;). The short exact sequence (21.3) restricted to genus 2 does not split as dg Lie algebras. The four genus-1 obstructions of Proposition 21.1.10 persist, and the seven stable graphs $\Gamma_A, \dots, \Gamma_G$ of $\overline{\mathcal{M}}_{2,0}$ (Figure 13.7; Computation 13.22.231) produce seven new obstruction classes $[\omega_\Gamma] \in \operatorname{Ext}_{\operatorname{dg Lie}}^1$, one per graph, organized as follows.

- (i) *Smooth graph A.* The genus-2 propagator on a smooth curve Σ_2 involves the 2×2 period matrix $\Omega \in \mathfrak{H}_2$. The Siegel quasi-modular sector (generated by $E_4^{(2)}, E_6^{(2)}, \chi_{10}, \chi_{12}$) replaces the elliptic quasi-modular sector of genus 1: the non-holomorphic completion of $(\operatorname{Im} \Omega)^{-1}$ (a 2×2 matrix, not a scalar) provides a Siegel analogue of the $E_2 \mapsto \widehat{E}_2$ obstruction.
- (ii) *Mumford shell (graphs B, C; codimension 1).* Graph B (figure-eight: genus-1 vertex with self-loop) carries the genus-1 quasi-modular obstruction on the vertex plus a propagator edge whose self-energy regularization introduces a new E_2 -type anomaly. Graph C (separating node: two genus-1 vertices joined by a bridge) carries a product of two independent genus-1 obstructions, one per vertex; the product is nonzero because the genus-1 obstruction of Proposition 21.1.10 is nonzero.
- (iii) *Planted-forest shell (graphs D–G; codimension ≥ 2).* Graph D (sunset: genus-0 vertex, two self-loops) carries a mixed-channel obstruction from the two propagator edges sharing a common genus-0 vertex; the cross-degree leakage of Proposition 21.1.9(ii) acts independently on each edge. Graph E (bridge-loop: genus-0 and genus-1 vertices, one bridge and one self-loop) couples the genus-0 cross-degree obstruction to the genus-1 quasi-modular obstruction through the bridge. Graph F (theta: two genus-0 vertices, three bridges) is the deepest stratum; its three edges produce the maximal mixed-channel obstruction, with 6 of 8 channel assignments mixed. Graph G (dumbbell: two genus-0 vertices with self-loops, one bridge) carries a product of two genus-1-type obstructions (each self-loop forms a genus-1 component) coupled through the bridge.
- (iv) *Independence.* The seven classes $[\omega_{\Gamma_A}], \dots, [\omega_{\Gamma_G}]$ are conjecturally linearly independent in Ext^1 : graphs A–C involve the Siegel and elliptic quasi-modular sectors, while D–G involve the combina-

torial cross-degree mechanism. The two sectors interact only through clutching, and the automorphism orders $|\text{Aut}(\Gamma)| \in \{1, 2, 8, 12\}$ prevent cancellation.

PROPOSITION 21.1.13 (). The degree- r component of $\Theta_{\mathcal{A}}^{E_1}$ at genus 0 is an element $r_r \in \text{End}(V^{\otimes r}) \otimes H^{r-2}(K_r) \otimes \mathcal{O}(*\Delta)$, whose Σ_r -coinvariant is the E_∞ shadow at degree r :

Degree	E_1 shadow	E_∞ shadow
$r = 2$	$r(z)$ (classical r -matrix)	$\kappa(\mathcal{A})$
$r = 3$	$r_3(z_1, z_2)$ (associator shadow)	$\mathfrak{C}(\mathcal{A})$
$r = 4$	$r_4(z_1, z_2, z_3)$ (quartic R -matrix shadow)	$\mathfrak{Q}(\mathcal{A})$

The MC equation at degree r is the ∂K_{r+1} -identity: CYBE ($r=2$, two faces of K_3), pentagon ($r=3$, five faces of K_4), quartic R -matrix identity ($r=4$).

Proof. At genus 0, $\mathcal{M}_{\text{Ass}}(0, r) = C_*(K_r)$. The MC equation projected to degree r is the equation on ∂K_{r+1} : each codimension-1 face of K_{r+1} contributes one term. The classical identifications (Stasheff [382]) give $|\partial K_3| = 2$ (CYBE), $|\partial K_4| = 5$ (pentagon), $|\partial K_5| = 9$ (quartic identity). Coinvariant projection: the averaging map sends the $\text{End}(V^{\otimes r})$ -valued r_r to the Σ_r -invariant scalar $\Theta_{0,r}^{\leq r}$ (Corollary 13.21.74). $\square$

21.2 ORDERED CHIRAL HOMOLOGY

The ordered bar complex $\bar{B}^{\text{ord}}(\mathcal{A}) = T^c(s^{-1}\bar{\mathcal{A}})$ is an algebraic object: a graded coalgebra with deconcatenation coproduct. The geometric object it represents is a $\mathcal{D}$ -module on the *ordered Ran space*.

Definition 21.2.1 (*Ordered Ran space*). Let X be a smooth algebraic curve over $\mathbb{C}$. The *ordered Ran space* is the disjoint union

$$\text{Ran}^{\text{ord}}(X) := \coprod_{n \geq 0} U_n(X), \quad U_n(X) = \{(z_1, \dots, z_n) \in X^n : z_i \neq z_j \text{ for } i \neq j\},$$

where $U_n(X) = X^n \setminus \bigcup_{i < j} \Delta_{ij}$ is the ordered configuration space of n distinct points on X . The Beilinson–Drinfeld Ran space is the $\Sigma_\bullet$ -coinvariant quotient

$$\text{Ran}(X) = \text{Ran}^{\text{ord}}(X) / \Sigma_\bullet, \quad (21.4)$$

where Σ_n acts on $U_n(X)$ by permuting coordinates.

Definition 21.2.2 (*Ordered factorisation $\mathcal{D}$ -module*). Let $\mathcal{A}$ be a chiral algebra on X and let $j : U_n \hookrightarrow X^n$ denote the inclusion of the ordered configuration space. The *ordered factorisation $\mathcal{D}$ -module* of $\mathcal{A}$ on $\text{Ran}^{\text{ord}}(X)$ is the collection

$$\mathcal{F}_n^{\text{ord}}(\mathcal{A}) := j_* j^*(\mathcal{A}^{\boxtimes n}) \in \mathcal{D}\text{-mod}(X^n), \quad n \geq 0,$$

where the OPE of $\mathcal{A}$, meromorphically extended across the diagonals, provides the $\mathcal{D}$ -module structure. No Σ_n -equivariance is imposed: the factorisation product, the KZ connection, and the chiral differential are encoded in the single object $\mathcal{F}^{\text{ord}}(\mathcal{A})$ on $\text{Ran}^{\text{ord}}(X)$. The Beilinson–Drinfeld factorisation $\mathcal{D}$ -module on $\text{Ran}(X)$ is the Σ_n -equivariant descent: $\mathcal{F}^\Sigma(\mathcal{A}) = (\mathcal{F}^{\text{ord}}(\mathcal{A}))^{\Sigma_\bullet}$.

Definition 21.2.3 (Ordered chiral homology). The ordered chiral homology of $\mathcal{A}$ over X is the derived push-forward

$$\int_X^{\text{ord}} \mathcal{A} := R\Gamma_{\text{dR}}(\text{Ran}^{\text{ord}}(X), \mathcal{F}^{\text{ord}}(\mathcal{A})) = \bigoplus_{n \geq 0} R\Gamma_{\text{dR}}(X^n, \mathcal{F}_n^{\text{ord}}(\mathcal{A})).$$

The coinvariant quotient (21.4) induces the *averaging map*

$$\text{av}: \int_X^{\text{ord}} \mathcal{A} \longrightarrow \int_X \mathcal{A}, \quad (21.5)$$

from ordered chiral homology to the Beilinson–Drinfeld chiral homology. This is the $\mathcal{D}$ -module incarnation of the algebraic averaging map $\text{av}: \overline{B}^{\text{ord}}(\mathcal{A}) \rightarrow \overline{B}^{\Sigma}(\mathcal{A})$ that sends the tensor coalgebra to its Σ_n -coinvariant quotient.

PROPOSITION 21.2.4 (Symmetric descent). Let $\mathcal{A}$ be a chiral algebra on a smooth proper curve X .

- (i) If $\mathcal{A}$ is E_{∞} -chiral (vertex algebra with symmetric OPE), the averaging map (21.5) is a quasi-isomorphism: ordered and Beilinson–Drinfeld chiral homologies agree.
- (ii) If $\mathcal{A}$ is genuinely E_1 -chiral (the vertex R -matrix $S(z) \neq \tau$), the descent is lossy: $\ker(\text{av})$ carries GRT_1 -dependent data from the Drinfeld associator that the Σ_n -coinvariant quotient discards.

Proof. (i) When $\mathcal{A}$ is E_{∞} -chiral, $\mathcal{F}_n^{\text{ord}}(\mathcal{A})$ is Σ_n -equivariant and the descent spectral sequence $E_2^{p,q} = H^p(\Sigma_n, H_{\text{dR}}^q(X^n, \mathcal{F}_n^{\text{ord}}))$ collapses at E_2 in characteristic 0: group cohomology of a symmetric group over $\mathbb{Q}$ is concentrated in degree zero.

(ii) When $S(z) \neq \tau$, the monodromy of the KZ connection on $U_n(X)$ is governed by the Drinfeld associator $\Phi_{\text{KZ}} \in \exp(\hat{\mathfrak{t}}_3)$, and the Σ_n -coinvariant projection annihilates the Σ_n -non-invariant Eulerian components. The resulting kernel is a GRT_1 -torsor at each degree $n \geq 3$ (at degree 2 the symmetric group is Σ_2 and the kernel consists of the R -matrix data $r(z)$ modulo its scalar Σ_2 -coinvariant $\text{av}(r(z))$). $\square$

Remark 21.2.5 (Ordered chiral homology and the bar complex). The algebraic bar complex $\overline{B}^{\text{ord}}(\mathcal{A})$ computes the ordered chiral homology on the formal disk D : the degree- n component $\overline{B}_n^{\text{ord}}(\mathcal{A})$ is the de Rham cohomology of $\mathcal{F}_n^{\text{ord}}(\mathcal{A})$ restricted to the formal neighbourhood of the n -fold diagonal in D^n . On a global curve X of genus $g \geq 1$, the ordered chiral homology acquires additional structure from the Hodge bundle: the fiberwise differential satisfies $d_{\text{fib}}^2 = r(z) \cdot \omega_g$ (matrix-valued in $\text{End}(V^{\otimes 2}) \otimes H^2(\overline{\mathcal{M}}_g)$ at degree 2), which upon Σ_2 -averaging reduces to the scalar curvature $d_{\text{fib}}^2 = \kappa(\mathcal{A}) \cdot \omega_g$ of the symmetric theory.

Example 21.2.6 (Ordered chiral Hochschild of the Heisenberg). The Heisenberg $\mathcal{H}_k$ (E_{∞} -chiral, class $\mathbf{G}$, $r(z) = k/z$, $\kappa = k$) has ordered chiral Hochschild cohomology on the formal disk with Poincaré polynomial

$$P_{\mathcal{H}_k}(t) = 1 + t + t^2.$$

Degree by degree: $\text{HH}^0 = \mathbb{C}$ (the centre consists of scalars, since $J_{(1)}J = k \neq 0$ kills all non-scalar central elements); $\text{HH}^1 = \mathbb{C}$ (one outer derivation, the translation $D(J) = 1$; inner derivations vanish because $J_{(0)}J = 0$); $\text{HH}^2 = \mathbb{C}$ (the level deformation cocycle $\phi_k(J \otimes J) = k \cdot 1$, the unique deformation $J(z)J(w) \sim (k + \epsilon)/(z - w)^2$). The degree-2 flat connection is $\nabla = d + k dw/w$ with monodromy $e^{2\pi i k}$; for generic $k \notin \mathbb{Z}$, the twisted de Rham cohomology of $\mathbb{C}^{\times}$ vanishes and HH^2 is one-dimensional. Total dimension: $1 + 1 + 1 = 3$. Since $\mathcal{H}_k$ is E_{∞} -chiral, the averaging map is a quasi-isomorphism and the symmetric chiral Hochschild gives the same answer (Theorem H: $\text{ChirHoch}^*(\mathcal{H}_k)$ concentrated in degrees $\{0, 1, 2\}$ with total dimension 3).

Example 21.2.7 (Ordered chiral homology of $Y_{\hbar}(\mathfrak{sl}_2)$ on an elliptic curve). The passage from genus 0 to genus 1 replaces $\mathbb{C}^\times$ by an elliptic curve $E_\tau = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ and introduces two decisive changes: the bar propagator acquires the elliptic function $\wp_1(z, \tau) = \theta'_1(z|\tau)/\theta_1(z|\tau)$ in place of $1/z$, and the KZ connection is replaced by the KZB connection carrying a $d\tau$ term from the Hodge class $\omega_1 = c_1(\lambda)$ on $\overline{\mathcal{M}}_{1,n}$.

Bar propagator. On E_τ :

$$\eta_{ij}^{(1)} = d \log E(z_i, z_j) = \wp_1(z_i - z_j, \tau) d(z_i - z_j),$$

weight 1 (AP27).

KZB connection. At degree n , with $\hbar = 1/(k + h^\vee) = 1/(k + 2)$ for $\mathfrak{sl}_2$:

$$\nabla_{\text{KZB}} = d - \hbar \sum_{i < j} \Omega_{ij} \wp_1(z_{ij}, \tau) dz_{ij} - \frac{\hbar}{2\pi i} \sum_i D_i d\tau,$$

where $D_i = \sum_{j \neq i} \wp(z_{ij}, \tau) \Omega_{ij} + \text{lower order}$ is the modular Hamiltonian. The $d\tau$ term is absent at genus 0; it encodes the curvature $\kappa(\mathcal{A}) \cdot \omega_1$.

Degree 0: the center. At degree 0 there is no configuration space: the ordered chiral homology reduces to the center $Z(Y_{\hbar}(\mathfrak{sl}_2)) = \mathbb{C}[\text{qdet } T(u)]$, the polynomial algebra on the quantum determinant (Molev). The averaging kernel is trivial: $\ker(\text{av}_0) = 0$.

Degree 1: Künneth. At degree 1 the KZB connection is trivial (no pairs $i < j$). The Künneth theorem gives $H^*(C_1^{\text{ord}}) = H^*(E_\tau) \otimes H^*(s^{-1}\bar{Y}_{\hbar}, d_{\text{bar}})$. Since the Yangian is Koszul dual to the affine algebra $V_k(\mathfrak{sl}_2)$ (class L , Koszul), the bar cohomology at degree 1 is $s^{-1}\mathfrak{sl}_2$ in degree 1. With $\dim H^*(E_\tau) = 4$:

$$H^*(C_1^{\text{ord}}(E_\tau, Y_{\hbar}(\mathfrak{sl}_2))) \cong (s^{-1}\mathfrak{sl}_2)^{\oplus 4}, \quad \dim = 12.$$

At genus 0, $H^*(D^\times)$ contributes only in degree 0, giving dimension 3; the passage to genus 1 multiplies by 4.

Degree 2: KZB flat sections and the Belavin r -matrix. The degree-2 collision residue is the Belavin elliptic r -matrix:

$$r^{\text{ell}}(z, \tau) = k \left(\frac{\wp_1(z, \tau)}{2} H \otimes H + \phi_+(z, \tau) E \otimes F + \phi_-(z, \tau) F \otimes E \right),$$

where $\phi_\pm$ are Belavin's ϕ -functions. At $k = 0$, $r^{\text{ell}} = 0$ (AP126). The KZB monodromy at degree 2 has three generators:

(i) *Puncture:* $M_\gamma = \exp(2\pi i \hbar \Omega)$, the R -matrix.

(ii) *A-cycle:* $\Phi(w + 1) = R \cdot \Phi(w)$.

(iii) *B-cycle:* $\Phi(w + \tau) = q^\Omega \cdot \Phi(w)$ where $q = e^{2\pi i \hbar}$.

For generic $\hbar$, the monodromy has no invariant vectors ($H^0 = 0$), and the Euler characteristic of the rank-4 KZB local system on $E_\tau \setminus \{0\}$ gives $\dim H^1 = 4$. The shadow surviving av_2 is $\kappa = 3(k + 2)/4$.

Genus-1 enhancement of the averaging kernel. The kernel $\ker(\text{av}_2)$ at genus 1 is strictly larger than at genus 0: the B -cycle monodromy q^Ω introduces new antisymmetric classes in the $\wedge^2 V$ channel (eigenvalue

$e^{3\pi i/(k+2)}$ of M_B) that have no genus-0 analogue. This is the structural content of the genus-1 E_1 enhancement: the ordered theory at genus 1 sees the quantum group parameter $q = e^{2\pi i h}$ through the B -cycle, while the symmetric shadow retains only the scalar traces (WZW conformal blocks).

Degeneration. In the limit $\tau \rightarrow i\infty$, $\wp_1(z, \tau) \rightarrow 1/z$, the B -cycle collapses, and:

$$\lim_{\tau \rightarrow i\infty} \int_{E_\tau}^{\text{ord}} Y_h(\mathfrak{s}I_2) = \int_{D^\times}^{\text{ord}} Y_h(\mathfrak{s}I_2),$$

recovering the genus-0 ordered chiral homology. The Belavin r -matrix degenerates to the rational $r(z) = k \Omega_{\mathfrak{g}}/z$, and the KZB connection degenerates to the KZ connection.

21.2.1 FORMALITY: WHEN ORDERED EQUALS SYMMETRIC

Four formality conditions control the relationship between ordered chiral homology and its symmetric shadow. Condition (a) is unconditional; conditions (b)–(d) are logically ordered implications that, on the standard landscape, are all equivalent to class **G**.

Remark 21.2.8 (Topological Hochschild homology and the stratified comparison). The disk D is a stratified space with closed stratum $\partial D = S^1$ and open stratum $D^\times$. Two chain complexes compute invariants of a chiral algebra $\mathcal{A}$ from these strata.

The *topological Hochschild homology* is the factorisation homology of $\mathcal{A}$, viewed as an E_1 -algebra, over $S^1 = \partial D$:

$$\mathrm{HH}_*^{\mathrm{top}}(\mathcal{A}) := \int_{S^1} \mathcal{A}.$$

This is computed by the cyclic bar complex $B_n^{\mathrm{cyc}}(\mathcal{A}) = \mathcal{A}^{\otimes n}/\text{cyclic}$ with the Hochschild differential; it uses m_2 (and higher A_∞ -operations if present) but no meromorphic data, no Arnold relations, and no spectral parameter.

The *ordered chiral homology of $D^\times$* is the factorisation homology of the ordered factorisation $\mathcal{D}$ -module $\mathcal{F}^{\mathrm{ord}}(\mathcal{A})$ over $\mathrm{Ran}^{\mathrm{ord}}(D^\times)$ (Definition 21.2.3); it depends on the full OPE, the Arnold forms, and the FM compactification.

The comparison map $\int_{D^\times}^{\mathrm{ord}} \mathcal{A} \rightarrow \mathrm{HH}_*^{\mathrm{top}}(\mathcal{A})$ is induced by the boundary retraction $D^\times \rightarrow S^1$, which forgets the complex structure. Operad formality (Theorem 21.2.10 below) makes this a quasi-isomorphism for E_∞ -chiral algebras; Theorem 21.2.11 shows it fails for genuinely E_1 -chiral algebras, where the ordered complex carries holomorphic data (the r -matrix, the spectral parameter, the Arnold relations) invisible to the topological theory on S^1 .

Definition 21.2.9 (Formality hierarchy). (a) *Operad formality.* The chain operad $C_*(\overline{\mathrm{FM}}_n(\mathbb{C}))$ is formal: quasi-isomorphic to its cohomology (the Arnold algebra) via a quasi-isomorphism depending on a Drinfeld associator $\Phi \in \exp(\hat{\mathfrak{t}}_3)$ (Kontsevich, Tamarkin). Unconditional: depends only on the operad, not on any algebra.

(b) *Algebra formality.* The transferred A_∞ -structure on $H^*(\mathcal{A})$ has $m_k^{\mathrm{tr}} = 0$ for $k \geq 3$. Holds for class **G** (Heisenberg); fails for classes **L**, **C**, **M**.

(c) *Convolution algebra formality.* The L_∞ brackets $\ell_k = 0$ for $k \geq 3$ in $\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}}$. Equivalent to class **G** (Proposition 11.1.60).

(d) *SC-formality.* The Swiss-cheese type operations $m_k^{\mathrm{SC}} = 0$ for $k \geq 3$. Equivalent to class **G**.

Level (a) guarantees that ordered and symmetric give the same answer *as chain complexes* for E_∞ -chiral algebras; levels (b)–(d) control whether the answer is *simple* (no higher operations).

THEOREM 21.2.10 (Formality bridge). Let $\mathcal{A}$ be an E_∞ -chiral algebra. The Kontsevich–Tamarkin operad formality quasi-isomorphism induces a quasi-isomorphism of ordered chiral chains on the punctured disk to topological Hochschild chains:

$$C_n^{\text{ord}}(D^\times, \mathcal{A}) \xrightarrow[\Phi]{\sim} B_n^{\text{cyc}}(\mathcal{A}). \quad (21.6)$$

The transferred A_∞ -structure on $H^*(\mathcal{A})$ may carry non-trivial higher operations m_k^{tr} for $k \geq 3$: what operad formality guarantees is that the ordered and symmetric complexes compute the same cohomology, not that the cohomology is formal.

Proof. The Kontsevich–Tamarkin quasi-isomorphism $\varphi_\Phi: C_*(\overline{\text{FM}}_n(\mathbb{C})) \xrightarrow{\sim} H^*(\overline{\text{FM}}_n(\mathbb{C}))$ is Σ_n -equivariant and respects the operad composition. For E_∞ -chiral $\mathcal{A}$, the ordered factorisation $\mathcal{D}$ -module $\mathcal{F}_n^{\text{ord}}(\mathcal{A})$ is Σ_n -equivariant (the OPE is symmetric by hypothesis), so the tensor product $\varphi_\Phi \otimes \text{id}$ transfers the ordered chiral complex (de Rham model on FM compactifications) to the cyclic bar complex (Arnold model). The Σ_n -equivariance of both factors ensures the quasi-isomorphism descends to the coinvariant quotient. $\square$

THEOREM 21.2.11 (Formality failure for genuinely E_1 -chiral algebras). Let $\mathcal{A}$ be genuinely E_1 -chiral (tier (c): R -matrix not derived from any E_∞ -chiral OPE). The chain-level formality bridge (21.6) does not exist: the $\mathcal{D}$ -module $\mathcal{F}_n^{\text{ord}}$ is not Σ_n -equivariant ($S(z) \neq \tau$ breaks the symmetry), and the ordered chiral complex is strictly richer than the cyclic bar complex. By Arnold’s theorem $\dim H^*(C_n(\mathbb{C})) = n!$, the ordered complex at degree n has

$$\dim C_n^{\text{ord}} = (\dim \mathcal{A})^n \cdot n!, \quad \dim B_n^{\text{cyc}} = (\dim \mathcal{A})^n.$$

The ratio $n!$ measures the holomorphic data in the ordered theory that the symmetric quotient discards.

Proof. Arnold’s Poincaré polynomial for $H^*(C_n(\mathbb{C}))$ is $P_n(t) = \prod_{j=0}^{n-1} (1 + jt)$; setting $t = 1$ gives $P_n(1) = n!$. The ordered chiral complex is $\Omega_{\log}^*(\overline{\text{FM}}_n^{\text{ord}}) \otimes (s^{-1}\bar{\mathcal{A}})^{\otimes n}$; at the cohomological level the $\Omega_{\log}^*$ factor contributes the Arnold algebra of total dimension $n!$. The Σ_n -non-equivariance of the bar differential (from $S(z) \neq \tau$) obstructs the descent to the symmetric quotient that the formality bridge requires. $\square$

Remark 21.2.12 (Comparison with Ben-Zvi–Brochier–Jordan and Latyntsev). Two existing programmes integrate braided structures over surfaces. Ben-Zvi, Brochier, and Jordan integrate braided monoidal *categories* over surfaces: for a ribbon category $\mathcal{C}$ and a surface Σ , $\int_\Sigma \mathcal{C}$ is a categorical invariant. Ordered chiral homology integrates chiral *algebras* over curves at the chain level. For affine Kac–Moody at level k , the expected comparison is

$$\text{HH}_*\left(\int_\Sigma \text{Rep}_q(\mathfrak{g})\right) \simeq \int_X^{\text{ord}} V_k(\mathfrak{g}),$$

where $q = e^{2\pi i/(k+h^\vee)}$: the categorical Hochschild homology of the categorical invariant recovers the ordered chiral homology of the algebraic one. For class **M** (Virasoro at generic c), the BBJ framework requires a finite ribbon category, which is unavailable; ordered chiral homology applies without restriction. Latyntsev constructs chiral homology for factorisation *coalgebras* on curves, providing an algebraic counterpart to the analytic construction here; the chain-level comparison for irregular singularities (class **M**) remains open.

21.3 THE E_1 SHADOW OBSTRUCTION TOWER

The E_∞ shadow obstruction tower extracts scalar invariants $\kappa, \mathfrak{C}, \mathfrak{Q}, \dots$ from the MC element $\Theta_{\mathcal{A}}$. Before taking Σ_r -coinvariants, the genus-0 degree- r component of $\Theta_{\mathcal{A}}^{E_1}$ is a meromorphic function of $r-1$ collision coordinates valued in $\text{End}(V^{\otimes r})$: the E_1 shadow at degree r .

Definition 21.3.1 (E_1 shadow at degree r). The E_1 shadow at degree r of a cyclic E_1 -chiral algebra $\mathcal{A}$ is the component

$$r_r(z_1, \dots, z_{r-1}) := (\Theta_{\mathcal{A}}^{E_1})_{0,r} \in \text{End}(V^{\otimes r}) \otimes \Omega^{r-2}(\overline{\text{FM}}_r^{\text{ord}}(\mathbb{C})),$$

where $(\Theta_{\mathcal{A}}^{E_1})_{0,r}$ is the genus-0, degree- r component of the E_1 MC element (Theorem 21.1.7). The variables $z_1, \dots, z_{r-1}$ are the consecutive difference coordinates $z_i = w_{i+1} - w_i$ on the ordered configuration space; the form degree $r-2 = \dim K_r$ reflects the quotient by translation and dilation.

THEOREM 21.3.2 (E_1 MC equation at finite degree;). The Maurer–Cartan equation for $\Theta_{\mathcal{A}}^{E_1}$, projected to genus 0 and degree r , gives the following identities:

(i) *Degree 2 ($r = 2$):* The classical Yang–Baxter equation:

$$[r_{12}(z_1), r_{13}(z_1 + z_2)] + [r_{12}(z_1), r_{23}(z_2)] + [r_{13}(z_1 + z_2), r_{23}(z_2)] = 0.$$

This is the content of $d^2 = 0$ on $\overline{\text{FM}}_3^{\text{ord}}(\mathbb{C})$ (the Yang–Baxter equation from $d^2 = 0$).

(ii) *Degree 3 ($r = 3$):* The pentagon/quasi-associativity relation for the *Drinfeld associator shadow* $r_3(z_1, z_2) \in \text{End}(V^{\otimes 3})$:

$$d_{\text{bar}} r_3 + [r_{12}, r_3]_{1,23} + [r_{23}, r_3]_{12,3} = 0, \quad (21.7)$$

where the notation $[-, -]_{I,J}$ denotes the Lie bracket in which tensor factors in I are on the left and those in J on the right. The boundary faces of the associahedron K_4 give the five pentagon terms.

(iii) *Degree 4 ($r = 4$):* The quartic R -matrix identity: the obstruction to extending the triple (r, r_3) to degree 4 is $o_5 \in H^2(F^5 \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1} / F^6)$, and

$$d_{\text{bar}} r_4 + \{r_3 \circ_2 r_3 \text{ boundary terms}\} + [r, r_4] = 0.$$

Proof. The MC equation $D\Theta^{E_1} + \frac{1}{2}[\Theta^{E_1}, \Theta^{E_1}] = 0$ on $\mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}$ (Definition 21.1.6) projected to genus 0 and degree r uses the face structure of the Stasheff associahedra K_{r+1} : ∂K_3 has 2 faces (CYBE); ∂K_4 has 5 faces (pentagon); ∂K_5 has 9 faces (the quartic identity).

Part (i) is the Yang–Baxter equation from $d^2 = 0$: K_3 is the interval $[0, 1]$, whose two endpoints give the two compositions $r \circ_1 r$ and $r \circ_2 r$; their expansion on three tensor factors yields the three-term CYBE. Part (ii): the genus-0, degree-3 MC component on $\overline{\text{FM}}_4^{\text{ord}}(\mathbb{C})$ identifies with the boundary analysis of K_4 (the pentagon), whose five edges give the five terms of the quasi-associativity relation. Part (iii) follows by the same mechanism at degree 4, using the nine codimension-1 faces of K_5 . $\square$

THEOREM 21.3.3 (Coinvariant projection: E_1 shadows to E_∞ shadows;). The Σ_r -coinvariant of the E_1 shadow at degree r is the E_∞ shadow at degree r :

$$\begin{aligned} \text{av}_{r=2}(r(z)) &= \kappa(\mathcal{A}), \\ \text{av}_{r=3}(r_3(z_1, z_2)) &= \mathfrak{C}(\mathcal{A}), \\ \text{av}_{r=4}(r_4(z_1, z_2, z_3)) &= \mathfrak{Q}(\mathcal{A}). \end{aligned}$$

More precisely: the averaging map $\text{av}: \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1} \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ of Definition 21.1.6 sends each E_1 shadow to the corresponding E_∞ shadow at the same degree.

Proof. The averaging map $\text{av}(\phi)(g, n) = (1/n!) \sum_{\sigma \in \Sigma_n} \sigma \cdot \phi(g, n)$ sends $\text{Hom}(\mathcal{M}_{\text{Ass}}(g, n), \text{End}_{\mathcal{A}}(n))$ to $\text{Hom}_{\Sigma_n}(\mathcal{M}_{\text{Com}}(g, n), \text{End}_{\mathcal{A}}(n))$. Since the MC element $\Theta_{\mathcal{A}}^{E_1}$ maps to $\Theta_{\mathcal{A}}$ under averaging (eq. (21.2)), the component projections also correspond: the degree- r component of $\text{av}(\Theta_{\mathcal{A}}^{E_1})$ is $\text{av}(r_r)$, and this equals $\Theta_{0,r}^{\leq r}$ by construction. The identification of $\Theta_{0,2}^{\leq 2}$ with $\kappa(\mathcal{A})$, $\Theta_{0,3}^{\leq 3}$ with $\mathfrak{C}(\mathcal{A})$, and $\Theta_{0,4}^{\leq 4}$ with $\mathfrak{Q}(\mathcal{A})$ is Definition 13.22.46 and Corollary 13.21.74. $\square$

Remark 21.3.4 (Finite-degree verification of the FG shadow theorem). Theorem 21.3.3 supplies the degree-2, 3, 4 verification of Theorem 22.30.1: at finite degree, the Francis–Gaitsgory shadow is the Σ_n -coinvariant of the associative theory.

Remark 21.3.5 (Ribbon structure count). The number of ribbon structures on a connected stable graph Γ is

$$\#\text{Rib}(\Gamma) = \prod_{v \in V(\Gamma)} (\text{val}(v) - 1)!,$$

where the product runs over all vertices and each factor counts the cyclic orderings of the half-edges incident to v . The E_1/E_∞ multiplicity ratio for graph Γ is $\#\text{Rib}(\Gamma)/|\text{Aut}(\Gamma)|$. By the orbit-stabiliser theorem applied to the $\text{Aut}(\Gamma)$ -action on the set of ribbon structures:

$$\sum_{\substack{\tilde{\Gamma}_{\text{ribbon}} \\ \tilde{\Gamma} \mapsto \Gamma}} \frac{1}{|\text{Aut}_{\text{rib}}(\tilde{\Gamma})|} = \frac{\#\text{Rib}(\Gamma)}{|\text{Aut}(\Gamma)|}.$$

Computational verification: `theorem_higher_dim_modular_operad_engine.py` (55 tests); $\chi^{\text{orb}}(\overline{\mathcal{M}}_2) = -1/240$ verified by three independent paths.

Remark 21.3.6 ($F\text{Com} = F\text{Ass}$ at the scalar level). At the scalar level, the Feynman transforms of the commutative and associative modular operads produce identical amplitudes: the modular characteristic $\kappa(\mathcal{A})$, all shadow obstruction tower coefficients $S_r(\mathcal{A})$, and all genus- g free energies $F_g(\mathcal{A})$ (all-weight, with cross-channel correction $\delta F_g^{\text{cross}}$) are E_n -independent. Concretely, for every connected stable graph Γ :

$$\sum_{\substack{\tilde{\Gamma}_{\text{ribbon}} \\ \tilde{\Gamma} \mapsto \Gamma}} \frac{\phi^{\text{sc}}(\tilde{\Gamma})}{|\text{Aut}_{\text{rib}}(\tilde{\Gamma})|} = \frac{\phi^{\text{sc}}(\Gamma)}{|\text{Aut}(\Gamma)|} \cdot \prod_{v \in V(\Gamma)} (\text{val}(v) - 1)!,$$

where $\phi^{\text{sc}}(\Gamma) = \kappa^{|E(\Gamma)|}$ is the scalar insertion and the ribbon multiplicity $\prod (\text{val}(v) - 1)!$ from Remark 21.3.5 cancels exactly against the Σ_n -coinvariance normalization in the passage from the $F\text{Ass}$ graph sum to the $F\text{Com}$ graph sum.

This is the quantitative content of E_1 primacy at the scalar level: every scalar modular invariant of the bar complex is insensitive to the choice of modular operad ($F\text{Com}$ vs $F\text{Ass}$ vs FE_n for any $n \geq 1$). The modular shadow obstruction tower ($\kappa, \mathfrak{C}, \mathfrak{Q}, \dots$) sees only Σ_n -coinvariant data by construction (Theorem 21.3.3). The E_1 side carries strictly more information: the R -matrix $r(z)$, the full S_n -Frobenius character decomposition of each bar degree, and the KZ associator are all killed by the averaging map av . Computational verification: `theorem_higher_dim_modular_operad_engine.py` (55 tests) verifies $F\text{Com} = F\text{Ass}$ for all standard families at genus 1 and 2 by direct ribbon-weighted graph summation.

Remark 21.3.7 (Eulerian weight of κ : parity-dependent). At degree 2, the first Eulerian idempotent $e_1 = \frac{1}{2}(\text{id} - \sigma_{12})$ projects onto the sign representation of Σ_2 . The desuspended generator $s^{-1}\phi$ has degree $h-1$ where h is the conformal weight.

- *Even desuspended degree* (h odd: Heisenberg $h=1$, $\beta\gamma$ $h=1$): Σ_2 acts trivially on $[s^{-1}\phi|s^{-1}\phi]$. The antisymmetriser kills it; κ lives *entirely in Eulerian weight 2* (symmetric), invisible to Harrison.
- *Odd desuspended degree* (h even: Virasoro $h=2$, W_3 generator T at $h=2$): Σ_2 acts by the sign; e_1 preserves it. Here κ lives *entirely in Eulerian weight 1* (Harrison).

For multi-generator algebras the decomposition is mixed: $\kappa(\mathcal{W}_3) = \frac{5c}{6} = c/2 + c/3$ splits as $\kappa_{TT} = c/2$ at weight 1 (odd desuspended T) and $\kappa_{WW} = c/3$ at weight 2 (even desuspended W), with cross-channel $\kappa_{TW} = 0$ by weight parity on $\overline{\mathcal{M}}_{1,1}$. Computational verification: `eulerian_weight_mc_engine.py` (67 tests).

Remark 21.3.8 (The MC equation is not Eulerian-weight-graded). Neither the Lie bracket on $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ nor the differential D preserves Eulerian weight. The Lie bracket is determined by the weight-1 (Harrison/Lie^c) restriction via the PBW universal property, but individual MC elements (including κ for even-degree generators) live in higher weights. At genus ≥ 1 , the BV operator Δ_{cyc} further mixes weights. Consequence: the shadow obstruction tower $(\kappa, \mathfrak{C}, \mathfrak{Q}, \dots)$ cannot be recovered from the Harrison part alone. Instead, the *derivative tower* $\{\partial^k \phi\}_{k \geq 0}$, with desuspended degree $h+k-1$ alternating in parity, supplies all Eulerian weight classes at every degree, explaining how the Virasoro algebra (single generator, odd desuspended degree) achieves infinite shadow depth.

Example 21.3.9 (The E_1 shadow archetypes).

	$r^{\text{coll}}(z)$	$r_3(z_1, z_2)$	$r_4(z_1, z_2, z_3)$
Heisenberg $\mathcal{H}_k$	k/z	0	0
Affine $\hat{\mathfrak{g}}_k$	$k\Omega/z$	KZ associator $\Phi_{\text{KZ}}(\hat{\mathfrak{g}}_k)$	0
$\beta\gamma$	$\Theta_{\beta\gamma}$ (nilpotent, no pole)	0	$\mathfrak{Q}^{\text{ct}} \neq 0$
Virasoro	$(c/2)/z^3 + 2T/z$	non-trivial	non-trivial
$Y_h(\mathfrak{g})$	$r_{\text{YB}}(z)$	Drinfeld associator $\Phi_h(\mathfrak{g})$	non-trivial

Remark 21.3.10 (Three r -matrices: Laplace kernel, collision residue, pre-dualisation form). Three distinct objects share the notation $r(z)$ in this text. Each is a meromorphic function of the separation $z = z_1 - z_2$; they differ in pole orders, target spaces, and normalisation.

- (a) *Laplace kernel* $r_{\mathcal{A}}^{\text{L}}(z) = \int_0^\infty e^{-\lambda z} \{\cdot_\lambda \cdot\} d\lambda \in \mathcal{A} \widehat{\otimes} \mathcal{A}[[z^{-1}]]$: the full OPE generating function, encoding every singular term of the operator product expansion as a Laurent series in z^{-1} . Pole orders match the OPE directly.

$$\begin{aligned}
 \text{Heisenberg } \mathcal{H}_k: & \quad r^{\text{L}}(z) = k/z^2 \\
 \text{Affine } \hat{\mathfrak{g}}_k: & \quad r^{\text{L}}(z) = k \kappa^{ab}/z^2 + f^{ab}{}_c J^c/z \\
 \text{Virasoro:} & \quad r^{\text{L}}(z) = (c/2)/z^4 + 2T/z^2 + \partial T/z
 \end{aligned}$$

- (b) *Collision residue* $r_{\mathcal{A}}^{\text{coll}}(z) = \text{Res}_{0,2}^{\text{coll}}(\Theta_{\mathcal{A}}) \in \mathcal{A}^! \widehat{\otimes} \mathcal{A}^!$: the bar-theoretic r -matrix, extracted by residue along the collision divisor using the $d \log(z_1 - z_2)$ measure. Because $d \log$ absorbs one power of $(z_1 - z_2)$, every pole order drops by one relative to the Laplace kernel. For bosonic algebras,

only odd-order poles survive (even-order OPE poles descend to odd-order residues). The target space is $\mathcal{A}^! \otimes \mathcal{A}^!$: passage to the Koszul dual is part of the construction.

$$\begin{array}{ll} \text{Heisenberg } \mathcal{H}_k: & r^{\text{coll}}(z) = k/z \quad (\text{simple pole; OPE had double}) \\ \text{Affine } \hat{\mathfrak{g}}_k: & r^{\text{coll}}(z) = k \Omega_{\mathfrak{g}}/z \quad (\text{level-prefixed; vanishes at } k = 0) \\ \text{Virasoro:} & r^{\text{coll}}(z) = (c/2)/z^3 + 2T/z \quad (\text{cubic + simple; no even poles}) \end{array}$$

This is the master object from which the others descend: the genus-0, degree-2 shadow $r^{\text{coll}}(z) = \text{Sh}_{0,2}(\Theta_{\mathcal{A}})(z)$.

- (c) *Pre-dualisation form* $r^{\text{pre}}_{\mathcal{A}}(z) \in \mathcal{A} \otimes \mathcal{A}$: the collision residue computed in $\mathcal{A} \otimes \mathcal{A}$, before applying the Koszul pairing to pass one or both factors to $\mathcal{A}^!$. Pole orders are identical to (b); the target space and normalisation differ (the Koszul pairing absorbs a scalar factor).

$$\begin{array}{ll} \text{Heisenberg } \mathcal{H}_k: & r^{\text{pre}}(z) = k/z \\ \text{Affine } \hat{\mathfrak{g}}_k: & r^{\text{pre}}(z) = k \Omega_{\mathfrak{g}}/z \\ \text{Virasoro:} & r^{\text{pre}}(z) = (c/2)/z^3 + 2T/z \end{array}$$

Relations. The three are connected by two operations.

- $d \log$ extraction: $r^{\text{L}}(z) \xrightarrow{\text{Res}_{d \log}} r^{\text{pre}}(z)$. Every pole order drops by one. Mnemonic: $z^{-n} dz = z^{-(n-1)} d \log z$, so the residue along $d \log(z_1 - z_2)$ of a pole of order n in the OPE is a pole of order $n - 1$ in the collision residue.
- Koszul dualisation: $r^{\text{pre}}(z) \xrightarrow{\text{id} \otimes \kappa} r^{\text{coll}}(z)$. Same pole structure, different target space ($\mathcal{A} \otimes \mathcal{A} \rightarrow \mathcal{A}^! \otimes \mathcal{A}^!$).

The archetype table (Example 21.3.9) lists the collision residue $r^{\text{coll}}(z)$. The E_1 scalar shadow $r^{\text{sc}}(z) \in \mathbb{C}(z)$ is its vacuum projection; the Σ_2 -coinvariant of $r^{\text{sc}}(z)$ is the scalar curvature $\kappa(\mathcal{A})$.

Normalisation note for affine Kac–Moody. The archetype table (Example 21.3.9) lists $r(z) = k\Omega/z$: the canonical affine collision residue, with target fixed by context. Some formal constructions (e.g. the KZ connection, eq. (21.8)) use the Sugawara-normalised coefficient $(k+h^\vee)^{-1}\Omega z^{-1}$ in the connection kernel. That coefficient is not the canonical affine r -matrix: the latter carries the explicit level prefix k and vanishes at $k = 0$. For $k \neq 0$, the two expressions are related by the separate Koszul-pairing and Sugawara normalizations, which contribute factors of k and $(k+h^\vee)$ respectively. (The Koszul-dual level shift $k \mapsto -k - 2h^\vee$ is a *separate* operation on the underlying family of chiral algebras; it is not accomplished by this rescaling alone. See in the concordance.)

Convention. When the text writes $r(z)$ unqualified, the context determines which variant is meant. In the archetype table (Example 21.3.9) and the holographic datum (Chapter ??), $r(z) = r^{\text{coll}}(z)$ is the collision residue. In the Σ_2 -coinvariant projection to $\kappa(\mathcal{A})$, $r(z) = r^{\text{sc}}(z)$ is the scalar shadow. In explicit OPE computations, $r(z) = r^{\text{L}}(z)$ is the Laplace kernel.

Remark 21.3.11 (Arithmetic refinement of E_1 shadow depth). The E_1 shadow depth r_{max} admits a finer decomposition $d = 1 + d_{\text{arith}} + d_{\text{alg}}$ via Theorem S.9.1 (Chapter S), where d_{arith} counts critical lines of L -functions governing the spectral curve and d_{alg} records the algebraic shadow obstruction tower contribution.

Construction 21.3.12 (KZ associator as degree-3 E_1 shadow of $\hat{\mathfrak{g}}_k$). For $\mathcal{A} = \hat{\mathfrak{g}}_k$ (affine Kac–Moody algebra), the ordered bar complex on $\overline{\text{FM}}_3^{\text{ord}}(\mathbb{C})$ carries the KZ connection

$$\nabla_{\text{KZ}} = d - \frac{1}{k + h^\vee} \left(\frac{\Omega_{12}}{z_1 - z_2} dz_{12} + \frac{\Omega_{23}}{z_2 - z_3} dz_{23} \right), \quad (21.8)$$

where $\Omega_{ij} = \sum_a t_i^a \otimes t_j^a$ is the Casimir acting on the i -th and j -th tensor factors. The monodromy of this connection as the ordered pair (z_1, z_2, z_3) traverses the boundary cycle of $\overline{\text{FM}}_3^{\text{ord}}(\mathbb{C})$ is the *KZ associator*

$$\Phi_{\text{KZ}} = \sum_{w \in \{t_{12}, t_{23}\}^*} \zeta(w) w \in \exp(\widehat{\text{Lie}}(t_{12}, t_{23})),$$

with $\zeta(w)$ the Drinfeld–Kontsevich multiple zeta values. This is the degree-3 E_1 shadow:

$$r_3(\hat{\mathfrak{g}}_k) = \Phi_{\text{KZ}}(\hat{\mathfrak{g}}_k) = \Phi_{\text{KZ}}\left(\frac{1}{k+h^\vee} \Omega_{12}, \frac{1}{k+h^\vee} \Omega_{23}\right).$$

The coinvariant $\text{av}(\Phi_{\text{KZ}}) = \mathfrak{C}(\hat{\mathfrak{g}}_k)$ is the cubic shadow: the Σ_3 -averaged monodromy reduces to $\kappa(\hat{\mathfrak{g}}_k) \cdot (x, [y, z])$.

Construction 21.3.13 (Formal ordered degree-2 shadow series). The genus-refined degree-2 projection of the ordered E_1 Maurer–Cartan element defines the formal series

$$R^{E_1, \text{bin}}(z; \hbar) = \sum_{g \geq 0} \hbar^{2g} r_g(z)$$

with genus-0 term $r_0(z) = R(z)$ equal to the ordered genus-0 exchange kernel. This series is the formal ordered degree-2 shadow package attached to $\Theta_{\mathcal{A}}^{E_1}$.

Its coefficientwise Maurer–Cartan relations come from the degree-2 projection of the ordered E_1 MC equation. On affine or free benchmark surfaces one expects elliptic/genus-1 formulas for the first correction $r_1(z)$, but such line-side modular-kernel realizations are not part of the proved theorem surface of this chapter.

21.4 THE E_1 FIVE MAIN THEOREMS AT ALL GENERA

The genus-0 theory promoted each E_∞ shadow invariant to an E_1 shadow at the same degree: the scalar κ to the spectral r -matrix, the cubic shadow $\mathfrak{C}$ to the Drinfeld associator. The genus tower so far still uses the commutative modular operad $\mathcal{M}_{\text{Com}}$; the promotion is incomplete until the same replacement happens at every genus. The genus- g ordered bar complex on $\mathcal{M}_{\text{Ass}}$ supplies the missing structure: the r -matrix acts on internal edges, the associator controls vertex reordering, and the genus- g partition function acquires a ribbon surface decomposition invisible to Σ_n -coinvariants. The five theorems $A^{E_1} - H^{E_1}$ below extend the bar–cobar package at all cyclic genera (g, n) with $2g - 2 + n > 0$.

THEOREM 21.4.1 (*Theorem A^{E_1} at all genera: ordered bar–cobar adjunction;*). Let $\mathcal{A}$ be a cyclic E_1 -chiral algebra. The genus- g ordered bar complex $\overline{B}^{\text{ch ord}}(\mathcal{A})(g, n)$ is an $F\text{Ass}$ -coalgebra (Definition 21.1.3) with differential satisfying $D^2 = 0$. The bar and cobar functors at genus g form an adjunction

$$\Omega^{(g)} \dashv \overline{B}^{\text{ch}(g)} : \text{Alg}_{F\text{Ass}} \rightleftarrows \text{Coalg}_{F\text{Ass}}.$$

Koszul exchange carries the formal ordered degree-2 shadow series $R^{E_1, \text{bin}}(z; \hbar)$ (Construction 21.3.13): its genus- g coefficient records the ordered degree-2 correction on this bar-level surface. Interpreting this series as a genuine higher-genus line-side modular R -matrix requires extra Yangian input not proved here. The coinvariant projection $F\text{Ass}/\Sigma_n \xrightarrow{\sim} F\text{Com}$ (Theorem 21.1.5) recovers Theorem A from Theorem A E_1 .

Proof. The $F\text{Ass}$ -coalgebra structure on the ordered bar complex follows from the universal property of the Feynman transform: $D_{F\text{Ass}}^2 = 0$ (Theorem 21.1.4) gives the differential on the graph complex, and the bar differential of $\mathcal{A}$ at each vertex is compatible with the operad composition maps of $\mathcal{M}_{\text{Ass}}$. The adjunction follows by the same argument as in the E_∞ case (Theorem 7.0.51), replacing the commutative modular operad by $\mathcal{M}_{\text{Ass}}$: the cobar construction $\Omega^{(g)}$ is defined as the tensor algebra over $F\text{Ass}$ with differential dual to the coalgebra structure.

The formal ordered degree-2 shadow package: at each genus g , the opposite-duality identification $\overline{B}^{\text{chord}}(\mathcal{A}^{\text{op}}) \cong \overline{B}^{\text{chord}}(\mathcal{A})^{\text{cop}}$ is encoded at the degree-2 shadow level by $R^{E_1, \text{bin}}(z; \hbar)$ restricted to genus $\leq g$. This is the E_1 analogue of Verdier intertwining on the ordered bar surface. $\square$

THEOREM 21.4.2 (*Theorem B E_1 at all genera: ordered bar-cobar inversion;*). On the E_1 Koszul locus, the counit

$$\Omega^{(g)}(\overline{B}^{\text{chord}}(\mathcal{A})(g, \bullet)) \xrightarrow{\sim} \mathcal{A}$$

is a quasi-isomorphism at every genus g , and the E_1 Koszul dual $\mathcal{A}^{!, E_1}$ is an E_1 -chiral algebra at all genera.

Proof. PBW-completeness transfers from genus 0 to genus g via the MC perturbation lemma: the genus- g differential is a perturbation of the genus-0 differential by curvature $\kappa(\mathcal{A}) \cdot \omega_g$, and this perturbation preserves the PBW filtration (the curvature is in the center of the algebra). The inversion theorem for perturbed complexes (the filtered quasi-isomorphism criterion of Theorem 8.6.1) then gives the result at each genus. $\square$

THEOREM 21.4.3 (*Theorem C E_1 at all genera: ordered complementarity;*). At genus g and each degree n with $2g - 2 + n > 0$, the ordered complementarity takes the form

$$Q_{g,n}^{E_1}(\mathcal{A}) + Q_{g,n}^{E_1}(\mathcal{A}^{!, E_1}) = H^*(\overline{\mathcal{M}}_{g,n}^{\text{rib}}, Z^{E_1}(\mathcal{A})),$$

where $Q_{g,n}^{E_1}(\mathcal{A}) := C_{\Delta}^{(g,n)} \square_{C^{e,(g,n)}}^{\mathbf{R}} C_{\Delta}^{(g,n)}$ is the genus- g , degree- n ordered partition function and $Z^{E_1}(\mathcal{A})$ is the E_1 center (the space of R -matrix-equivariant elements).

The scalar complementarity identity $\kappa(\mathcal{A}) + \kappa(\mathcal{A}^!) = 0$ for KM/free fields ($\kappa(\mathcal{A}) + \kappa(\mathcal{A}^!) = \varrho \cdot K$ for W -algebras, Theorem 13.21.44) is unchanged; the ordered refinement enriches it with R -matrix-equivariance on the ambient cohomology.

Proof. The genus- g ordered complementarity extends from genus 0 (the genus-0 ordered complementarity theorem) by the same modular extension principle used for the E_∞ complementarity (Theorem 13.15.14): the E_1 MC element $\Theta_{\mathcal{A}}^{E_1}$ gives a genus- g deformation of the genus-0 diagonal bicomodule, and the ordered Hochschild-coHochschild identification carries through at each genus. The E_1 center $Z^{E_1}(\mathcal{A})$ is the subspace of elements satisfying $R(z) \cdot a = a$ (braiding-invariant), replacing the naive center of the E_∞ theory. $\square$

THEOREM 21.4.4 (*Theorem D E_1 at all genera: formal ordered degree-2 shadow series;*). The formal ordered degree-2 shadow series $R^{E_1, \text{bin}}(z; \hbar) = \sum_{g \geq 0} \hbar^{2g} r_g(z)$ obtained from the genus-refined degree-2

projection of $\Theta_{\mathcal{A}}^{E_1}$ is the E_1 degree-2 characteristic package of $\mathcal{A}$. It satisfies the degree-2 projection of the ordered Maurer–Cartan equation

$$D R^{E_1, \text{bin}} + \frac{1}{2} [R^{E_1, \text{bin}}, R^{E_1, \text{bin}}] = 0 \quad (21.9)$$

in $\mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}$, and its properties mirror those of the scalar $\kappa(\mathcal{A})$:

- (i) *Universality*: $R^{E_1, \text{bin}}$ depends only on the E_1 -chiral algebra $\mathcal{A}$, not on auxiliary choices.
- (ii) *Additivity*: for $\mathcal{A} = \mathcal{A}_1 \otimes \mathcal{A}_2$ with vanishing mixed OPE, $R_{\mathcal{A}_1 \otimes \mathcal{A}_2}^{E_1, \text{bin}} = R_{\mathcal{A}_1}^{E_1, \text{bin}} \otimes 1 + 1 \otimes R_{\mathcal{A}_2}^{E_1, \text{bin}}$.
- (iii) *Anti-symmetry*: $R_{\mathcal{A}^{\text{op}}}^{E_1, \text{bin}}(z; \hbar) = R_{\mathcal{A}}^{E_1, \text{bin}}(z; \hbar)^{-1}$ on the ordered bar surface.
- (iv) *Coinvariant recovery*: $\text{av}(R^{E_1, \text{bin}}(z; \hbar)) = \kappa(\mathcal{A}) + O(\hbar^2)$.

This theorem packages the ordered degree-2 shadow data only. A genuine higher-genus line-side modular R -matrix interpretation is additional Yangian input and is not proved here.

Proof. The degree-2 ordered Maurer–Cartan relation (21.9) is the degree-2 MC equation in $\mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}$: it follows from $D_{F\text{Ass}}^2 = 0$ by restriction to the two-point component.

(i) Universality: $R^{E_1, \text{bin}}$ is determined by the $F\text{Ass}$ -coalgebra structure on $\overline{B}^{\text{chord}}(\mathcal{A})$, which depends only on $\mathcal{A}$.

(ii) Additivity: for $\mathcal{A} = \mathcal{A}_1 \otimes \mathcal{A}_2$ with vanishing mixed OPE, the ordered bar complex decomposes as a product $\overline{B}^{\text{chord}}(\mathcal{A}_1 \otimes \mathcal{A}_2) \cong \overline{B}^{\text{chord}}(\mathcal{A}_1) \otimes \overline{B}^{\text{chord}}(\mathcal{A}_2)$ (ordered shuffle theorem), and the monodromy of a product connection is additive.

(iii) Anti-symmetry: opposite-duality gives $\overline{B}^{\text{chord}}(\mathcal{A}^{\text{op}}) \cong \overline{B}^{\text{chord}}(\mathcal{A})^{\text{cop}}$, and the monodromy of the co-opposite is the inverse.

(iv) Coinvariant: by Theorem 21.3.3 at degree 2. $\square$

THEOREM 21.4.5 (*Theorem H^{E_1} at all genera: ordered Hochschild at genus g ;*). For every genus g and complete $\mathcal{A}$ -bimodule M , the genus- g ordered Hochschild homology is computed coalgebraically:

$$\text{HH}_{\bullet}^{\text{ch}, (g)}(\mathcal{A}, M) \simeq \text{coHH}_{\bullet}^{\text{ch}, (g)}(C, \mathbb{K}_{\mathcal{A}}^{\text{bi}}(M)),$$

where $C = \overline{B}^{\text{chord}}(\mathcal{A})$ and the genus- g twisted differential uses the curvature $\kappa(\mathcal{A}) \cdot \omega_g$. The Σ_n -coinvariant of the ordered Hochschild complex recovers the symmetric Hochschild complex of Theorem H.

Proof. The genus- g extension of the Hochschild–coHochschild dictionary (the genus-0 ordered Hochschild theorem) follows by the same modular perturbation argument as Theorem 21.4.2: the genus- g perturbation preserves the bimodule-bicomodule equivalence. $\square$

Remark 21.4.6 (*Resolution of the ordered associative modular Maurer–Cartan theorem*). Theorems 21.4.1–21.4.5 establish the associative modular MC theory asked for by Theorem 22.30.5: the E_1 deformation complex is $\mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1}$ (Definition 21.1.6), and the canonical MC element is $\Theta_{\mathcal{A}}^{E_1} := D_{\mathcal{A}}^{E_1} - d_0$. The “ordered cyclic compactification” sought in the proof-obligations remark is exactly the Feynman transform $F\text{Ass}$ of the ribbon modular operad (Definition 21.1.3).

Remark 21.4.7 (Symmetric-ordered comparison table). The following table summarises the five theorems and their ordered counterparts. Each symmetric theorem is the Σ_n -coinvariant of the corresponding ordered theorem.

	Symmetric (E_∞)	Ordered (E_1)	Refinement
A (existence)	$\overline{B}^{\text{ch}}(\mathcal{A}): F\text{Com-coalgebra}$	$\overline{B}^{\text{chord}}(\mathcal{A}): F\text{Ass-coalgebra}$	associahedra replace permutohedra
B (inversion)	$\Omega(\overline{B}^{\text{ch}}(\mathcal{A})) \simeq \mathcal{A}$	$\Omega^{\text{ord}}(\overline{B}^{\text{chord}}(\mathcal{A})) \simeq \mathcal{A}$	retains R -matrix and associator
C (complementarity)	$Q_g + Q_g^! = H^*(\overline{\mathcal{M}}_{g,n}, Z)$	$Q_g^{E_1} + Q_g^{!,E_1} = H^*(\overline{\mathcal{M}}_{g,n}^{\text{rib}}, Z^{E_1})$	R -equivariant center replaces center
D (leading coeff.)	$\kappa(\mathcal{A})$ (scalar)	$r(z) = \text{collision residue (spectral)}$	scalar $\rightarrow$ meromorphic function
H (chiral Hochschild)	$\text{HH}^{\text{ch}}(\mathcal{A}, \mathcal{A}) \simeq Z^{\text{der}}(\mathcal{A})$	$\text{HH}^{E_1}(\mathcal{A}, M) \simeq \text{ordered center}$	ordered Hochschild $\rightarrow$ line algebra

Physically, the symmetric column governs the *bulk* (closed-string/holomorphic) sector: the partition function, the deformation ring, the genus tower. The ordered column governs the *line-operator* (open-string/topological) sector: the R -matrix, the Drinfeld associator, the spectral genus tower. The coinvariant projection $\text{av}: \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1} \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ is the functor that forgets the ordering and recovers the bulk from the boundary.

Remark 21.4.8 (E_1 primitive kernel). The cofree-coderivation principle for $F\text{Ass}$ yields an E_1 primitive kernel

$$K_{\mathcal{A}}^{E_1} := \log_{\star}(\Theta_{\mathcal{A}}^{E_1}) \in \prod_{\substack{g,n \\ 2g-2+n>0}} \text{End}(V^{\otimes n}) \otimes \Omega^{n-2}(\overline{\text{FM}}_n^{\text{ord}}(\mathbb{C})),$$

where $\log_{\star}$ is the operadic logarithm on the $F\text{Ass}$ -coalgebra $\overline{B}^{\text{chord}}(\mathcal{A})$, decomposing the full MC element into primitive (one-vertex) contributions.

Coinvariant recovery. The averaging map of Definition 21.1.6 sends the E_1 primitive kernel to the E_∞ primitive kernel:

$$\text{av}(K_{\mathcal{A}}^{E_1}) = K_{\mathcal{A}}.$$

This is the primitive-level refinement of Theorem 21.3.3: the coinvariant projection is compatible with the operadic logarithm because av is a dg Lie morphism.

Low-degree identifications.

- (i) $(K_{\mathcal{A}}^{E_1})_{0,2} = r(z)$, the classical r -matrix (genus 0, degree 2). The coinvariant $\text{av}(r(z)) = \kappa(\mathcal{A})$ recovers the scalar curvature.
- (ii) $(K_{\mathcal{A}}^{E_1})_{0,3} = \Phi_{\text{KZ}}(\mathcal{A})$, the KZ/Drinfeld associator (genus 0, degree 3, for affine algebras; Construction 21.3.12). Coinvariant: $\text{av}(\Phi_{\text{KZ}}) = \mathfrak{C}(\mathcal{A})$, the cubic shadow.
- (iii) $(K_{\mathcal{A}}^{E_1})_{1,1}$ is the genus-1 primitive, whose coinvariant gives the genus-1 curvature $\kappa(\mathcal{A}) \cdot \lambda_1$ (all-weight, with cross-channel correction $\delta F_g^{\text{cross}}$; at $g = 1$ this correction vanishes).

E_1 primitive master equation. The MC equation $D\Theta^{E_1} + \frac{1}{2}[\Theta^{E_1}, \Theta^{E_1}] = 0$ expressed in primitive generators takes the form

$$dK_{\mathcal{A}}^{E_1} + K_{\mathcal{A}}^{E_1} \star_{E_1} K_{\mathcal{A}}^{E_1} = 0, \quad (21.10)$$

where $\star_{E_1}$ is the convolution product on the $F\text{Ass}$ modular cooperad, whose degree- r component is governed by the face structure of the Stasheff associahedron K_{r+1} . In particular, the degree-2 component of (21.10) is the classical Yang–Baxter equation, and the degree-3 component is the pentagon equation. Averaging recovers the E_∞ primitive master equation $dK_{\mathcal{A}} + K_{\mathcal{A}} \star K_{\mathcal{A}} + \hbar \Delta_{\text{ns}}(K_{\mathcal{A}}) = 0$.

Remark 21.4.9 (Lie/associative dichotomy in the averaging kernel). The averaging map $\text{av}: \mathfrak{g}_{\mathcal{A}}^{\text{mod } E_1} \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ exhibits a Lie/associative dichotomy: at degree 3, the linearized Drinfeld associator $[t_{12}, t_{23}]$ (a Lie commutator) lies entirely in $\ker(\text{av})$: its Σ_3 -average vanishes exactly because the commutator is antisymmetric under the transposition $(1 \leftrightarrow 3)$. The modular cubic shadow $\mathfrak{C}(\mathcal{A}) = \text{av}(\Phi_{\text{KZ}})$ receives contributions only from the symmetric/associative products $t_{12}t_{23} + t_{23}t_{12}$ in the full KZ associator Φ_{KZ} . The modular shadow sees only the associative content of quantization, not the Lie content. Physically: the closed-sector (modular) invariants encode the Hilbert-space tensor product structure (associative), while the open-sector (E_1) invariants encode the braiding/ R -matrix structure (Lie bracket content).

PROPOSITION 21.4.10 (Σ_n -irreducible decomposition of the ordered bar complex;). Let $V = \bigoplus_i \mathbb{C} \cdot \phi_i$ be the generating space of a chiral algebra $\mathcal{A}$, with $\dim V = d$ and desuspended degree $|s^{-1}\phi_i| = h_i - 1$ where h_i is the conformal weight of ϕ_i . The Σ_n -action on the ordered bar component $B^{\text{ord}, n}(\mathcal{A}) \supset V^{\otimes n}$ has:

(i) *Schur–Weyl decomposition.* As a $\text{GL}(V) \times \Sigma_n$ -representation:

$$V^{\otimes n} = \bigoplus_{\substack{\lambda \vdash n \\ \ell(\lambda) \leq d}} \mathbf{S}^\lambda(V) \otimes V_\lambda,$$

where $\mathbf{S}^\lambda(V)$ is the Schur functor and V_λ is the irreducible Σ_n -representation indexed by λ . The multiplicity of V_λ equals $\dim \mathbf{S}^\lambda(V)$, computed by the Weyl dimension formula.

(ii) *Frobenius characteristic.* The character of the Σ_n -representation on $V^{\otimes n}$ is

$$\text{ch}(V^{\otimes n}) = \sum_{\lambda \vdash n} \dim(\mathbf{S}^\lambda(V)) s_\lambda,$$

where s_λ is the Schur function. This encodes which Σ_n -irreps contribute at each bar degree.

(iii) *Kernel of av.* The averaging map av projects onto a single isotypic component: for generators of even desuspended degree (h odd: Heisenberg, affine KM), av retains the *trivial* representation $V_{(n)}$; for generators of odd desuspended degree (h even: Virasoro), the Koszul sign makes av retain the *sign* representation $V_{(1^n)}$. All other isotypic components lie in $\ker(\text{av})$ and are annihilated.

(iv) *Information ratio.* The fraction of ordered bar data surviving av is

$$\frac{\dim \text{im}(\text{av}|_{V^{\otimes n}})}{\dim V^{\otimes n}} = \frac{\binom{d+n-1}{n}}{d^n} \quad (\text{even desuspended degree}), \quad \frac{\binom{d}{n}}{d^n} \quad (\text{odd desuspended degree}).$$

For $\mathfrak{sl}_2$ ($d = 3$) at $n = 4$: $\dim V^{\otimes 4} = 81$, $\dim \text{Sym}^4(V) = 15$, ratio $\approx 18.5\%$. For Virasoro single generator ($d = 1$), the ratio is $1/1 = 100\%$ at every n (consistent with the trivial Σ_n -action on a one-dimensional space).

Proof. Part (i) is the Schur–Weyl theorem for $\text{GL}_d \times \Sigma_n$ acting on $V^{\otimes n}$ (Fulton–Harris [185], Appendix A). Part (ii) is its translation into the symmetric-function basis. Part (iii): the Reynolds operator $(1/n!) \sum_{\sigma} \sigma$

projects onto the Σ_n -invariant subspace, which for degree-0 elements is $\text{Sym}^n(V)$ (the trivial isotypic) and for degree-1 elements acquires Koszul signs that convert the trivial projection into the sign projection. Part (iv): $\dim \text{Sym}^n(V) = \binom{d+n-1}{n}$ and $\dim \Lambda^n(V) = \binom{d}{n}$ are the standard multiset and subset counts. Computational verification: `sn_bar_irrep_decomp_engine.py` (Schur–Weyl decomposition, character tables for Σ_1 – Σ_5 , hook-length formula, 120+ tests). $\square$

21.5 CYCLIC TRACE, RIBBON STRUCTURE, AND THE $1/N$ EXPANSION

The E_1 modular theory organises amplitudes by genus through the ribbon modular operad, but a bare stable graph carries no canonical N -weight: the Euler characteristic $\chi(\Sigma_\Gamma)$ requires a ribbon surface, hence a cyclic ordering at each vertex. The missing datum is a cyclic trace on the open-color algebra.

LEMMA 21.5.1 (*Bare graphs do not determine a 't Hooft expansion*;). A bare modular stable-graph expansion does not canonically define a 't Hooft N -expansion.

Proof. The N -weight in a 't Hooft expansion is $N^{V-E+F} = N^{\chi(\Sigma_\Gamma)}$, determined by the number of faces F of the thickened surface Σ_Γ . A bare stable graph does not specify cyclic orderings of half-edges at vertices; hence it does not determine a ribbon surface, hence does not determine F , hence carries no canonical N -power. The same underlying graph admits inequivalent ribbon structures with different genera. $\square$

THEOREM 21.5.2 (*Cyclicity is the ribbon-enabling datum*;). Let $(O, m_\bullet, \tau)$ be a graded vector space with multilinear operations $m_n: O^{\otimes n} \rightarrow O$ and a degree-zero nondegenerate bilinear pairing $\tau: O \otimes O \rightarrow k$. Define the cyclic tensors

$$\tilde{m}_n(x_0, \dots, x_n) := \tau(m_n(x_1, \dots, x_n), x_0).$$

If $\tilde{m}_n$ satisfies cyclic invariance $\tilde{m}_n(x_0, \dots, x_n) = (-1)^\epsilon \tilde{m}_n(x_1, \dots, x_n, x_0)$ (with Koszul sign ϵ), then each operation m_n determines a cyclic $(n+1)$ -tensor, and every Feynman graph built from these tensors canonically thickens to a ribbon graph.

Proof. The pairing identifies $\text{Hom}(O^{\otimes n}, O) \cong \text{Hom}(O^{\otimes(n+1)}, k)$. Under this identification, m_n becomes the $(n+1)$ -linear form $\tilde{m}_n$. Cyclic invariance means $\tilde{m}_n$ descends to a function on cyclic words of length $n+1$: there is no distinguished output among the $n+1$ legs. Each vertex therefore carries a cyclic order on its incident half-edges, which is exactly the data needed for canonical ribbon thickening: at each vertex, the cyclic order determines the local surface, and gluing via internal edges produces a global ribbon surface Σ_Γ with a well-defined face decomposition. $\square$

COROLLARY 21.5.3 (*Operads are too small for traces*;). Any open/closed theory closed under Swiss-cheese composition and trace-contraction cannot be encoded by a rooted operad. The minimal closure is a wheeled two-colored operadic object; for multi-interface gluing, a properad.

Proof. Operadic composition is indexed by rooted trees (acyclic, one output per vertex). Trace-contraction $\sum_i m_2(x, e_i) \otimes e^i$ creates a one-vertex graph with a loop, not an operadic graph. The closure under both composition and contraction generates graphs with arbitrary numbers of loops: wheeled graphs. Properadic structure allows multiple outputs per vertex, accommodating multi-boundary and multi-interface gluing. $\square$

THEOREM 21.5.4 (*Exact N^χ weighting from traced open color;*). Let $(O, m_\bullet, \tau)$ be a cyclic A_∞ -algebra with matrix realization $O_N := \text{Mat}_N \otimes O_0$ and trace $\tau_N := \text{Tr}_N \otimes \tau_0$. For a connected ribbon graph Γ with V vertices, E edges, and F faces, the bare amplitude scales as N^F (one factor per closed index loop). Under 't Hooft rescaling $g^2 \mapsto \lambda/N$, the rescaled amplitude factors as

$$\text{Amp}_\Gamma^\lambda(O_N) = N^{V-E+F} \cdot \text{Amp}_\Gamma^{\text{red}}(O_0, \lambda) = N^{\chi(\Sigma_\Gamma)} \cdot \text{Amp}_\Gamma^{\text{red}}(O_0, \lambda).$$

The total genus expansion is then

$$\sum_{\Gamma \text{ ribbon}} \frac{N^{\chi(\Sigma_\Gamma)}}{|\text{Aut}_{\text{rib}}(\Gamma)|} W_\Gamma \Phi_\Gamma^T = \sum_{g=0}^{\infty} N^{2-2g} F_g(\lambda),$$

(all-weight, with cross-channel correction $\delta F_g^{\text{cross}}$). where $\lambda = g_{\text{YM}}^2 N$. This is a literal 't Hooft expansion: the N -power is determined by the Euler characteristic of the thickened surface.

Proof. Cyclic structure (Theorem 21.5.2) gives canonical ribbon thickening, so faces are well-defined. We count N -powers in two steps.

Step 1: bare double-line counting. With the normalization $\tau_N = \text{Tr}_N$ (not $(1/N) \text{Tr}_N$), the propagator $\tau_N^{-1} = \sum_{i,j} E_{ij} \otimes E_{ji}$ carries no explicit N -factor: it merely routes double-line indices through each internal edge. Likewise, vertex traces route indices but produce no bare N -powers. The only source of N is the summation over each closed index loop: every face of the ribbon graph Γ corresponds to one such loop, contributing a factor of N . Hence the bare amplitude scales as N^F .

Step 2: 't Hooft rescaling. Writing the action with overall normalization $g^{-2} \tau_N(\cdots)$, each propagator acquires g^2 and each vertex g^{-2} , giving total coupling $g^{2(E-V)}$. Setting $\lambda = g^2 N$ yields $g^{2(E-V)} = (\lambda/N)^{E-V}$, so the rescaled amplitude carries N -power $F - (E - V) = V - E + F = \chi(\Sigma_\Gamma)$ by Euler's formula. $\square$

Remark 21.5.5 (*The logical chain*).

$$\text{modular graph sum} + \text{cyclic trace} + \text{matrix realization} \implies \text{literal 't Hooft sum}.$$

Plain modular E_1 gives genus-organized expansion. Cyclic traced modular E_1 gives 't Hooft expansion. Ribbonized modular Swiss-cheese gives holographic open/closed 't Hooft language.

Definition 21.5.6 (*Ribbonized modular Swiss-cheese theory*). The *ribbonized modular Swiss-cheese theory* $\text{RSC}_{\text{tr}}^{\text{mod}}$ is the two-colored wheeled modular properad with:

- (i) *closed color*: the modular/chiral sector (Chapters 13.21–21);
- (ii) *open color*: the E_1 /chiral or A_∞ -chiral line sector;
- (iii) *mixed operations*: bulk-to-boundary and boundary-to-line interactions;
- (iv) *trace data*: a nondegenerate invariant pairing τ on the open color;
- (v) *wheel operations*: contractions of outputs with inputs via τ ;
- (vi) *ribbon data*: cyclic order at each open vertex, so every open graph thickens to a surface (Theorem 21.5.2).

The open input is a cyclic A_∞ -object $(O, m_\bullet, \tau)$; the closed input is the modular datum $\Theta_{\mathcal{A}}$. The tree part recovers the Boardman–Vogt resolution $W(\mathrm{SC}^{\mathrm{ch}, \mathrm{top}})$ of the Swiss-cheese operad (Volume II, §K.7.1).

Remark 21.5.7 (The correct holographic language). The three levels of language are:

Language	Content
plain modular E_1	genus-organized expansion
cyclic traced modular E_1	't Hooft $1/N$ expansion
ribbonized modular Swiss-cheese	holographic open/closed 't Hooft language

Chapter 22

Ordered Associative Chiral Koszul Duality

22.1 INTRODUCTION

The ordered bar complex $\overline{B}^{\text{ch,ord}}(A)$ of a chiral algebra A is the cofree coalgebra $T^c(s^{-1}\bar{A})$ with differential extracting collision residues at consecutive points and coproduct from interval-cutting. Its linear dual, on the chirally Koszul locus, is the dg-shifted Yangian.

Three bar complexes coexist and must not be conflated. The Francis–Gaitsgory bar $\overline{B}^{\text{ch,FG}}(A)$ uses only the zeroth product $a_{(0)}b$ and sees the chiral Lie structure. The symmetric bar $\overline{B}^{\text{ch},\Sigma}(A)$ uses all OPE products and takes Σ_n -coinvariants; this is the bar complex of Theorem A. The ordered bar $\overline{B}^{\text{ch,ord}}(A)$ uses all OPE products but retains the linear ordering on configurations, with no Σ_n quotient. The natural map $\overline{B}^{\text{ch,ord}} \rightarrow \overline{B}^{\text{ch},\Sigma}$ takes coinvariants; the associated graded of $\overline{B}^{\text{ch},\Sigma}$ recovers $\overline{B}^{\text{ch,FG}}$.

Let $C = \overline{B}^{\text{ch}}(A)$ denote the ordered bar coalgebra. The coalgebra-side avatar of the diagonal bimodule ${}_A A_A$ is the *diagonal bicomodule* C_Δ , the coalgebra C equipped with its coproduct on both sides. Interval composition on the algebra side is derived tensor over A ; on the coalgebra side it is derived cotensor over C . The annulus is the self-cotensor:

$$\mathrm{HH}_\bullet^{\text{ch}}(A) \simeq C_\Delta \square_{C^e}^{\mathbf{R}} C_\Delta.$$

The ordered bar complex presents the E_1 -chiral Koszul dual as the Steinberg variety presents the Hecke algebra: the associative dual already remembers the open boundary formalism.

22.2 THE STRONGLY ADMISSIBLE REGIME AND THE FOUNDATIONAL INPUTS

We work over a field k of characteristic 0. Let X be a smooth curve over k , and let $\mathcal{D}(X)$ denote the relevant derived category of D -modules on X (or on the Ran space of X) endowed with the chiral tensor product

$$\otimes^{\text{ch}} := \boxtimes_{D_X}.$$

An E_1 -chiral algebra means an algebra over the non- Σ operad Ass^{ch} .

Definition 22.2.1 (Strongly admissible associative chiral algebra). An augmented E_1 -chiral algebra A on X is called *strongly admissible* if the following hold.

- (a) A is pro-nilpotent and equipped with an exhaustive separated descending PBW-type filtration $F^\bullet A$ which is complete for the induced topology.
- (b) Every associated graded piece and every finite filtration quotient is bounded below and perfect enough that completed tensor products, totalizations, and normalized chains behave exactly on these pieces.
- (c) The reduced ordered bar coalgebra

$$C := \overline{B}^{\text{ch}}(A)$$

is conilpotent, and the corresponding coderived category of bicomodules admits enough coflat resolutions so that derived cotensor products are defined and associative.

- (d) Whenever linear duality is invoked, each graded/conformal piece of the object under consideration is finite-dimensional.

Remark 22.2.2. These hypotheses ensure that every totalization, completion, normalization, and passage to coderived categories is legitimate. The arguments below require nothing more.

Hypothesis 22.2.3 (Repository inputs). We assume the repository has already established the following.

- (I) **Associative chiral bar–cobar.** For every augmented pro-nilpotent strongly admissible E_1 -chiral algebra A there is a quasi-isomorphism

$$\Omega \overline{B}^{\text{ch}}(A) \xrightarrow{\sim} A,$$

and, on the appropriate coalgebra side, the corresponding bar–cobar adjunction is an equivalence.

- (I) **One-sided module/comodule duality.** For every such A there is an equivalence between complete left A -modules and conilpotent left $\overline{B}^{\text{ch}}(A)$ -comodules, with the usual coderived/contraderived refinement in the curved or completed regime.

- (I) **Enveloping algebra formalism.** The chiral enveloping algebra

$$A^e := A \otimes^{\text{ch}} A^{\text{op}}$$

is defined, and A -bimodules are equivalently left A^e -modules.

Definition 22.2.4 (Universal twisting cochain). Let A be strongly admissible and set $C := \overline{B}^{\text{ch}}(A)$. The bar–cobar equivalence produces a canonical twisting cochain

$$\tau : C \rightarrow A$$

characterized by the Maurer–Cartan equation

$$d\tau + \tau \star \tau = 0.$$

We call τ the *universal twisting cochain*.

Definition 22.2.5 (Opposite and diagonal objects). Let A be an associative chiral algebra and let C be a coaugmented dg coalgebra.

- (a) A^{op} is the same underlying object with multiplication reversed.
- (b) C^{cop} is the same underlying object with coproduct flipped.
- (c) The *coalgebraic enveloping object* is

$$C^e := C \widehat{\otimes} C^{\text{cop}}.$$

- (d) The *diagonal bicomodule* C_Δ is C equipped with left and right coactions both equal to Δ_C .

LEMMA 22.2.6 (*Bicomodules as comodules over the enveloping coalgebra*). Let C be a coaugmented conilpotent dg coalgebra. Then left C^e -comodules are canonically the same thing as C -bicomodules.

Proof. Given a left C^e -coaction

$$\rho^e : M \rightarrow C \otimes C^{\text{cop}} \otimes M,$$

compose with the counit on the second factor and on the first factor to obtain

$$\lambda = (\text{id}_C \otimes \varepsilon \otimes \text{id}_M) \rho^e : M \rightarrow C \otimes M,$$

$$\rho = (\varepsilon \otimes \text{id}_{C^{\text{cop}}} \otimes \text{id}_M) \rho^e : M \rightarrow M \otimes C.$$

These are a left and a right C -coaction, and coassociativity of ρ^e is equivalent to the usual bicomodule compatibility condition.

Conversely, given commuting left and right coactions λ and ρ , define

$$\rho^e = (\text{id}_C \otimes \tau_{C,M} \otimes \text{id}_M) \circ (\lambda \otimes \text{id}_M) \circ \rho : M \rightarrow C \otimes C^{\text{cop}} \otimes M,$$

where $\tau_{C,M}$ swaps the middle two factors. The bicomodule axioms are precisely the coassociativity and counitality conditions for ρ^e . $\square$

Definition 22.2.7 (*Chiral Hochschild and coHochschild theories*). Let A be a strongly admissible associative chiral algebra and $C = \overline{B}^{\text{ch}}(A)$. For an A -bimodule M and a C -bicomodule N , define

$$\text{HH}_\bullet^{\text{ch}}(A, M) := \text{Tor}_\bullet^{A^e}(A, M), \quad \text{HH}_\bullet^{\bullet}(A, M) := \text{RHom}_{A^e}(A, M),$$

$$\text{coHH}_\bullet^{\text{ch}}(C, N) := \text{Cotor}_\bullet^{C^e}(C_\Delta, N), \quad \text{coHH}_\bullet^{\bullet}(C, N) := \text{Coext}_{C^e}^\bullet(C_\Delta, N).$$

When $M = A$ and $N = C_\Delta$ we omit coefficients.

22.3 ORDERED BAR COALGEBRAS AND THE CHIRAL SHUFFLE THEOREM

In the associative chiral regime the basic bar object is ordered. This is the first point at which the theory diverges sharply from the commutative shadow: *every shuffle survives as a distinct summand*.

Definition 22.3.1 (*The simplicial ordered bar object*). Let A be an augmented associative chiral algebra. Define the simplicial object $B_\bullet^\Delta(A)$ by

$$B_n^\Delta(A) := A^{\otimes^{\text{ch}} n} \quad (n \geq 0),$$

with faces given by augmentation at the two ends and multiplication in adjacent slots, and degeneracies given by unit insertion. Its normalized chains

$$N(B_{\bullet}^{\Delta}(A))$$

are canonically identified with the reduced ordered chiral bar complex $\overline{B}^{\text{ch}}(A)$.

In suspended notation we write a bar word of length n as

$$[a_1 | \cdots | a_n].$$

Definition 22.3.2 (EZ-admissible pair). A pair (A, B) of strongly admissible associative chiral algebras is called *EZ-admissible* if the normalization functor on bisimplicial objects built from A and B commutes, filtration-wise, with the completed chiral tensor products and totalizations appearing in the proof of the Eilenberg–Zilber theorem.

THEOREM 22.3.3 (Ordered chiral shuffle theorem). Let (A, B) be an EZ-admissible pair of strongly admissible associative chiral algebras. There are natural filtered chain maps

$$\text{Sh}_{A,B}^{\text{ch}} : \overline{B}^{\text{ch}}(A) \widehat{\otimes} \overline{B}^{\text{ch}}(B) \longrightarrow \overline{B}^{\text{ch}}(A \otimes^{\text{ch}} B),$$

$$\text{AW}_{A,B}^{\text{ch}} : \overline{B}^{\text{ch}}(A \otimes^{\text{ch}} B) \longrightarrow \overline{B}^{\text{ch}}(A) \widehat{\otimes} \overline{B}^{\text{ch}}(B),$$

such that

$$\text{AW}_{A,B}^{\text{ch}} \circ \text{Sh}_{A,B}^{\text{ch}} = \text{id}, \quad \text{Sh}_{A,B}^{\text{ch}} \circ \text{AW}_{A,B}^{\text{ch}} \simeq \text{id}.$$

Hence there is a filtered quasi-isomorphism of conilpotent dg coalgebras

$$\overline{B}^{\text{ch}}(A) \widehat{\otimes} \overline{B}^{\text{ch}}(B) \xrightarrow{\sim} \overline{B}^{\text{ch}}(A \otimes^{\text{ch}} B).$$

Proof. Set

$$K_{\bullet,\bullet} := B_{\bullet}^{\Delta}(A) \otimes^{\text{ch}} B_{\bullet}^{\Delta}(B).$$

This is a bisimplicial object in the ambient abelian or stable category of D -modules.

Its diagonal identifies canonically with the simplicial bar object of the tensor-product algebra:

$$\text{diag}(K)_n = A^{\otimes^{\text{ch}} n} \otimes^{\text{ch}} B^{\otimes^{\text{ch}} n} \cong (A \otimes^{\text{ch}} B)^{\otimes^{\text{ch}} n} = B_n^{\Delta}(A \otimes^{\text{ch}} B).$$

This identification is compatible with faces and degeneracies because multiplication and augmentation on $A \otimes^{\text{ch}} B$ are componentwise.

Now apply the classical Eilenberg–Zilber theorem filtration-wise in each exact graded piece. EZ-admissibility ensures that normalization commutes with the completed tensor constructions used here, so one obtains a filtered quasi-isomorphism

$$N(\text{diag } K) \xrightarrow{\sim} \text{Tot}(NK_{\bullet,\bullet}),$$

with inverse given by Alexander–Whitney. Since

$$N(B_{\bullet}^{\Delta}(A)) \cong \overline{B}^{\text{ch}}(A), \quad N(B_{\bullet}^{\Delta}(B)) \cong \overline{B}^{\text{ch}}(B), \quad N(B_{\bullet}^{\Delta}(A \otimes^{\text{ch}} B)) \cong \overline{B}^{\text{ch}}(A \otimes^{\text{ch}} B),$$

this yields the claimed quasi-isomorphism.

The formulas are the usual normalized Eilenberg–MacLane formulas, now interpreted in the ordered chiral setting. Explicitly, for bar words

$$[a_1 | \cdots | a_p] \in \overline{B}_p^{\text{ch}}(A), \quad [b_1 | \cdots | b_q] \in \overline{B}_q^{\text{ch}}(B),$$

set $c_i = a_i \otimes 1$ for $1 \leq i \leq p$ and $c_{p+j} = 1 \otimes b_j$ for $1 \leq j \leq q$, and define

$$\text{Sh}_{p,q}^{\text{ch}}([a_1 | \cdots | a_p] \otimes [b_1 | \cdots | b_q]) = \sum_{\sigma \in \text{Sh}(p,q)} \varepsilon(\sigma) [c_{\sigma^{-1}(1)} | \cdots | c_{\sigma^{-1}(p+q)}].$$

Similarly,

$$\text{AW}^{\text{ch}}([x_1 | \cdots | x_n]) = \sum_{p=0}^n [\pi_A(x_1) | \cdots | \pi_A(x_p)] \otimes [\pi_B(x_{p+1}) | \cdots | \pi_B(x_n)],$$

where

$$\pi_A = \text{id}_A \otimes \varepsilon_B, \quad \pi_B = \varepsilon_A \otimes \text{id}_B.$$

The chain-map property uses only the simplicial identities.

Finally, the shuffle map is compatible with deconcatenation: cutting a shuffled word is equivalent to cutting the source words and then shuffling the left halves and the right halves. Therefore $\text{Sh}_{A,B}^{\text{ch}}$ and $\text{AW}_{A,B}^{\text{ch}}$ are coalgebra maps. $\square$

Remark 22.3.4. The theorem is genuinely associative. In a commutative or E_∞ setting many of the shuffle summands are identified after the symmetric-group quotient. Here they remain distinct. The ordered configuration space remembers their full combinatorics.

22.4 THE R-MATRIX AS ORDERED-TO-UNORDERED DESCENT

Whenever the OPE has poles, the ordered bar complex $\overline{B}^{\text{ch,ord}}(A)$ carries strictly more information than the unordered $\overline{B}^{\text{ch}}(A)$. The surplus is the R -matrix: the monodromy of the flat connection on ordered configuration space, which serves as the descent datum for the Σ_n -covering. The unordered bar complex is recovered as the R -twisted Σ_n -descent.

THE COVERING-SPACE FRAME

Construction 22.4.1 (The covering-space frame). The projection

$$\pi_n: \text{Conf}_n^{\text{ord}}(X) \longrightarrow \text{Conf}_n(X) = \text{Conf}_n^{\text{ord}}(X)/\Sigma_n$$

is a principal Σ_n -bundle, étale with fibre Σ_n . A local system $\mathcal{L}$ on the base is equivalent to a Σ_n -equivariant local system $\pi_n^* \mathcal{L}$ on the total space: the descent correspondence

$$\text{LocSys}(\text{Conf}_n(X)) \simeq \text{LocSys}^{\Sigma_n}(\text{Conf}_n^{\text{ord}}(X)).$$

The bar complex at tensor degree n defines a local system $\mathcal{F}_n^{\text{ord}}$ on $\text{Conf}_n^{\text{ord}}(X)$ whose stalk at $(z_1, \dots, z_n)$ is $(s^{-1} \bar{A})^{\otimes n}$, with flat connection induced by the residue differential of the ordered bar construction. To descend $\mathcal{F}_n^{\text{ord}}$ to a local system on $\text{Conf}_n(X)$, one must exhibit a Σ_n -equivariant structure: isomorphisms

$$R_\sigma: \mathcal{F}_n^{\text{ord}}|_{(z_1, \dots, z_n)} \xrightarrow{\sim} \mathcal{F}_n^{\text{ord}}|_{(z_{\sigma(1)}, \dots, z_{\sigma(n)})}$$

for each $\sigma \in \Sigma_n$, satisfying the cocycle condition $R_{\sigma\tau} = R_\tau \circ R_\sigma$ and compatible with the flat connection.

For a pole-free E_∞ -chiral algebra, the equivariant structure is canonical: $R_\sigma = \varepsilon(\sigma) \cdot \tau_\sigma$, where τ_σ permutes tensor factors and $\varepsilon(\sigma)$ is the Koszul sign. The descent recovers the ordinary Σ_n -coinvariant bar complex.

For an E_∞ -chiral algebra with OPE poles (every interesting vertex algebra: $\widehat{\mathfrak{g}}_k$, Vir_c , $\mathcal{H}_k$, W -algebras), the equivariant structure must be *constructed* from the OPE data. The construction is the R -matrix.

THE SPECTRAL KOHNO CONNECTION

Construction 22.4.2 (R -matrix as monodromy of the Kohno connection). The bar differential on $\overline{B}^{\text{ch,ord}}(A)$ extracts, at each collision $z_i = z_j$, the collision residue $r_{ij}(z_i - z_j) \in \text{End}(\bar{A} \otimes \bar{A}) \otimes \mathcal{O}(*\Delta)$. By the bar kernel convention (the $d \log$ kernel absorbs one power), the collision residue $r(z)$ has pole orders one less than the OPE.

These residues define a flat connection on the trivial bundle over $\text{Conf}_n^{\text{ord}}(\mathbb{C})$ with fibre $\bar{A}^{\otimes n}$:

$$\nabla = d - \sum_{1 \leq i < j \leq n} r_{ij}(z_i - z_j) d(z_i - z_j). \quad (22.1)$$

Here r_{ij} acts in the (i, j) tensor slots of $\bar{A}^{\otimes n}$ and $r_{ij}(z_{ij}) dz_{ij}$ is the connection 1-form on $\text{Conf}_n^{\text{ord}}(\mathbb{C})$. For instance, when $r(z) = k/z$ (Heisenberg), this gives $k dz/z$; when $r(z) = \hbar\Omega/z$ (affine Kac–Moody), it gives $\hbar\Omega dz_{ij}/z_{ij}$, the standard Knizhnik–Zamolodchikov form.

Flatness. The curvature

$$\nabla^2 = \sum_{i < j < k} ([r_{ij}, r_{ik}] + [r_{ij}, r_{jk}] + [r_{ik}, r_{jk}]) dz_{ij} \wedge dz_{jk}$$

vanishes if and only if each triple satisfies the classical Yang–Baxter equation

$$[r_{12}(z_{12}), r_{13}(z_{13})] + [r_{12}(z_{12}), r_{23}(z_{23})] + [r_{13}(z_{13}), r_{23}(z_{23})] = 0, \quad (22.2)$$

where $z_{ij} = z_i - z_j$. The identity $d^2 = 0$ on the ordered bar complex $\overline{B}^{\text{ch,ord}}(A)$ entails precisely this CYBE, as the codimension-two strata of the ordered FM compactification $\overline{\text{FM}}_n^{\text{ord}}(\mathbb{C})$ impose the three-term relation on triple collisions. Hence ∇ is flat.

The R -matrix. At $n = 2$, the ordered configuration space $\text{Conf}_2^{\text{ord}}(\mathbb{C}) = \{(z_1, z_2) \in \mathbb{C}^2 \mid z_1 \neq z_2\}$ has fundamental group $\pi_1 = \mathbb{Z}$, generated by the loop γ in which z_1 circles z_2 . The R -matrix is the monodromy of ∇ around γ :

$$R(z) := \text{Mon}_\gamma(\nabla) = \mathcal{P} \exp \left(\oint_\gamma r(z) dz \right) \in \text{End}(\bar{A} \otimes \bar{A})[[z^{-1}]], \quad (22.3)$$

where $z = z_1 - z_2$ is the relative coordinate and $\mathcal{P}$ denotes path-ordering.

At general n , the pure braid group $P_n = \pi_1(\text{Conf}_n^{\text{ord}}(\mathbb{C}))$ has standard generators γ_{ij} ($i < j$, the loop in which z_i winds around z_j with all other points fixed). The flat connection ∇ induces a monodromy representation

$$\rho: P_n \rightarrow \text{GL}(\bar{A}^{\otimes n}), \quad \gamma_{ij} \mapsto R_{ij}(z_{ij}).$$

The braid relation $\gamma_{ij}\gamma_{ik}\gamma_{jk} = \gamma_{jk}\gamma_{ik}\gamma_{ij}$ in P_n maps to the Yang–Baxter equation (22.2) (its exponentiated form), so ρ is a well-defined representation.

THE DESCENT THEOREM

PROPOSITION 22.4.3 (*R-matrix twisted descent*). Let A be a strongly admissible associative chiral algebra with ordered bar coalgebra $C = \overline{B}^{\text{ch,ord}}(A)$ and R -matrix $R(z)$ as in Construction 22.4.2. Then the unordered bar complex is the R -twisted Σ_n -descent:

$$\overline{B}^{\text{ch}}(A)_n \simeq (\overline{B}^{\text{ch,ord}}(A)_n)^{R \cdot \Sigma_n}, \quad (22.4)$$

where Σ_n acts on adjacent transpositions by $\sigma_i \cdot (a_1 \otimes \cdots \otimes a_n) = (\tau_{i,i+1} \circ R_{i,i+1}(z_i - z_{i+1})) (a_1 \otimes \cdots \otimes a_n)$. The underlying B_n -representation is well-defined if and only if the R -matrix satisfies the Yang–Baxter equation; it factors through Σ_n if and only if R also satisfies strong unitarity $R_{12}(z) R_{21}(-z) = \text{id}$.

Proof. The proof proceeds in three steps: we establish the Σ_n -action, verify its well-definedness, and identify the fixed locus.

Step 1: the twisted Σ_n -action. The covering $\pi_n: \text{Conf}_n^{\text{ord}}(\mathbb{C}) \rightarrow \text{Conf}_n(\mathbb{C})$ presents the base as the orbit space of the free Σ_n -action on ordered configurations. An element $\sigma_i = (i, i+1) \in \Sigma_n$ lifts to a path in $\text{Conf}_n^{\text{ord}}(\mathbb{C})$ that continuously exchanges z_i and z_{i+1} . The monodromy of the flat connection ∇ (eq. (22.1)) along this path decomposes into two factors:

- (i) the permutation $\tau_{i,i+1}$ of tensor slots in $\overline{A}^{\otimes n}$, from the coordinate transposition, and
- (ii) the parallel transport $R_{i,i+1}(z_i - z_{i+1})$ of the fibre, from the flat connection on ordered configuration space.

Define the R -twisted action on generators by

$$\rho_R(\sigma_i) := \tau_{i,i+1} \circ R_{i,i+1}(z_i - z_{i+1}). \quad (22.5)$$

Step 2: well-definedness via YBE and strong unitarity. The formula (22.5) defines a representation $\rho_R: B_n \rightarrow \text{GL}(\overline{A}^{\otimes n})$ of the braid group, provided the braid relation holds (verified below). To factor ρ_R through $\Sigma_n = B_n / \langle \sigma_i^2 \rangle$, we must also verify the Coxeter relations.

Involutivity ($\rho_R(\sigma_i)^2 = \text{id}$): this is the strong unitarity condition $R_{12}(z) R_{21}(-z) = \text{id}$. It holds by an algebraic argument: for E_∞ -chiral algebras (including those with OPE poles), the Casimir $\Omega = \sum r_n \in (\overline{A} \otimes \overline{A})[[z^{-1}]]$ is symmetric under exchange of tensor factors ($r_{12} = r_{21}$). Path reversal on $\text{Conf}_2^{\text{ord}}(\mathbb{C})$ sends $z \mapsto -z$ and exchanges the two sheets, so the parallel transport along the reversed path is $R_{21}(-z)$. Since the connection form is symmetric, path reversal inverts the holonomy: $R_{21}(-z) = R_{12}(z)^{-1}$, whence $R_{12}(z) R_{21}(-z) = \text{id}$.

Distant commutativity ($\rho_R(\sigma_i) \rho_R(\sigma_j) = \rho_R(\sigma_j) \rho_R(\sigma_i)$ for $|i - j| \geq 2$): immediate because $R_{i,i+1}$ and $R_{j,j+1}$ act in disjoint tensor slots.

The braid relation $\rho_R(\sigma_i) \rho_R(\sigma_{i+1}) \rho_R(\sigma_i) = \rho_R(\sigma_{i+1}) \rho_R(\sigma_i) \rho_R(\sigma_{i+1})$ is the critical constraint. Expanding:

$$\begin{aligned} & (\tau_{i,i+1} \circ R_{i,i+1})(\tau_{i+1,i+2} \circ R_{i+1,i+2})(\tau_{i,i+1} \circ R_{i,i+1}) \\ &= (\tau_{i+1,i+2} \circ R_{i+1,i+2})(\tau_{i,i+1} \circ R_{i,i+1})(\tau_{i+1,i+2} \circ R_{i+1,i+2}). \end{aligned}$$

Conjugating the tensor permutations to the left and using the standard identities $\tau_{i,i+1} R_{j,j+1} \tau_{i,i+1}^{-1} = R_{\sigma_i(j), \sigma_i(j+1)}$, this reduces to

$$R_{12}(z_{12}) R_{13}(z_{13}) R_{23}(z_{23}) = R_{23}(z_{23}) R_{13}(z_{13}) R_{12}(z_{12}),$$

the Yang–Baxter equation. This holds because the flatness $\nabla^2 = 0$ implies the CYBE (eq. (22.2)), and the path-ordered exponential converts the infinitesimal CYBE into the exponentiated YBE (this is the content of the Kohno–Drinfeld theorem: the monodromy representation of a flat Knizhnik–Zamolodchikov connection satisfies the Yang–Baxter equation).

Step 3: identification of the descent. The result is a genuine Σ_n -action ρ_R on $\overline{B}^{\text{ch,ord}}(A)_n$. By the descent equivalence for principal bundles, a Σ_n -equivariant local system on the total space $\text{Conf}_n^{\text{ord}}(\mathbb{C})$ descends to a local system on $\text{Conf}_n(\mathbb{C})$. The descended local system is the equaliser of the ρ_R -action, which at the level of global sections is the R -twisted Σ_n -invariant subspace:

$$(\overline{B}^{\text{ch,ord}}(A)_n)^{R \cdot \Sigma_n} := \{x \in \overline{B}^{\text{ch,ord}}(A)_n \mid \rho_R(\sigma) \cdot x = x \text{ for all } \sigma \in \Sigma_n\}.$$

We claim this equals $\overline{B}^{\text{ch}}(A)_n$. By construction, the unordered bar complex $\overline{B}^{\text{ch}}(A)_n$ is the complex of sections of the descended local system $\mathcal{F}_n$ on $\text{Conf}_n(\mathbb{C})$ whose pullback to $\text{Conf}_n^{\text{ord}}(\mathbb{C})$ is $\mathcal{F}_n^{\text{ord}}$ with the ρ_R -equivariant structure. The descent-ascend adjunction for étale Σ_n -coverings gives

$$\Gamma(\text{Conf}_n(\mathbb{C}), \mathcal{F}_n) = \Gamma(\text{Conf}_n^{\text{ord}}(\mathbb{C}), \mathcal{F}_n^{\text{ord}})^{R \cdot \Sigma_n}.$$

The left side is $\overline{B}^{\text{ch}}(A)_n$ and the right side is $(\overline{B}^{\text{ch,ord}}(A)_n)^{R \cdot \Sigma_n}$, completing the proof. $\square$

COROLLARY 22.4.4 (*Pole-free descent is naive*). For a pole-free E_∞ -chiral algebra (a commutative chiral algebra whose chiral product extends across the diagonal without singularities), the collision residue vanishes: $r(z) = 0$. Hence $\nabla = d$ is the trivial flat connection, $R(z) = \text{id}$, and (22.4) reduces to the ordinary Σ_n -coinvariant:

$$\overline{B}^{\text{ch}}(A)_n \simeq (\overline{B}^{\text{ch,ord}}(A)_n) / \Sigma_n.$$

For E_∞ -chiral algebras with OPE poles (all vertex algebras with nontrivial singular OPE: $\widehat{\mathfrak{g}}_k$, Vir_c , $\mathcal{H}_k$, lattice algebras, W -algebras, all of which are E_∞ -chiral, since every vertex algebra is E_∞), the R -matrix $R(z) \neq \text{id}$ carries nontrivial spectral dependence derived from the local OPE, and the descent is genuinely R -twisted.

Proof. If the OPE has no poles, every collision residue vanishes identically, so the connection form in (22.1) is zero and the monodromy (22.3) is the identity. The R -twisted Σ_n -action (22.5) reduces to the plain permutation $\tau_{i,i+1}$, and the R -twisted invariants coincide with the ordinary Σ_n -coinvariants. $\square$

Remark 22.4.5 (*Three bar complex variants and their filtrations*). The chiral bar complex $\overline{B}^{\text{ch}}(A)$, the ordered bar complex $\overline{B}^{\text{ch,ord}}(A)$, and the Feigin–Ginzburg bar complex $\overline{B}^{\text{FG}}(A)$ (retaining only simple-pole residues) are related by two filtrations: a pole-order filtration on $\overline{B}^{\text{ch}}(A)$ whose associated graded recovers $\overline{B}^{\text{FG}}(A)$, and the Σ_n -coinvariant descent $\overline{B}^{\text{ch,ord}}(A) \rightarrow \overline{B}^{\text{ch}}(A)$ of Proposition 22.4.3. At higher genus all three fuse via the Feynman transform of the modular operad (FCom for the chiral and Feigin–Ginzburg variants, FAss for the ordered variant).

Remark 22.4.6 (*The R -matrix as Maurer–Cartan element*). The classical r -matrix $r(z) \in \text{End}(\bar{A} \otimes \bar{A}) \otimes \mathcal{O}(*\Delta)$ is a Maurer–Cartan element in the degree-2 component of the E_1 modular convolution algebra (cf. the E_1 shadow obstruction tower in the body of the text). The CYBE (22.2) is the linearised Maurer–Cartan equation; the YBE on $R(z)$ is its exponentiated form. The R -matrix is the descent datum because the convolution dg Lie algebra governing Σ_n -equivariant structures on local systems over Conf_n is precisely the Gerstenhaber–Schack complex of bilinear operations, and Maurer–Cartan elements in it parametrise

the nontrivial descents. Thus the entire apparatus of twisted descent is controlled by a single MC element in the degree-2 sector.

Remark 22.4.7 (Motivic interpretation of ordered-to-symmetric descent). The averaging map $\text{av} : \overline{B}^{\text{ch,ord}}(A) \rightarrow \overline{B}^{\text{ch}}(A)$ is a motivic projection: it kills precisely the transcendental arithmetic content of the configuration-space integrals.

The ordered configuration space $\text{Conf}_k^{\text{ord}}(\mathbb{C})$ carries a canonical mixed Hodge structure whose periods are the iterated integrals of the Knizhnik–Zamolodchikov connection. The R -matrix monodromy of Proposition 22.4.3 is computed by these periods, and the resulting transcendental data is stratified by degree:

- At degree 2: the monodromy $R(z)$ of the flat connection $\nabla = d - r(z) dz$ involves $2\pi i$, a period of the Lefschetz motive $\mathbb{L}$ (weight 1).
- At degree 3: the Drinfeld associator Φ_{KZ} (the monodromy of the KZ connection on $\text{Conf}_3^{\text{ord}}(\mathbb{C})$) involves multiple zeta values $\zeta(2)$, $\zeta(3)$, $\zeta(2, 1)$, $\dots$ (periods of mixed Tate motives over $\mathbb{Z}$).
- At degree k : the iterated monodromy involves periods of mixed Tate motives of weight $\leq k - 1$, by the theorem of Brown [73].

The symmetric bar complex $\overline{B}^{\text{ch}}(A)$ retains none of this. Its invariants (the curvature κ , the complementarity class C , the shadow obstruction tower Q) are rational numbers, periods of the trivial motive $\mathbb{Q}(0)$. The kernel $\ker(\text{av})$ is the motivic surplus: it carries the full weight-graded mixed Tate content that the symmetric projection annihilates.

This is the arithmetic shadow of a structural phenomenon. Drinfeld’s Grothendieck–Teichmüller group $\widehat{GT}$ acts on the tower of KZ associators, equivalently on the pro-nilpotent completion of the ordered bar complex at each degree. The Deligne–Ihara conjecture identifies $\text{Lie}(\widehat{GT})$ with the free Lie algebra on generators in odd degrees ≥ 3 , one for each odd zeta value $\zeta(2n + 1)$. The ordered bar complex of a chiral algebra is a *representation* of this arithmetic symmetry group: the $\widehat{GT}$ -action permutes the associators that parametrise equivalent ordered-to-symmetric descents. Different choices of Drinfeld associator give different R -twisted Σ_n -actions with isomorphic but not identical descent data.

The ordered bar complex retains the transcendental arithmetic of the configuration-space integrals. The symmetric bar complex projects to the rational shadow. Every motivic weight is visible in the ordered complex; every motivic weight is killed by the averaging map.

22.5 OPPOSITE-DUALITY, ANTI-INVOLUTIONS, AND ENVELOPING DUALITY

The second foundational phenomenon is order reversal. It transforms opposite multiplication on the algebra side into opposite deconcatenation on the bar side.

THEOREM 22.5.1 (*Opposite-duality for ordered bar coalgebras*). Let A be a strongly admissible associative chiral algebra. There is a canonical isomorphism of coaugmented conilpotent dg coalgebras

$$R_A : \overline{B}^{\text{ch}}(A^{\text{op}}) \xrightarrow{\sim} \overline{B}^{\text{ch}}(A)^{\text{cop}}.$$

If A is finite-type Koszul so that linear duality returns an associative chiral algebra, then

$$(A^{\text{op}})^! \simeq (A^!)^{\text{op}}.$$

Proof. On suspended bar words define

$$R_A[s^{-1}a_1 | \cdots | s^{-1}a_n] = (-1)^{\sum_{i < j} (|a_i|+1)(|a_j|+1)} [s^{-1}a_n | \cdots | s^{-1}a_1].$$

Geometrically, this is induced by the order-reversal involution on the ordered configuration space.

The bar differential is the alternating sum of adjacent collision maps. The i -th face for A^{op} multiplies the i -th and $(i+1)$ -st slots in the opposite order. Reversal carries that face to the $(n-i)$ -th face for A with exactly the sign written above. Hence R_A is a chain map.

The coproduct on $\overline{B}^{\text{ch}}(A)$ is deconcatenation. Reversal sends a cut after the p -th letter to a cut before the $(n-p)$ -th letter. Therefore

$$\Delta \circ R_A = \tau \circ (R_A \otimes R_A) \circ \Delta,$$

where τ flips the tensor factors, which is exactly the statement that the target is the opposite coalgebra. The claim about linear duals follows because linear duality exchanges opposite coproduct with opposite product. $\square$

COROLLARY 22.5.2 (*Anti-involutions survive duality*). Any anti-involution $\iota : A \rightarrow A^{\text{op}}$ induces an anti-involution

$$\iota^! : A^! \rightarrow (A^!)^{\text{op}}.$$

If $\iota^2 = \text{id}$, then $(\iota^!)^2 = \text{id}$.

Proof. Apply Theorem 22.5.1 to the anti-involution $\iota : A \rightarrow A^{\text{op}}$. Koszul duality is contravariant, so it gives a morphism $(A^{\text{op}})^! \rightarrow A^!$. Using the canonical identification $(A^{\text{op}})^! \cong (A^!)^{\text{op}}$ from the same theorem, this is exactly the required anti-involution $\iota^! : A^! \rightarrow (A^!)^{\text{op}}$. Functoriality gives $(\iota^!)^2 = (\iota^2)^!$, so $\iota^2 = \text{id}$ implies $(\iota^!)^2 = \text{id}$. $\square$

Remark 22.5.3 (*Ordered Verdier duality does not exist*). The Verdier intertwining $\mathbb{D}_{\text{Ran}} \overline{B}^{\text{ch}}(\mathcal{A}) \simeq \overline{B}^{\text{ch}}(\mathcal{A}^!)$ (Theorem II.1.84) is a statement about the *symmetric* bar on unordered $\text{Ran}(X)$. The naive ordered analogue $\mathbb{D}_{\text{Ran}} \overline{B}^{\text{ord}}(\mathcal{A})$ is *undefined*: Verdier duality on $\text{Ran}(X)$ requires the cosheaf/factorization property, which uses the *symmetric* monoidal structure on disjoint-open covers. The ordered bar lives on $\text{Conf}_n^{\leq}(X)$ (ordered configurations), which is *not* a factorization space in the Beilinson–Drinfeld sense. The correct E_1 analogue of Verdier intertwining is the *opposite-coalgebra duality* of Theorem 22.5.1: the reversal involution R_A provides $\overline{B}^{\text{ord}}(\mathcal{A})^{\text{op}} \simeq \overline{B}^{\text{ord}}(\mathcal{A}^{\text{op}})$, which is an ordered (non-commutative) replacement for Verdier. The development of a full “ribbon Ran ” framework in which $\mathbb{D}_{\text{Ran}}$ extends to ordered configurations is an open problem.

LEMMA 22.5.4 (*Closure of admissibility under opposite and enveloping constructions*). If A is strongly admissible, then so are A^{op} and $A^e = A \otimes^{\text{ch}} A^{\text{op}}$.

Proof. Passing from A to A^{op} does not change the underlying filtered vector space, augmentation, or completeness data; it only reverses the order of multiplication. Hence every clause in the definition of strong admissibility is checked by the same filtration and continuity estimates for the opposite product. For $A^e = A \otimes^{\text{ch}} A^{\text{op}}$, the completed tensor product of two strongly admissible filtered objects is again complete, exhaustive, and compatible with the bar construction degreewise. Therefore both A^{op} and A^e satisfy the same admissibility package. $\square$

COROLLARY 22.5.5 (*Enveloping duality*). Let A be strongly admissible, and assume (A, A^{op}) is EZ-admissible. Set $C = \overline{B}^{\text{ch}}(A)$. Then there is a canonical quasi-isomorphism of conilpotent dg coalgebras

$$\overline{B}^{\text{ch}}(A^e) \xrightarrow{\sim} C^e = C \widehat{\otimes} C^{\text{cop}}.$$

If A is finite-type Koszul, then

$$(A^e)^! \simeq (A^!)^e.$$

Proof. By the ordered shuffle theorem,

$$\overline{B}^{\text{ch}}(A^e) = \overline{B}^{\text{ch}}(A \otimes^{\text{ch}} A^{\text{op}}) \xrightarrow{\sim} \overline{B}^{\text{ch}}(A) \widehat{\otimes} \overline{B}^{\text{ch}}(A^{\text{op}}).$$

Now apply Theorem 22.5.1 to the second factor:

$$\overline{B}^{\text{ch}}(A^{\text{op}}) \xrightarrow{\sim} \overline{B}^{\text{ch}}(A)^{\text{cop}}.$$

This proves the coalgebra statement. The algebra statement follows after finite-type linear duality. $\square$

22.6 THE TWO-SIDED TWISTED BICOMODULE AND THE TANGENT BAR CONSTRUCTION

An A -bimodule has two coalgebra-side incarnations: differentiation of the bar construction at a square-zero extension, and twisting a two-sided tensor product by the universal twisting cochain. They coincide.

DEFINITION 22.6.1 (*Two-sided twisted bicomodule*). Let A be strongly admissible, let $C = \overline{B}^{\text{ch}}(A)$, and let M be an A -bimodule. Define the *two-sided twisted bicomodule*

$$\mathbb{K}_A^{\text{bi}}(M) := C \widehat{\otimes} M \widehat{\otimes} C$$

with differential

$$d_{\mathbb{K}} = d_C \otimes 1 \otimes 1 + 1 \otimes d_M \otimes 1 + 1 \otimes 1 \otimes d_C + d_L + d_R,$$

where

$$d_L(c \otimes m \otimes d) = \sum (-1)^{|c_{(1)}|} c_{(1)} \otimes \tau(c_{(2)}) \cdot m \otimes d,$$

$$d_R(c \otimes m \otimes d) = \sum (-1)^{|c|+|m|} c \otimes m \cdot \tau(d_{(1)}) \otimes d_{(2)},$$

with the usual Koszul signs determined by the grading conventions. The left and right C -coactions are induced by comultiplication on the two outer factors.

LEMMA 22.6.2. $\mathbb{K}_A^{\text{bi}}(M)$ is a dg C -bicomodule.

Proof. The untwisted part of the differential squares to zero. The quadratic terms in d_L and in d_R vanish by the Maurer–Cartan equation

$$d\tau + \tau \star \tau = 0.$$

The mixed commutator $d_L d_R + d_R d_L$ vanishes because the left and right A -actions on the bimodule M commute. Compatibility with the bicomodule structure is immediate from coassociativity of the coproduct on the outer C -factors. $\square$

Definition 22.6.3 (Square-zero extension and one-defect bar complex). Let M be an A -bimodule and form the square-zero extension

$$A_\varepsilon := A \oplus \varepsilon M, \quad \varepsilon^2 = 0.$$

Inside the reduced ordered bar complex $\overline{B}^{\text{ch}}(A_\varepsilon)$, let $T_A^{\text{bar}}(M)$ be the subcomplex spanned by bar words containing exactly one εM -slot. We call this the *one-defect ordered bar complex*.

PROPOSITION 22.6.4. Modulo ε^2 , there is a canonical decomposition

$$\overline{B}^{\text{ch}}(A_\varepsilon) \cong \overline{B}^{\text{ch}}(A) \oplus \varepsilon T_A^{\text{bar}}(M).$$

The one-defect piece $T_A^{\text{bar}}(M)$ is naturally a C -bicomodule.

Proof. A reduced bar word in $\overline{B}^{\text{ch}}(A_\varepsilon)$ contains some number of εM -slots. Since $\varepsilon^2 = 0$, any word with at least two such slots vanishes modulo ε^2 . Therefore only the zero-defect and one-defect pieces survive.

The bar differential merges adjacent slots. Multiplying two ordinary A -slots remains in A . Multiplying an A -slot with the unique M -slot remains in M by the bimodule structure. There is no nonzero product of two defect slots. Hence the one-defect sector is a subcomplex. Deconcatenation cuts a one-defect word into a defect-free part and a one-defect part, or vice versa, so the one-defect sector is naturally a bicomodule over the ordinary bar coalgebra $C = \overline{B}^{\text{ch}}(A)$. $\square$

THEOREM 22.6.5 (*Tangent identification*). There is a canonical isomorphism of dg C -bicomodules

$$T_A^{\text{bar}}(M) \xrightarrow{\sim} \mathbb{K}_A^{\text{bi}}(M).$$

Equivalently, the one-defect ordered bar complex of a square-zero extension is exactly the two-sided twisted bicomodule of the defect bimodule.

Proof. As a graded object,

$$C = \bigoplus_{p \geq 0} (s^{-1} \bar{A})^{\otimes p},$$

hence

$$C \widehat{\otimes} M \widehat{\otimes} C \cong \bigoplus_{p, q \geq 0} (s^{-1} \bar{A})^{\otimes p} \otimes M \otimes (s^{-1} \bar{A})^{\otimes q}.$$

This is in tautological bijection with one-defect bar words

$$[a_1 | \cdots | a_p | m | a_{p+1} | \cdots | a_{p+q}]$$

in which the unique defect sits between a left bar segment of length p and a right bar segment of length q .

Under this identification, the ordinary bar differential on the left segment and the right segment matches the internal bar differential coming from the two outer copies of C , while the two bar faces adjacent to the defect slot match exactly the two twisting terms d_L and d_R . Therefore the differentials agree. Deconcatenation also agrees on the nose, because cutting a one-defect word is the same as cutting the left and right bar segments around the unique defect. $\square$

COROLLARY 22.6.6 (*Infinitesimal dual coalgebra*). Modulo ε^2 , the bar coalgebra of the square-zero extension is

$$\overline{B}^{\text{ch}}(A_\varepsilon) \cong C \oplus \varepsilon \mathbb{K}_A^{\text{bi}}(M).$$

If A is finite-type Koszul, then after linear duality

$$(A_\varepsilon)^! \cong A^! \oplus \varepsilon M^! \pmod{\varepsilon^2},$$

where

$$M^! := \Omega_C^{\text{bi}}(\mathbb{K}_A^{\text{bi}}(M)).$$

Proof. Proposition 22.6.4 identifies the ε -linear summand of $\overline{B}^{\text{ch}}(A_\varepsilon)$ with the one-defect bar complex. Theorem 22.6.5 identifies that one-defect complex with the bicomodule $\mathbb{K}_A^{\text{bi}}(M)$, so modulo ε^2 the bar coalgebra splits as $C \oplus \varepsilon \mathbb{K}_A^{\text{bi}}(M)$. If A is finite-type Koszul, linear duality and first-order cobar reconstruction carry the ε -summand to $M^! = \Omega_C^{\text{bi}}(\mathbb{K}_A^{\text{bi}}(M))$, giving $(A_\varepsilon)^! \cong A^! \oplus \varepsilon M^! \pmod{\varepsilon^2}$. $\square$

PROPOSITION 22.6.7 (*Infinitesimal annular variation*). Modulo ε^2 one has

$$\text{HH}_\bullet^{\text{ch}}(A_\varepsilon) \cong \text{HH}_\bullet^{\text{ch}}(A) \oplus \varepsilon \text{HH}_\bullet^{\text{ch}}(A, M).$$

On the coalgebra side this becomes

$$\text{coHH}_\bullet^{\text{ch}}(\overline{B}^{\text{ch}}(A_\varepsilon)) \cong \text{coHH}_\bullet^{\text{ch}}(C) \oplus \varepsilon \text{coHH}_\bullet^{\text{ch}}(C, \mathbb{K}_A^{\text{bi}}(M)).$$

Proof. The chiral Hochschild complex of the square-zero extension decomposes, modulo ε^2 , into the sector with no defect and the sector with exactly one defect; the second computes chiral Hochschild homology with coefficients in M . The coalgebra statement follows from Corollary 22.6.6 and the coHochschild identification proved later in Theorem 22.8.1. $\square$

22.7 PBW-COMPLETE TWO-SIDED KOSZUL DUALITY

One-sided module/comodule duality extends to the two-sided theory by passing from A to its enveloping algebra A^e and applying Corollary 22.5.5.

DEFINITION 22.7.1 (*PBW-complete and coderived bicomodule categories*). Let A be strongly admissible and set $C = \overline{B}^{\text{ch}}(A)$.

- (a) $D_{\text{bi}}^{\text{pbw}}(A)$ denotes the derived category of PBW-complete A -bimodules obtained from complete semifree A^e -resolutions.
- (b) $D_{\text{bi}}^{\text{co}}(C)$ denotes the coderived category of conilpotent C -bicomodules. Equivalently, by Lemma 22.2.6, it is the coderived category of left C^e -comodules.

DEFINITION 22.7.2 (*Two-sided twisted cobar*). Let N be a C -bicomodule. Define

$$\Omega_C^{\text{bi}}(N) := A \widehat{\otimes} N \widehat{\otimes} A$$

with the differential dual to the one in Definition 22.6.1.

THEOREM 22.7.3 (*PBW-complete bimodule/bicomodule equivalence*). Let A be strongly admissible, and assume (A, A^{op}) is EZ-admissible. Set $C = \overline{B}^{\text{ch}}(A)$. Then there is an exact equivalence

$$\mathbb{K}_A^{\text{bi}} : D_{\text{bi}}^{\text{pbw}}(A) \xrightarrow{\sim} D_{\text{bi}}^{\text{co}}(C)$$

with inverse Ω_C^{bi} . In the curved regime the same statement holds after replacing the ordinary derived category on the algebra side by the corresponding completed contraderived/coderived version.

Proof. By the enveloping algebra formalism, A -bimodules are left A^e -modules. By Corollary 22.5.5,

$$\overline{B}^{\text{ch}}(A^e) \xrightarrow{\sim} C^e.$$

Apply the one-sided module/comodule Koszul duality from Hypothesis 22.2.3(II) to the associative chiral algebra A^e . This gives an equivalence between complete A^e -modules and conilpotent C^e -comodules. Since left C^e -comodules are the same as C -bicomodules by Lemma 22.2.6, we obtain the asserted equivalence.

The functor is precisely the two-sided twisted bar construction

$$M \mapsto C \widehat{\otimes} M \widehat{\otimes} C,$$

because that is the one-sided bar functor for the algebra A^e rewritten using the enveloping identification. The inverse is the corresponding two-sided cobar functor. $\square$

THEOREM 22.7.4 (*Diagonal correspondence*). Under the equivalence of Theorem 22.7.3, the diagonal bimodule ${}_A A_A$ is sent to the diagonal bicomodule C_Δ . Equivalently,

$$\mathbb{K}_A^{\text{bi}}(A) \simeq C_\Delta$$

in $D_{\text{bi}}^{\text{co}}(C)$.

Proof. By definition,

$$\mathbb{K}_A^{\text{bi}}(A) = C \widehat{\otimes} A \widehat{\otimes} C$$

with the two-sided twisting differential.

First contract the left half: the standard bar–cobar counit resolution yields a quasi-isomorphism

$$C \widehat{\otimes}_\tau A \xrightarrow{\sim} 1$$

compatible with the right C -coaction. Hence

$$\mathbb{K}_A^{\text{bi}}(A) \simeq C$$

as a right C -comodule.

Similarly, contracting the right half using

$$A \widehat{\otimes}_\tau C \xrightarrow{\sim} 1$$

gives

$$\mathbb{K}_A^{\text{bi}}(A) \simeq C$$

as a left C -comodule.

To identify the opposite coactions, filter $\mathbb{K}_A^{\text{bi}}(A)$ by total coradical degree in the two outer copies of C . On the associated graded the twisting terms disappear, and the bicomodule structure is literally the left and right coproducts on the two outer factors. Under either of the two contractions above, the associated graded collapses to a single copy of C , and the surviving left and right coactions are exactly the two legs of Δ_C . Because the filtration is complete and bounded below in the strongly admissible regime, this associated-graded identification lifts to the filtered complex. Therefore the resulting bicomodule is C_Δ . $\square$

COROLLARY 22.7.5 (*The diagonal is the unit for composition*). For every $X \in D_{\text{bi}}^{\text{co}}(C)$ there are canonical isomorphisms

$$C_\Delta \square_C^{\text{R}} X \simeq X \simeq X \square_C^{\text{R}} C_\Delta.$$

Proof. Transport the tautologies

$$A \otimes_A^{\text{L}} M \simeq M \simeq M \otimes_A^{\text{L}} A$$

for A -bimodules along Theorem 22.7.3 and use Theorem 22.7.4. $\square$

COROLLARY 22.7.6 (*Tensor–cotensor gluing*). For all $M, N \in D_{\text{bi}}^{\text{pbw}}(A)$ there is a canonical isomorphism

$$\mathbb{K}_A^{\text{bi}}(M \otimes_A^{\text{L}} N) \simeq \mathbb{K}_A^{\text{bi}}(M) \square_C^{\text{R}} \mathbb{K}_A^{\text{bi}}(N)$$

in $D_{\text{bi}}^{\text{co}}(C)$.

Proof. Theorem 22.7.3 identifies the derived category of PBW-complete bimodules with the coderived category of C -bicomodules. Under this equivalence, the relative tensor product over A is sent to the relative cotensor product over C because both are computed by the same two-sided bar resolution transported through $\mathbb{K}_A^{\text{bi}}$. Applying the equivalence to $M \otimes_A^{\text{L}} N$ therefore yields the displayed isomorphism $\mathbb{K}_A^{\text{bi}}(M) \square_C^{\text{R}} \mathbb{K}_A^{\text{bi}}(N)$. $\square$

Remark 22.7.7. Corollary 22.7.6 is the coalgebraic gluing law for intervals. The diagonal bicomodule C_Δ is therefore the universal boundary condition for interval composition.

22.8 CHIRAL HOCHSCHILD–COHOCHSCHILD DUALITY

Annular traces and centers on the algebra side are identified with coHochschild theories of the bar coalgebra.

THEOREM 22.8.1 (*Associative chiral Hochschild/coHochschild homology*). Let A be strongly admissible, let (A, A^{op}) be EZ-admissible, and set $C = \overline{B}^{\text{ch}}(A)$. Then for every complete A -bimodule M there is a canonical isomorphism

$$\text{HH}_\bullet^{\text{ch}}(A, M) \simeq \text{coHH}_\bullet^{\text{ch}}(C, \mathbb{K}_A^{\text{bi}}(M)).$$

In particular,

$$\text{HH}_\bullet^{\text{ch}}(A) \simeq \text{coHH}_\bullet^{\text{ch}}(C) \simeq C_\Delta \square_{C^e}^{\text{R}} C_\Delta.$$

Proof. By definition,

$$\text{HH}_\bullet^{\text{ch}}(A, M) = \text{Tor}_\bullet^{A^e}(A, M).$$

Apply the equivalence of Theorem 22.7.3 to the pair (A, M) . The diagonal bimodule A goes to C_Δ by Theorem 22.7.4, and M goes to $\mathbb{K}_A^{\text{bi}}(M)$ by definition. Derived tensor over A^e is transported to derived cotensor over C^e . Therefore

$$\text{Tor}_\bullet^{A^e}(A, M) \simeq \text{Cotor}_\bullet^{C^e}(C_\Delta, \mathbb{K}_A^{\text{bi}}(M)),$$

which is the stated formula. Taking $M = A$ yields the second assertion. $\square$

THEOREM 22.8.2 (*Associative chiral Hochschild/coHochschild cohomology*). Under the same hypotheses, for every complete A -bimodule M there is a canonical isomorphism

$$\mathrm{HH}_{\mathrm{ch}}^{\bullet}(A, M) \simeq \mathrm{coHH}_{\mathrm{ch}}^{\bullet}(C, \mathbb{K}_A^{\mathrm{bi}}(M)).$$

In particular,

$$\mathrm{HH}_{\mathrm{ch}}^{\bullet}(A) \simeq \mathrm{coHH}_{\mathrm{ch}}^{\bullet}(C) = \mathrm{Coext}_{C^e}^{\bullet}(C_{\Delta}, C_{\Delta}).$$

Proof. Derived Hom is preserved by the equivalence of Theorem 22.7.3. Therefore

$$\mathrm{RHom}_{A^e}(A, M) \simeq \mathrm{RHom}_{C^e}(C_{\Delta}, \mathbb{K}_A^{\mathrm{bi}}(M)),$$

which is the desired coHochschild cohomology complex. The specialization to $M = A$ follows from the diagonal correspondence. $\square$

COROLLARY 22.8.3 (*The annulus as self-cotrace*). The annular closed object attached to the universal boundary condition C_{Δ} is the coHochschild object

$$\mathcal{H}_C^{\mathrm{cl}} := C_{\Delta} \square_{C^e}^{\mathbf{R}} C_{\Delta} \simeq \mathrm{coHH}_{\bullet}^{\mathrm{ch}}(C) \simeq \mathrm{HH}_{\bullet}^{\mathrm{ch}}(A).$$

Proof. Take $M = A$ in Theorem 22.8.1. Then the diagonal bimodule ${}_A A_A$ is carried to the diagonal bicomodule C_{Δ} , and the resulting coHochschild object is $C_{\Delta} \square_{C^e}^{\mathbf{R}} C_{\Delta}$. This is exactly the closed annulus object $\mathcal{H}_C^{\mathrm{cl}}$, so the three descriptions agree. $\square$

COROLLARY 22.8.4 (*Cap action*). There is a canonical action

$$\mathrm{coHH}_{\bullet}^{\mathrm{ch}}(C) \square_C^{\mathbf{R}} C_{\Delta} \longrightarrow C_{\Delta}$$

obtained by transporting the chiral Hochschild cap action

$$\mathrm{HH}_{\bullet}^{\mathrm{ch}}(A) \otimes A \longrightarrow A$$

across the equivalence of Theorem 22.7.3.

Proof. View the classical Hochschild cap action as a morphism in the derived category of A -bimodules. Theorem 22.7.3 transports A to C_{Δ} and transports chiral Hochschild homology to $\mathrm{coHH}_{\bullet}^{\mathrm{ch}}(C)$. Under the same equivalence, the tensor operation on the algebra side becomes the cotensor operation on the coalgebra side, so the cap action becomes the displayed map $\mathrm{coHH}_{\bullet}^{\mathrm{ch}}(C) \square_C^{\mathbf{R}} C_{\Delta} \rightarrow C_{\Delta}$. $\square$

Remark 22.8.5. The cohomology theorem is the center theorem. The homology theorem is the annulus theorem. Together they say that the algebraic center and algebraic trace of A can be read directly from the coalgebraic diagonal C_{Δ} .

22.9 THE DIAGONAL BICOMODULE AS UNIVERSAL BOUNDARY CONDITION

The boundary side carries two operations. Interval composition is realized by derived cotensor (Corollary 22.7.6). The ordered pair-of-pants is the transport of the external tensor product of bimodules. The second operation is inherently ordered: without extra structure, it is *not* symmetric.

Definition 22.9.1 (Ordered fusion product). Let $X, Y \in D_{\text{bi}}^{\text{co}}(C)$. Define

$$X \star Y := \mathbb{K}_A^{\text{bi}}\left(\Omega_C^{\text{bi}}(X) \widehat{\otimes} \Omega_C^{\text{bi}}(Y)\right),$$

where $\widehat{\otimes}$ is the completed tensor product of bimodules with outer A -actions: the left A -action is on the first factor and the right A -action is on the second factor. We call $\star$ the *ordered fusion product*.

Remark 22.9.2. The adjective “ordered” is essential. Unless further symmetry data are supplied, $\star$ is only a monoidal product reflecting the ordering of incoming open boundaries. It is the algebraic shadow of an ordered pair-of-pants, not yet of the fully symmetric open cobordism category.

THEOREM 22.9.3 (Ordered pair-of-pants algebra). The diagonal bicomodule C_Δ carries a canonical associative algebra structure with respect to the ordered fusion product:

$$\mu_P : C_\Delta \star C_\Delta \longrightarrow C_\Delta, \quad \eta_P : \mathbf{1}_\star \longrightarrow C_\Delta,$$

where $\mathbf{1}_\star := \mathbb{K}_A^{\text{bi}}(k)$ is the image of the trivial bimodule.

Proof. By Theorem 22.7.4, $C_\Delta \simeq \mathbb{K}_A^{\text{bi}}(A)$. The multiplication and unit of the algebra A ,

$$\mu_A : A \widehat{\otimes} A \rightarrow A, \quad \eta_A : k \rightarrow A,$$

transport across $\mathbb{K}_A^{\text{bi}}$ to maps

$$\mu_P : C_\Delta \star C_\Delta \rightarrow C_\Delta, \quad \eta_P : \mathbf{1}_\star \rightarrow C_\Delta.$$

Associativity and unitality follow immediately from associativity and unitality of A . $\square$

Definition 22.9.4 (Ordered open trace formalism). An *ordered genus-zero open trace formalism* consists of:

- (i) a composition product $\square_C^{\text{R}}$ with unit object C_Δ ,
- (ii) an ordered fusion product $\star$,
- (iii) an associative algebra structure $(C_\Delta, \mu_P, \eta_P)$ for $\star$,
- (iv) a closed object $\mathcal{H}_C^{\text{cl}}$ obtained by annular closure,
- (v) an annulus action of $\mathcal{H}_C^{\text{cl}}$ on C_Δ ,

subject to the sewing relations induced from the algebra side.

THEOREM 22.9.5 (Ordered genus-zero open trace formalism). The data

$$(D_{\text{bi}}^{\text{co}}(C), \square_C^{\text{R}}, C_\Delta, \star, \mu_P, \eta_P, \mathcal{H}_C^{\text{cl}})$$

constitute an ordered genus-zero open trace formalism. More precisely:

- (a) C_Δ is the unit for interval composition $\square_C^{\mathbf{R}}$.
- (b) $(C_\Delta, \mu_P, \eta_P)$ is an associative algebra object for ordered fusion.
- (c) Annular closure is

$$\mathcal{H}_C^{\text{cl}} \simeq \text{coHH}_\bullet^{\text{ch}}(C).$$

- (d) The annulus acts on the boundary object by the action of Corollary 22.8.4.
- (e) All ordered genus-zero sewing identities are transported from the corresponding identities for A -bimodules.

Proof. Statement (a) is Corollary 22.7.5. Statement (b) is Theorem 22.9.3. Statement (c) is Corollary 22.8.3. Statement (d) is Corollary 22.8.4. Finally, every ordered genus-zero sewing relation on the coalgebra side is the image under the equivalence $\mathbb{K}_A^{\text{bi}}$ of the corresponding relation on the algebra side. $\square$

Remark 22.9.6 (What is proved and what is not). The theorem gives the algebraic ordered open package. Upgrading to a fully symmetric one-brane open TCFT requires additional structure symmetrizing ordered fusion (a boundary symmetry datum or a geometric realization by bordered configuration spaces). This is part of the conjectural frontier below.

22.9.1 CALABI–YAU TRANSPORT

The ordered open trace formalism acquires a Frobenius structure under a Calabi–Yau hypothesis on A .

Definition 22.9.7 (Complete chiral Calabi–Yau structure). A strongly admissible associative chiral algebra A is called *d-Calabi–Yau* if:

- (a) A is perfect as an A^e -module, and
- (b) there is an isomorphism in $D_{\text{bi}}^{\text{pbw}}(A)$

$$\varphi_A : A \xrightarrow{\sim} \text{RHom}_{A^e}(A, A^e)[d].$$

Equivalently, A carries a nondegenerate d -shifted derived trace pairing.

THEOREM 22.9.8 (Shifted ordered Frobenius structure). Assume A is d -Calabi–Yau. Then the underlying complex of C_Δ carries a canonical d -shifted ordered Frobenius structure. More precisely:

- (i) the ordered pair-of-pants multiplication μ_P and unit η_P are as above;
- (ii) there is a trace

$$\varepsilon_P : C_\Delta \rightarrow k[-d]$$

transported from the Calabi–Yau trace on A ;

- (iii) there is a coproduct

$$\Delta_P : C_\Delta \rightarrow C_\Delta \star C_\Delta[d]$$

adjoint to μ_P under ε_P ;

(iv) the ordered Frobenius identities

$$(\mu_P \star \text{id}) \circ (\text{id} \star \Delta_P) = \Delta_P \circ \mu_P = (\text{id} \star \mu_P) \circ (\Delta_P \star \text{id})$$

hold.

Proof. On the algebra side, the Calabi–Yau structure identifies A with its bimodule dual shifted by d . Therefore multiplication

$$\mu_A : A \widehat{\otimes} A \rightarrow A$$

admits a unique adjoint coproduct

$$\Delta_A : A \rightarrow A \widehat{\otimes} A[d]$$

with respect to the trace pairing $\varepsilon_A : A \rightarrow k[-d]$; explicitly one may define Δ_A as the adjoint of μ_A under φ_A . The ordered Frobenius identities are formal consequences of associativity of μ_A and the nondegeneracy of the pairing.

Transport the entire package $(\mu_A, \eta_A, \varepsilon_A, \Delta_A)$ across the equivalence $\mathbb{K}_A^{\text{bi}}$ and use Theorem 22.7.4. The resulting structure maps are $\mu_P, \eta_P, \varepsilon_P, \Delta_P$, and all identities are preserved because the equivalence preserves composition. $\square$

COROLLARY 22.9.9 (*Cardy operator on the coalgebra side*). Under the hypotheses of Theorem 22.9.8, the ordered annulus endomorphism of the universal boundary object is

$$\text{Ann}_{C_\Delta} := \mu_P \circ \Delta_P \in \text{End}(C_\Delta)[d].$$

Its annular closure factors through the closed object

$$\mathcal{H}_C^{\text{cl}} \simeq \text{coHH}_\bullet^{\text{ch}}(C).$$

Proof. For a Calabi–Yau algebra, the open annulus operator is the composite $\mu_A \circ \Delta_A$ on the diagonal bimodule. Applying $\mathbb{K}_A^{\text{bi}}$ transports the diagonal bimodule to C_Δ and transports multiplication and comultiplication to the ordered pair-of-pants maps μ_P and Δ_P . Hence the ordered annulus endomorphism on the coalgebra side is $\mu_P \circ \Delta_P$. Corollary 22.8.3 identifies its annular closure with $\mathcal{H}_C^{\text{cl}} \simeq \text{coHH}_\bullet^{\text{ch}}(C)$. $\square$

22.10 A MASTER THEOREM AND ITS CONCEPTUAL FORM

The preceding results assemble into a single statement.

THEOREM 22.10.1 (*Master theorem*). Let A be a strongly admissible augmented associative chiral algebra on X , assume (A, A^{op}) is EZ-admissible, and set

$$C := \overline{B}^{\text{ch}}(A).$$

Then:

(1) **Ordered shuffle.** There is a quasi-isomorphism of conilpotent dg coalgebras

$$\overline{B}^{\text{ch}}(A \otimes^{\text{ch}} B) \simeq \overline{B}^{\text{ch}}(A) \widehat{\otimes} \overline{B}^{\text{ch}}(B)$$

for every EZ-admissible partner B .

- (2) **Opposite-duality.** There is a canonical isomorphism

$$\overline{B}^{\text{ch}}(A^{\text{op}}) \simeq \overline{B}^{\text{ch}}(A)^{\text{cop}}.$$

- (3) **Enveloping duality.** There is a canonical quasi-isomorphism

$$\overline{B}^{\text{ch}}(A^e) \simeq C^e.$$

- (4) **Two-sided bimodule/bicomodule duality.** There is an exact equivalence

$$D_{\text{bi}}^{\text{pbw}}(A) \simeq D_{\text{bi}}^{\text{co}}(C).$$

- (5) **Diagonal correspondence.** Under this equivalence one has

$${}_A A_A \longleftrightarrow C_{\Delta}.$$

- (6) **Composition.** The diagonal bicomodule is the unit for derived cotensor:

$$C_{\Delta} \square_C^{\mathbf{R}} X \simeq X \simeq X \square_C^{\mathbf{R}} C_{\Delta}.$$

- (7) **chiral Hochschild/coHochschild homology.** For every complete A -bimodule M ,

$$\text{HH}_{\bullet}^{\text{ch}}(A, M) \simeq \text{coHH}_{\bullet}^{\text{ch}}(C, \mathbb{K}_A^{\text{bi}}(M)).$$

- (8) **chiral Hochschild/coHochschild cohomology.** For every complete A -bimodule M ,

$$\text{HH}_{\text{ch}}^{\bullet}(A, M) \simeq \text{coHH}_{\text{ch}}^{\bullet}(C, \mathbb{K}_A^{\text{bi}}(M)).$$

- (9) **Tangent theory.** For a square-zero extension $A_{\varepsilon} = A \oplus \varepsilon M$,

$$\overline{B}^{\text{ch}}(A_{\varepsilon}) \cong C \oplus \varepsilon \mathbb{K}_A^{\text{bi}}(M) \pmod{\varepsilon^2}.$$

- (10) **Ordered open trace formalism.** The coalgebraic boundary object C_{Δ} carries ordered pair-of-pants, annulus, and composition operations transported from the algebra side, and if A is d -Calabi–Yau then the underlying complex of C_{Δ} becomes a d -shifted ordered Frobenius object.

Proof. This is a summary of Theorems 22.3.3, 22.5.1, 22.7.3, 22.7.4, 22.8.1, 22.8.2, 22.6.5, and 22.9.5, together with Corollaries 22.5.5, 22.7.5, and 22.6.6, and Theorem 22.9.8. $\square$

22.II CONFIGURATION SPACE GEOMETRY OF THE ORDERED BAR COMPLEX

The master theorem packages the ordered bar complex as an abstract dg coalgebra. The product $\text{FM}_k(\mathbb{C}) \times \text{Conf}_k^<(\mathbb{R})$ gives it a concrete body: the bar differential comes from the holomorphic factor, the coproduct from the topological factor.

22.II.1 ORDERED CONFIGURATION SPACES

Definition 22.II.1 (Ordered real configuration space). For $k \geq 1$, the *ordered real configuration space* is

$$\mathrm{Conf}_k^<(\mathbb{R}) := \{(t_1, \dots, t_k) \in \mathbb{R}^k \mid t_1 < t_2 < \dots < t_k\}.$$

This is a single open convex cell in $\mathbb{R}^k$, hence contractible.

PROPOSITION 22.II.2 (*Topology of ordered real configurations*;). (i) $\mathrm{Conf}_k^<(\mathbb{R})$ is contractible (it is a connected component of $\mathrm{Conf}_k^{\mathrm{ord}}(\mathbb{R})$, which consists of $k!$ contractible chambers).

- (ii) The natural projection $\pi_k: \mathrm{Conf}_k^{\mathrm{ord}}(\mathbb{R}) \rightarrow \mathrm{Conf}_k(\mathbb{R})/\Sigma_k$ is a $k!$ -sheeted covering. The fibre over a point $\{t_1, \dots, t_k\} \in \mathrm{Conf}_k(\mathbb{R})/\Sigma_k$ consists of the $k!$ orderings of the t_i .
- (iii) $\mathrm{Conf}_k^<(\mathbb{R})$ is a fundamental domain for the Σ_k -action: every unordered configuration can be uniquely ordered. This discreteness (each fibre is a set, not a path-connected space) is the geometric reason that the E_1 -structure (associativity) carries no homotopy-coherence data beyond the sequence of associahedra.

Proof. Part (i): $\mathrm{Conf}_k^<(\mathbb{R})$ is cut out by the strict linear inequalities $t_1 < t_2 < \dots < t_k$ inside $\mathbb{R}^k$, so it is an open convex cell and hence contractible. Permuting coordinates gives the other $k!$ chambers of $\mathrm{Conf}_k^{\mathrm{ord}}(\mathbb{R})$, and these chambers are disjoint because two different orderings cannot hold simultaneously. Part (ii): the Σ_k -action on $\mathrm{Conf}_k^{\mathrm{ord}}(\mathbb{R})$ is free, and quotienting by that action forgets the ordering while retaining the underlying set of points, so the fibre over an unordered configuration is exactly its $k!$ orderings. Part (iii): every unordered configuration admits a unique increasing representative, namely the one obtained by sorting its points from left to right. Thus $\mathrm{Conf}_k^<(\mathbb{R})$ is a fundamental domain, and the fact that the fibre is discrete explains why the ordered theory carries only E_1 -type coherence. $\square$

Definition 22.II.3 (Ordered holomorphic configuration space). For a smooth curve X and $k \geq 1$, the *ordered configuration space* is

$$\mathrm{Conf}_k^{\mathrm{ord}}(X) := \{(z_1, \dots, z_k) \in X^k \mid z_i \neq z_j \text{ for all } i \neq j\}.$$

The symmetric group Σ_k acts freely by permuting coordinates. The unordered configuration space is the quotient: $\mathrm{Conf}_k(X) = \mathrm{Conf}_k^{\mathrm{ord}}(X)/\Sigma_k$. For $X = \mathbb{C}$: $\pi_1(\mathrm{Conf}_k^{\mathrm{ord}}(\mathbb{C})) = P_k$, the pure braid group; $\pi_1(\mathrm{Conf}_k(\mathbb{C})) = B_k$, the full braid group.

22.II.2 THE PRODUCT SPACE AND ITS OPERADIC ROLE

Construction 22.II.4 (The $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$ operation space;). The two-coloured Swiss-cheese operad $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$ has operation spaces

$$\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}(k, m) = \mathrm{FM}_k(\mathbb{C}) \times E_1(m),$$

where $\mathrm{FM}_k(\mathbb{C})$ is the Fulton–MacPherson compactification of $\mathrm{Conf}_k(\mathbb{C})$ (the chiral, holomorphic factor) and $E_1(m)$ is the little-intervals operad (the coassociative, topological factor). Concretely, $E_1(m) \simeq \mathrm{Conf}_m^<(\mathbb{R})$ up to translation and scaling, which is contractible.

For the ordered bar complex of an E_1 -chiral algebra, the relevant spaces at tensor degree k are

$$\mathrm{FM}_k(\mathbb{C}) \times \mathrm{Conf}_k^<(\mathbb{R}).$$

A bar element of degree k is parametrised by this product: the coordinates $z_1, \dots, z_k \in \mathbb{C}$ live on the holomorphic curve, while the ordering $t_1 < t_2 < \dots < t_k$ records the position in the topological direction $\mathbb{R}_t$. The bar differential acts in the $\mathbb{C}$ -direction (extracting OPE residues); the deconcatenation coproduct acts in the $\mathbb{R}$ -direction (cutting the ordered sequence).

Remark 22.II.5 (The two colours). The product $\mathrm{FM}_k(\mathbb{C}) \times \mathrm{Conf}_k^<(\mathbb{R})$ is the geometric fingerprint of a 3d holomorphic-topological field theory on $\mathbb{C}_z \times \mathbb{R}_t$: observables factorise holomorphically in z and associatively in t . The bar differential is the chiral (holomorphic) component. The bar coproduct is the coassociative (topological) component.

Remark 22.II.6 (Codimension-one generators for $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$). The construction above gives the operation space, not yet a minimal generators-and-relations presentation, and by itself it does not equip the ordered bar complex with a full Swiss-cheese algebra structure. On compactified models the codimension-1 generator families are:

- (i) closed collision faces $\partial_S \mathrm{FM}_k(\mathbb{C})$ with $|S| \geq 2$;
- (ii) open interval-splitting faces in a Stasheff compactification of $E_1(m)$, equivalently cuts of the ordered open inputs into consecutive blocks;
- (iii) in the mixed space $\mathrm{FM}_k(\mathbb{C}) \times E_1(m)$, the product faces $\partial_S \mathrm{FM}_k(\mathbb{C}) \times E_1(m)$ and $\mathrm{FM}_k(\mathbb{C}) \times F$, with F an interval-splitting face as in (ii).

The codimension-2 relations are the intersections of these faces: Arnold–Orlik–Solomon in the closed factor, Stasheff associativity in the open factor, and mixed commuting squares comparing a closed collision with an open split.

22.II.3 THE ORDERED FM COMPACTIFICATION

Construction 22.II.7 (Ordered Fulton–MacPherson compactification;). The ordered FM compactification $\overline{\mathrm{FM}}_k^{\mathrm{ord}}(\mathbb{C})$ is the iterated real oriented blowup of $\mathrm{Conf}_k^{\mathrm{ord}}(\mathbb{C})$ along the *ordered* diagonals $D_{i,i+1} = \{z_i = z_{i+1}\}$ for $i = 1, \dots, k-1$. (In the unordered FM compactification, one blows up along all diagonals $D_S = \{z_i = z_j : i, j \in S\}$ for all subsets $S \subseteq \{1, \dots, k\}$ with $|S| \geq 2$. In the ordered case, only *consecutive* diagonals appear.)

The codimension-one boundary faces correspond to *consecutive* collisions $z_i \rightarrow z_{i+1}$, not to arbitrary subsets. A non-consecutive collision such as $z_1 \rightarrow z_3$ (with z_2 remaining separated) is not a codimension-one face of the ordered compactification.

Low-degree examples.

For $k = 2$: $\overline{\mathrm{FM}}_2^{\mathrm{ord}}(\mathbb{C}) \cong \overline{\mathbb{C}}$ (the Riemann sphere), with a single boundary divisor $D_{1,2} = \{z_1 = z_2\}$.

For $k = 3$: two codimension-one faces: $D_{1,2}$ (first pair collides) and $D_{2,3}$ (last pair collides). The face $D_{1,3}$ (first and third collide without the middle) is codimension 2: it requires both $D_{1,2}$ and $D_{2,3}$ to degenerate simultaneously. This is the associahedron K_3 : a line segment with two endpoints.

22.II.4 BOUNDARY STRATA: PLANTED FORESTS

Construction 22.II.8 (Boundary stratification by planted forests;). The boundary strata of $\overline{\mathrm{FM}}_k^{\mathrm{ord}}(\mathbb{C})$ are indexed by *planted forests*: ordered sequences of planar rooted trees.

A *planted forest* $F = (T_1, T_2, \dots, T_r)$ is an *ordered* sequence of planar rooted trees whose leaves, read from left to right across all trees, are labelled $1, 2, \dots, k$ in order. The trees $T_1, \dots, T_r$ correspond to the r clusters of points that remain separated at the given codimension; within each tree, the internal vertices record the collision history of points within that cluster.

The stratum indexed by F is the product

$$\partial_F \overline{\text{FM}}_k^{\text{ord}}(\mathbb{C}) \cong \prod_{j=1}^r \overline{\text{FM}}_{|T_j|}^{\text{ord}}(\mathbb{C}),$$

where $|T_j|$ is the number of leaves of T_j .

For the codimension-one faces: each is indexed by a forest with $k-1$ trees, $k-2$ of which are single leaves and one of which is a single binary tree with two leaves. Concretely, the face $D_{i,i+1}$ corresponds to the forest in which points i and $i+1$ form a binary tree (they collide) and all other points are isolated.

Contrast with the unordered case. In the unordered FM compactification, boundary strata are indexed by *trees* (rooted trees with unordered children). In the ordered case, the strata are indexed by *planted forests* (ordered sequences of planar trees): the ordering of trees within the forest records the linear order on the topological direction.

22.II.5 THE BAR DIFFERENTIAL FROM COLLISION RESIDUES

Construction 22.II.9 (Bar differential;). Let $\mathcal{A}$ be a strongly admissible E_1 -chiral algebra with structure constants $e_{I(n)} e_J = \sum_K c_{IJ;n}^K e_K$ relative to a homogeneous basis $\{e_I\}$ of the augmentation ideal $\bar{\mathcal{A}}$. The bar differential on $\bar{B}^{\text{ch,ord}}(\mathcal{A})$ decomposes as

$$d_{\bar{B}^{\text{ch,ord}}} = d_{\text{int}} + \sum_{i=1}^{k-1} d_{i,i+1},$$

where:

- d_{int} applies the internal differential of $\mathcal{A}$ to each tensor factor.
- $d_{i,i+1}$ extracts the collision residue at the codimension-one stratum $D_{i,i+1} = \{z_i = z_{i+1}\}$, using the ordered logarithmic propagator $\eta_{i,i+1} = d \log(z_i - z_{i+1})$.

Explicitly, the component $d_{i,i+1}$ acts on a bar word $[s^{-1}e_{I_1} | \dots | s^{-1}e_{I_k}]$ by contracting the i -th and $(i+1)$ -st slots via all OPE products:

$$d_{i,i+1}[s^{-1}e_{I_1} | \dots | s^{-1}e_{I_k}] = \sum_{K,n} \pm c_{I_i I_{i+1};n}^K [s^{-1}e_{I_1} | \dots | s^{-1}e_K | \dots | s^{-1}e_{I_k}] \otimes [\delta_{D_{i,i+1}}^{(n)}],$$

where the contracted pair is replaced by a single slot and $[\delta_{D_{i,i+1}}^{(n)}]$ is the n -th residue class at the collision divisor.

The sum runs only over *consecutive* collisions $i, i+1$: this is the ordered constraint. In the unordered bar complex (Vol. I, Theorem A), one sums over all pairs $\{i, j\}$ and then takes Σ_k -coinvariants.

The identity $d^2 = 0$ follows from Stokes' theorem applied to the boundary strata of $\overline{\text{FM}}_k^{\text{ord}}(\mathbb{C})$: the codimension-two strata receive two contributions from the two orderings of consecutive collisions, and the algebraic content of their cancellation is the associativity axiom for the chiral product (i.e. the E_1 -operad relation on the zeroth-mode component, supplemented by the higher-mode residue classes $[\delta_D^{(n)}]$ retained in the tensor decoration).

Remark 22.II.10 (Ordered vs. FG bar: the all-modes clause). The sum over all OPE modes n in the bar differential (eq. above) distinguishes the ordered bar from the Francis–Gaitsgory bar, which retains only the $n = 0$ slot. The higher-mode contributions are recorded on ordered bar words via the tensor decorations $[\delta_D^{(n)}]$; equivalently, scalar-valued higher-mode residues contribute to the curvature m_0 of the curved bar coalgebra (see the Heisenberg case, Theorem 22.I2.1), while field-valued higher-mode residues feed spectral A_∞ -corrections m_k at degree $k \geq 3$ (see the Virasoro case, §22.15). In every case the ordered bar extracts *all* OPE modes; the convention chosen here differs from the raw-OPE presentation on the right-hand side of the classical Laurent expansion by the single d log absorption step.

22.II.6 THE DECONCATENATION COPRODUCT

Construction 22.II.11 (Deconcatenation coproduct;). The ordered bar coalgebra carries a coassociative coproduct Δ defined by *deconcatenation*: cutting the ordered sequence at every possible position. For a bar word of length k :

$$\Delta[s^{-1}e_{I_1} | \cdots | s^{-1}e_{I_k}] = \sum_{p=0}^k [s^{-1}e_{I_1} | \cdots | s^{-1}e_{I_p}] \otimes [s^{-1}e_{I_{p+1}} | \cdots | s^{-1}e_{I_k}],$$

where the $p = 0$ and $p = k$ terms produce the coaugmentation.

This coproduct is the topological structure: it comes from the ordered configuration space $\text{Conf}_k^<(\mathbb{R})$ by cutting the ordered real line at a point between t_p and t_{p+1} . The p points to the left form one ordered subconfiguration; the $k-p$ points to the right form another. The coassociativity of Δ is the associativity of interval composition.

Contrast with the holomorphic differential. The bar differential d extracts residues in the holomorphic direction (collisions of points on $\mathbb{C}$). The coproduct Δ cuts in the topological direction (splitting the ordered sequence on $\mathbb{R}$). Together, the pair (d, Δ) encodes both components of the E_1 -chiral coalgebra:

Structure	Direction	Geometric source
Bar differential d	holomorphic ($\mathbb{C}_z$)	OPE residues on $\text{FM}_k(\mathbb{C})$
Coproduct Δ	topological ($\mathbb{R}_t$)	Deconcatenation of $\text{Conf}_k^<(\mathbb{R})$

22.II.7 THE COVERING SPACE FRAME

Construction 22.II.12 (Ordered-to-unordered covering;). The projection

$$\pi_k : \text{Conf}_k^{\text{ord}}(\mathbb{C}) \longrightarrow \text{Conf}_k(\mathbb{C}) = \text{Conf}_k^{\text{ord}}(\mathbb{C}) / \Sigma_k$$

is a principal Σ_k -bundle, étale with fibre Σ_k . The fibre is a $k!$ -element set.

In the topological direction, the analogous covering $\text{Conf}_k^{\text{ord}}(\mathbb{R}) \rightarrow \text{Conf}_k(\mathbb{R}) / \Sigma_k$ is also a $k!$ -sheeted covering, but here it is trivialised by the total order on $\mathbb{R}$: the component $\text{Conf}_k^<(\mathbb{R})$ is a fundamental domain. This triviality is why the topological direction carries an E_1 -structure (associative, no higher coherences from the covering) while the holomorphic direction carries monodromy (the R -matrix).

The bar complex at tensor degree k defines a local system $\mathcal{F}_k^{\text{ord}}$ on $\text{Conf}_k^{\text{ord}}(\mathbb{C})$ whose stalk at $(z_1, \dots, z_k)$ is $(s^{-1}\bar{\mathcal{A}})^{\otimes k}$, with flat connection induced by the residue differential d_{res} . The R -matrix is the monodromy of this flat connection.

To descend $\mathcal{F}_k^{\text{ord}}$ from ordered to unordered configurations requires a Σ_k -equivariant structure: isomorphisms $R_\sigma : \mathcal{F}_k^{\text{ord}}|_{(z_1, \dots, z_k)} \xrightarrow{\sim} \mathcal{F}_k^{\text{ord}}|_{(z_{\sigma(1)}, \dots, z_{\sigma(k)})}$ for each $\sigma \in \Sigma_k$, satisfying the cocycle condition and compatible with the flat connection.

For an E_∞ -chiral algebra (which is any vertex algebra, including those with OPE poles), the equivariant structure is canonical: $R_\sigma = \epsilon(\sigma) \cdot \tau_\sigma$, where τ_σ permutes tensor factors and $\epsilon(\sigma)$ is the Koszul sign. The descent then recovers the ordinary Σ_k -coinvariant bar complex (Vol. I, Theorem A).

For a genuinely E_1 -chiral algebra (where the ordering is primitive, not derived from a local OPE), the equivariant structure must be *constructed* from the OPE data. This construction is the R -matrix, and its existence imposes the Yang–Baxter equation (the content of $d^2 = 0$ at tensor degree 3).

Remark 22.11.13 (Why ordered spaces). The use of ordered versus unordered configuration spaces reflects the operadic symmetry of the algebra:

- An E_∞ -algebra (any vertex algebra, any BD chiral algebra) has operations that are Σ_n -equivariant: the factorisation structure is defined on the *unordered* configuration space $\text{Conf}_k(X)/\Sigma_k$. The ordering on the bar complex is a computational convenience that can be quotiented out.
- An E_1 -algebra (an associative chiral algebra, a quantum vertex algebra in the sense of Etingof–Kazhdan) has operations indexed by *ordered* compositions: its bar complex uses $\text{Conf}_k^{\text{ord}}(X)$. The ordering records the topological direction: in $\mathbb{C}_z \times \mathbb{R}_t$, points along $\mathbb{R}_t$ are ordered by time, and the E_1 -structure is the time-ordered product.
- The Swiss-cheese operad $\text{SC}^{\text{ch}, \text{top}}$ uses *both*: unordered configurations in the holomorphic direction (chiral component) and ordered configurations in the topological direction (coassociative component). The ordered bar complex of a vertex algebra, which is E_∞ -chiral, uses the ordered configuration space for the E_1 /coassociative component of $\text{SC}^{\text{ch}, \text{top}}$; this is the topological direction, not a claim that the algebra is nonlocal. The holomorphic component remains E_∞ .

The R -matrix $R(z) \in \text{End}(V \otimes V)((z))$ is the data needed to pass from ordered to unordered configurations in the holomorphic direction: it is the monodromy of the local system on $\text{Conf}_2^{\text{ord}}(\mathbb{C})$ around the generator of $\pi_1 = \mathbb{Z}$.

What does the machine produce for the simplest chiral algebra specifically, the Heisenberg at level k ?

22.12 THE HEISENBERG ORDERED BAR COMPLEX

Let $V = \mathbb{C} \cdot J$ be the one-dimensional vector space spanned by the Heisenberg current, let $k \in \mathbb{C}$ be the level, and let $\mathcal{H}_k$ be the Heisenberg chiral algebra with OPE

$$J(z)J(w) \sim \frac{k}{(z-w)^2}.$$

The Heisenberg algebra is E_∞ -chiral: it is a local vertex algebra with Σ_n -equivariant factorization structure. Its OPE has a double pole, but poles do not break E_∞ -locality.

The ordered bar complex $\overline{B}^{\text{ch}}(\mathcal{H}_k)$ is the cofree conilpotent coalgebra on the desuspension $s^{-1}\overline{\mathcal{H}}_k$, with the ordering of tensor factors recording the linear order $t_1 < \dots < t_n$ on $\mathbb{R}$. We compute the complex degree by degree.

THEOREM 22.12.1 (*The Heisenberg ordered bar complex;*). The ordered bar complex $\overline{B}^{\text{ch}}(\mathcal{H}_k)$ is a curved cofree conilpotent dg coalgebra $(T^c(s^{-1}V), d_{\overline{B}^{\text{ch}}}, m_0, \Delta)$ carrying the following data:

- (1) **Curvature.** The degree-0 component is

$$m_0 = k \cdot |0\rangle \in \overline{B}_0^{\text{ch}}(\mathcal{H}_k),$$

the constant extracted from the double-pole coefficient $J_{(1)}J = k$. This is the genus-zero Heisenberg curvature $\kappa(\mathcal{H}_k) = k$ of the Vol. I landscape census.

- (2) **Degree 1.** $\overline{B}_1^{\text{ch}}(\mathcal{H}_k) = \mathbb{C} \cdot [s^{-1}J]$, with $d_{\overline{B}^{\text{ch}}}[s^{-1}J] = 0$ (the linear bar differential is binary; a single element has no adjacent pair to collide).
- (3) **Degree 2.** $\overline{B}_2^{\text{ch}}(\mathcal{H}_k) = \mathbb{C} \cdot [s^{-1}J | s^{-1}J]$, a *single* generator (the ordered complex retains the linear order; there is no Σ_2 -identification). The linear bar differential vanishes:

$$d_{\overline{B}^{\text{ch}}}[s^{-1}J | s^{-1}J] = 0,$$

because the contraction of the two adjacent J -slots into a *single* bar slot must land in the augmentation ideal $\bar{\mathcal{H}}_k$, whereas the only nonvanishing OPE mode of two J 's is the central scalar $J_{(1)}J = k \in \mathbb{C}$. The scalar escapes the augmentation ideal entirely and is collected in the curvature m_0 upstream (item (1)), not in the linear differential d_1 .

- (4) **Degree n .** $\overline{B}_n^{\text{ch}}(\mathcal{H}_k) = \mathbb{C} \cdot [s^{-1}J | \cdots | s^{-1}J]$ (n copies), with $d_{\overline{B}^{\text{ch}}} = 0$ on every element. The argument is uniform: each adjacent collision either lands in a scalar (contributing to m_0) or vanishes, so no contribution survives in the augmentation ideal at positive degree.

- (5) **Coproduct.** The deconcatenation coproduct Δ on $\overline{B}^{\text{ch}}(\mathcal{H}_k)$ is

$$\Delta[s^{-1}J | \cdots | s^{-1}J] = \sum_{i=0}^n [s^{-1}J | \cdots | s^{-1}J]_i \otimes [s^{-1}J | \cdots | s^{-1}J]_{n-i},$$

where the subscript denotes the number of tensor factors. This is the tensor coalgebra coproduct, encoding interval-cutting in $\mathbb{R}$.

- (6) **Curved E_1 -chiral coalgebra structure.** The ordered bar coalgebra is the curved cofree object $(T^c(s^{-1}V), d_1 = 0, m_0 = k|0\rangle, \Delta)$: the linear differential vanishes identically, but the degree-0 curvature $m_0 = k|0\rangle$ is non-zero. The associated R-matrix $R(z) = e^{k\hbar/z}$ (Theorem 22.12.3) is the exponentiated form of the curvature seen on the ordered configuration space.

Proof. Heisenberg has the single generator J and the unique nonvanishing OPE mode $J_{(1)}J = k$, which is a scalar. The linear bar differential $d_1 : \overline{B}_n^{\text{ch}} \rightarrow \overline{B}_{n-1}^{\text{ch}}$ contracts an adjacent pair of slots into a single slot of the augmentation ideal $\bar{\mathcal{H}}_k$. The only output available from $J \cdot J$ contractions is the scalar k , which lies outside $\mathcal{H}_k$; hence $d_1 = 0$ on every bar word. The scalar contribution is collected separately in the degree-0 component, giving $m_0 = k|0\rangle$.

The deconcatenation coproduct is manifestly coassociative (it is the tensor coalgebra structure), and the curved bar identity reduces to $d_1 \circ d_1 = [m_0, -]_{\circ}$, both sides of which vanish on the augmentation ideal. $\square$

Remark 22.12.2 (Curvature, not differential). The mode $J_{(1)}J = k$ is the genus-zero curvature of the ordered Heisenberg bar coalgebra: it lives in the degree-0 component m_0 , not in the linear differential d_1 . In the *symmetric* bar complex $\overline{B}^\Sigma(\mathcal{H}_k)$ (Vol I, Theorem A) the same datum is conventionally recorded by $d_B[s^{-1}J | s^{-1}J] = k$, viewing the constant k as the value of d on the ground field copy inside the symmetric bar. In the ordered complex the constant is collected upstream in m_0 , and the corresponding holonomy on ordered configuration space is the R-matrix $R(z) = e^{k\hbar/z}$ (Theorem 22.12.3). The three pictures are equivalent presentations of the same genus-zero datum $\kappa(\mathcal{H}_k) = k$.

THEOREM 22.12.3 (Collision residue and R-matrix;). Let $z = z_1 - z_2$ denote the relative coordinate on $C_2^<(\mathbb{C})$. The collision residue of the Heisenberg double-pole OPE is

$$r^{\text{coll}}(z) = \frac{k}{z},$$

a *simple* pole obtained from the OPE double pole $k/(z_1 - z_2)^2$ by one step of $d \log$ absorption/lowerseveryOPEpoleorderby
The flat connection on the trivial bundle over $C_2^<(\mathbb{C})$ determined by the bar propagator is

$$\nabla = d - r^{\text{coll}}(z) dz = d - (k/z) dz,$$

and its monodromy around the origin is

$$\text{Mon}_0(\nabla) = e^{-2\pi i k}$$

(treating $k \in \mathbb{C}$ as a generic continuous parameter).

The spectral R -matrix on modules is

$$R(z) = e^{k\hbar/z} \quad (\text{NOT trivial}).$$

Since $\mathcal{H}_k$ is E_∞ -chiral, this R -matrix is *derived* from the local OPE via the monodromy of ∇ , not independent input. The Yang–Baxter equation is satisfied trivially because $R(z)$ is scalar ($\mathcal{H}_k$ has rank 1).

Proof. The OPE mode expansion is $J(z)J(w) = \sum_{n \geq 0} J_{(n)}J \cdot (z-w)^{-n-1}$, with the unique nonvanishing mode $J_{(1)}J = k$ giving the double-pole coefficient. Pairing the OPE density $k(z-w)^{-2}dz$ against the bar kernel $d \log(z-w)$ on $\text{FM}_2(\mathbb{C})$ and using $d \log(z-w) = -dw/(z-w)$ absorbs one power of $(z-w)^{-1}$, producing the simple-pole residue kernel $k/(z-w) dz$ on the ordered configuration space. Writing $z = z_1 - z_2$ for the relative coordinate, $r^{\text{coll}}(z) = k/z$ as claimed.

The connection $\nabla = d - (k/z) dz$ on the trivial line bundle over $\mathbb{C}^\times$ has flat sections $f(z) = z^k$; the associated parallel transport around $\gamma: z \mapsto e^{2\pi i t} z$ multiplies flat sections by $e^{2\pi i k}$, so the monodromy acting on parallel-transported vectors is $e^{-2\pi i k}$.

The spectral R -matrix is obtained by the Kohno exponentiation of the connection. On Fock modules $\mathcal{F}_\mu \otimes \mathcal{F}_\nu$ the Casimir collapses to the scalar $\mu\nu k$, and the path-ordered exponential reduces to the ordinary exponential $R(z) = \exp(\oint r^{\text{coll}}(z) dz) = e^{k\hbar/z}$ in the spectral variable, where $\hbar = \mu\nu$. The computation is scalar throughout because $\mathcal{H}_k$ is rank one. $\square$

Remark 22.12.4 (Non-triviality). The Heisenberg R-matrix $R(z) = e^{k\hbar/z}$ is *not* the trivial permutation $R = \tau$. For a generic level k and generic Fock charges, $R(z)$ is a non-identity scalar exponential series in $1/z$. The collision residue k/z is derived from the OPE double pole ($d \log$ absorption); attempting to read the R-matrix off the raw OPE without applying the step gives the incorrect answer k/z^2 and hence a wrong pole structure.

THEOREM 22.12.5 (*Open-colour Koszul dual: the abelian Yangian;*). The ordered (coassociative) Koszul dual of $\mathcal{H}_k$ is the abelian Yangian

$$\mathcal{H}_k^{1,\text{ord}} \simeq Y(\mathfrak{u}(1)) \simeq \mathbb{C}[h_0, h_1, h_2, \dots],$$

the polynomial algebra on generators h_n of degree $n + 1$, with product inherited from the linear dual of the deconcatenation coproduct. The spectral-parameter presentation identifies $h_n = \partial_u^n h(u)|_{u=0}$, where $h(u) = \sum_{n \geq 0} h_n u^{-n-1}$ is the generating current of the Yangian.

Proof. Since the bar differential vanishes on $\overline{B}^{\text{ch}}(\mathcal{H}_k)$, the Koszul dual is the linear dual of the bar coalgebra:

$$\mathcal{H}_k^{1,\text{ord}} = (\overline{B}^{\text{ch}}(\mathcal{H}_k))^\vee = (T^c(s^{-1}V))^\vee \simeq T(sV^\vee) \simeq \mathbb{C}[h],$$

where $h = (s^{-1}J)^\vee$ is the dual generator. The coalgebra $T^c(s^{-1}V)$ has deconcatenation coproduct; dualizing produces the concatenation (polynomial) product on $T(sV^\vee) = \mathbb{C}[h]$.

Since V is one-dimensional and $d_{\overline{B}^{\text{ch}}} = 0$, the Koszul dual algebra is freely generated by h with no relations. Restoring the spectral grading from the FM configuration-space stratification, the degree- n component corresponds to $\text{FM}_n(\mathbb{C})$, giving the generators $h_0, h_1, h_2, \dots$ of the abelian Yangian $Y(\mathfrak{u}(1))$.

Equivalently: the Koszul dual is the endomorphism algebra of the line operator b in the coassociative line category $\mathcal{C}_{\text{line}}$. The line category $\mathcal{C}_{\text{line}} \simeq \mathcal{H}_{-k}\text{-mod}$ is equivalent to modules over the negative-level Heisenberg, but the ordered Koszul dual $\mathcal{H}_k^{1,\text{ord}} = Y(\mathfrak{u}(1)) \simeq \mathbb{C}[h_0, h_1, \dots]$ is categorically distinct from $\mathcal{H}_{-k}$ as a chiral algebra, *not* $\mathcal{H}_{-k}$; they share the same modular characteristic $\kappa = -k$ but differ as algebras). $\square$

THEOREM 22.12.6 (*Formality: class G, shadow depth 2;*). The Heisenberg ordered bar complex is formal: the A_∞ -structure on $H^\bullet(\overline{B}^{\text{ch}}(\mathcal{H}_k))$ has $m_k = 0$ for all $k \geq 3$. The Heisenberg belongs to class G (shadow depth $r_{\text{max}} = 2$, the minimum for a nontrivial chiral algebra).

Proof. Since $d_{\overline{B}^{\text{ch}}} = 0$, the bar complex is its own cohomology. There is nothing to transfer: the A_∞ -structure on cohomology inherits the trivial differential and the deconcatenation coproduct, with all higher operations vanishing. The vanishing of $m_{k \geq 3}$ is equivalent to saying that the OPE has a single pole order (the double pole), and the collision residue $r^{\text{coll}} = k/z$ has a simple pole, which falls in class G. $\square$

Remark 22.12.7 (*Contrast with the chiral (symmetric) Koszul dual*). The chiral Koszul dual of $\mathcal{H}_k$ (Vol I) is the commutative chiral algebra

$$\mathcal{H}_k^{1,\text{ch}} = \text{Sym}^{\text{ch}}(V^*),$$

a free commutative vertex algebra on one generator. The ordered Koszul dual $Y(\mathfrak{u}(1))$ carries strictly more structure: the spectral parameter u (arising from the FM stratification in the ordered complex) is invisible in the symmetric Koszul dual. The passage from ordered to symmetric is R -matrix-twisted Σ_n -coinvariants: since $R(z) = e^{k\hbar/z} \neq \tau$ (the Koszul sign), the descent $\overline{B}^{\text{ch}}(\mathcal{H}_k) \rightarrow \overline{B}^\Sigma(\mathcal{H}_k)$ is genuinely twisted, and the spectral parameter information is lost in the quotient (absorbed into the bar differential of $\overline{B}^\Sigma$, where $d_{\overline{B}}[s^{-1}J | s^{-1}J] = k \neq 0$).

This is the three-tier picture in its simplest instance: the Heisenberg lives in tier (ii) (E_∞ -chiral with $R(z) \neq \tau$, derived from the local OPE). Tier (i) would require $R(z) = \tau$ (no OPE poles); tier (iii) would require $R(z)$ to be independent input (genuinely E_1).

Remark 22.12.8 (The Heisenberg as prototype). The Heisenberg ordered bar complex is the simplest instance of a general pattern. Each subsequent family generalises exactly one aspect of the structure, while preserving the others.

1. *$\beta\gamma$ system* (§22.24): The underlying vector space grows from $\dim V = 1$ to $\dim V = 2$, and the exponential R -matrix $e^{k\hbar/z}$ becomes nilpotent: $R = 1 + 2\pi i \Theta$ with $\Theta^2 = 0$. The bar differential remains trivial ($d_{\overline{B}^{\text{ch}}} = 0$) because the zeroth mode product $\beta_{(0)}\gamma = 1$ is a scalar, not a new generator. Formality persists: shadow depth is $r_{\max} = 4$ (class C).
2. *Affine $\widehat{\mathfrak{g}}_k$* (§22.16.1): The scalar collision residue k/z becomes the matrix-valued Casimir kernel $\hbar\Omega/z \in \text{End}(\mathfrak{g} \otimes \mathfrak{g})$, where $\hbar = 1/(k + h^\vee)$. The scalar R -matrix $e^{k\hbar/z}$ becomes the Yang R -matrix $1 + \hbar\Omega/z + O(\hbar^2)$. The abelian Yangian $Y(\mathfrak{u}(1))$ becomes $Y_{\hbar}(\mathfrak{g})$. The bar differential acquires nontrivial components from $[X, Y]_{(0)} \neq 0$, but formality persists: shadow depth is $r_{\max} = 3$ (class L).
3. *Virasoro* (§22.15): The double OPE pole becomes quartic: $T(z)T(w) \sim (c/2)/(z-w)^4 + \dots$. The simple collision residue k/z becomes the triple-pole residue $(c/2)/z^3 + 2T/z$. Formality breaks: $m_k \neq 0$ for all $k \geq 3$, so the A_∞ -structure is genuinely infinite. Shadow depth is $r_{\max} = \infty$ (class M). The nontrivial Yangian structure collapses to a single generator T , but the non-formal bar differential compensates: the complexity migrates from the algebra's rank to the differential's depth.

In summary: the Heisenberg is class G (shadow depth 2, formal, scalar). The $\beta\gamma$ system is class C (shadow depth 4, formal, nilpotent matrix). The affine is class L (shadow depth 3, formal, matrix). The Virasoro is class M (shadow depth ∞ , non-formal, collapsed rank). Each step from Heisenberg to Virasoro escalates exactly one structural parameter while the rest of the ordered bar architecture remains intact.

22.13 THE DRINFELD PRESENTATION OF $Y_{\hbar}(\mathfrak{sl}_2)$

The ordered bar complex $\overline{B}^{\text{ch}}(V_k(\mathfrak{sl}_2))$ produces the Yang R -matrix, the RTT presentation, and the Gauss decomposition. The *Drinfeld presentation* (the generating-current form that reveals the Yangian as a deformation of the current algebra $U(\mathfrak{sl}_2[t])$) emerges from the ordered bar data. The affine vertex algebra $V_k(\mathfrak{sl}_2)$ is E_∞ -chiral (it is a local vertex algebra with Σ_n -equivariant factorisation structure); the Yangian $Y_{\hbar}(\mathfrak{sl}_2)$ is the ordered Koszul dual living on the open boundary $\mathbb{R}_t$.

Generators

The Drinfeld generators are obtained from the Gauss decomposition of the transfer matrix $T(u) = F(u)K(u)E(u)$, where $F(u)$ is lower-triangular unipotent, $K(u) = \text{diag}(k_1(u), k_2(u))$ is diagonal, and $E(u)$ is upper-triangular unipotent. Define the Drinfeld currents:

$$\begin{aligned} E(u) &= \sum_{r \geq 0} E_r u^{-r-1}, \\ F(u) &= \sum_{r \geq 0} F_r u^{-r-1}, \\ H(u) &= 1 + \hbar \sum_{r \geq 0} H_r u^{-r-1} = \frac{k_1(u)}{k_2(u)}. \end{aligned}$$

The modes $\{E_r, F_r, H_r\}_{r \geq 0}$ generate $Y_{\hbar}(\mathfrak{sl}_2)$ as an associative algebra. At $\hbar = 0$, the identification $E_r \mapsto e \otimes t^r, F_r \mapsto f \otimes t^r, H_r \mapsto h \otimes t^r$ recovers $U(\mathfrak{sl}_2[t])$.

The Drinfeld relations from the bar complex

THEOREM 22.13.1 (*Drinfeld presentation of $Y_{\hbar}(\mathfrak{sl}_2)$*). The Yangian $Y_{\hbar}(\mathfrak{sl}_2)$, with $\hbar = 1/(k+2)$, is the associative algebra generated by $\{E_r, F_r, H_r\}_{r \geq 0}$ subject to the relations:

$$(D_1) \quad [H_r, H_s] = 0 \text{ for all } r, s \geq 0.$$

$$(D_2) \quad [H(u), E(v)] = \frac{2\hbar}{u-v} (E(u) - E(v)).$$

$$(D_3) \quad [H(u), F(v)] = -\frac{2\hbar}{u-v} (F(u) - F(v)).$$

$$(D_4) \quad [E(u), F(v)] = \frac{1}{u-v} (H(u) - H(v)).$$

$$(D_5) \quad (u-v) [E(u), E(v)] = \hbar (E(u) E(v) + E(v) E(u)) \text{ (deformed Serre relation).}$$

$$(D_6) \quad (u-v) [F(u), F(v)] = -\hbar (F(u) F(v) + F(v) F(u)) \text{ (deformed Serre relation).}$$

Proof. Relations (D1)–(D4) are extracted from the Gauss decomposition of the RTT equation $R_{12}(u-v) T_1(u) T_2(v) = T_2(v) T_1(u) R_{12}(u-v)$. The key step is the factorisation $T(u) = F(u) K(u) E(u)$: the diagonal entries produce (D1), the off-diagonal–diagonal cross-terms produce (D2)–(D3), and the purely off-diagonal cross-terms produce (D4).

For (D1): the RTT relations $[A(u), A(v)] = 0 = [D(u), D(v)]$ imply that $k_1(u), k_2(u)$ (and hence $H(u) = k_1(u)/k_2(u)$) generate a commutative subalgebra.

For (D2): the RTT relation $(u-v)[A(u), B(v)] = A(v)B(u) - A(u)B(v)$, rewritten via Gauss decomposition in terms of $H(u)$ and $E(u)$, yields the stated current-algebra relation. Expanding $A(u) = k_1(u)(1 + F(u) k_2(u) k_1(u)^{-1} E(u))$ and $B(u) = k_1(u) E(u)$, the diagonal factor cancels between left and right sides, and the residual identity in the off-diagonal is precisely (D2). Relation (D3) follows by the same argument applied to $(u-v)[A(u), C(v)] = C(v)A(u) - C(u)A(v)$.

For (D4): the RTT relation $(u-v)[B(u), C(v)] = D(v)A(u) - D(u)A(v)$ extracts, via Gauss decomposition, to $(u-v)[E(u), F(v)] = H(u) - H(v)$.

For (D5) and (D6): the RTT relation $[B(u), B(v)] = 0$ encodes $[E(u), E(v)]$ modulo diagonal factors. The precise computation: $[B(u), B(v)] = 0$ with $B(u) = k_1(u) E(u)$ gives, after extracting the non-commuting diagonal, $(u-v)[E(u), E(v)] = \hbar (E(u)E(v) + E(v)E(u))$. The sign in (D6) follows from $[C(u), C(v)] = 0$ by the same argument with F in place of E .

Every relation is a direct algebraic consequence of the RTT presentation, itself extracted from the degree-2 bar differential and the Yang R -matrix $R(u) = uI + P$. $\square$

Remark 22.13.2 (*Provenance from the bar complex*). The chain of identifications is:

$$\text{OPE of } \widehat{\mathfrak{sl}}_2 \xrightarrow{\text{bar differential}} r(z) = \frac{\hbar \Omega}{z} \xrightarrow{\text{exponentiation}} R(u) = uI + P \xrightarrow{\text{RTT}} (D_1)\text{--}(D_6).$$

The first arrow is (the $d \log$ kernel absorbs one pole from the affine double-pole OPE); the second is the monodromy of the Kohno connection on $\text{Conf}_2^{\text{ord}}(\mathbb{C})$ specialised to the fundamental representation; the third is the Gauss decomposition. The entire Drinfeld presentation is a derived algebraic consequence of the OPE of $V_k(\mathfrak{sl}_2)$.

Gauss decomposition

PROPOSITION 22.13.3 (*Gauss decomposition*). The transfer matrix $T(u) = \begin{pmatrix} A(u) & B(u) \\ C(u) & D(u) \end{pmatrix}$ factors uniquely as

$$T(u) = \underbrace{\begin{pmatrix} 1 & 0 \\ F(u) & 1 \end{pmatrix}}_{F(u)} \cdot \underbrace{\begin{pmatrix} k_1(u) & 0 \\ 0 & k_2(u) \end{pmatrix}}_{K(u)} \cdot \underbrace{\begin{pmatrix} 1 & E(u) \\ 0 & 1 \end{pmatrix}}_{E(u)},$$

with $A(u) = k_1(u) + F(u) k_2(u) E(u)$, $B(u) = k_1(u) E(u)$, $C(u) = F(u) k_2(u)$, $D(u) = k_2(u)(1 + F(u) E(u))$. The Drinfeld Cartan current is the ratio $H(u) = k_1(u)/k_2(u)$.

Proof. The upper-triangular unipotent factor is determined by $E(u) = k_1(u)^{-1} B(u)$; the lower-triangular unipotent factor by $F(u) = C(u) k_2(u)^{-1}$; the diagonal entries by $k_2(u) = D(u) - C(u) A(u)^{-1} B(u)$ (the Schur complement) and $k_1(u) = A(u) - B(u) D(u)^{-1} C(u)$. The quantum determinant $\text{qdet } T(u) = k_1(u) k_2(u - \hbar)$ is central in $Y_h(\mathfrak{sl}_2)$, confirming the factorisation is well-defined over the Yangian. $\square$

Twisted coproduct on Drinfeld generators

THEOREM 22.13.4 (*Twisted coproduct*). The twisted coproduct $\Delta_z : Y_h(\mathfrak{sl}_2) \rightarrow Y_h(\mathfrak{sl}_2) \otimes Y_h(\mathfrak{sl}_2)$ acts on the Drinfeld generators as:

$$\Delta_z(H(u)) = H(u) \otimes H(u-z), \quad (22.6)$$

$$\Delta_z(E(u)) = E(u) \otimes 1 + H(u-z) \otimes E(u-z), \quad (22.7)$$

$$\Delta_z(F(u)) = 1 \otimes F(u-z) + F(u) \otimes H(u-z)^{-1}. \quad (22.8)$$

At $z = 0$ this recovers the standard Hopf coproduct of $Y_h(\mathfrak{sl}_2)$.

Proof. The RTT coproduct is $\Delta_z(T(u)) = T(u) \dot{\otimes} T(u-z)$ (matrix multiplication in the auxiliary space, with spectral parameter shifted by z in the second tensor factor). Applying Gauss decomposition to both sides:

$$\Delta_z(T(u)) = F(u) K(u) E(u) \dot{\otimes} F(u-z) K(u-z) E(u-z).$$

The diagonal entry gives $\Delta_z(K(u)) = K(u) \otimes K(u-z)$, whence (22.6) follows by taking the ratio k_1/k_2 . The off-diagonal entry $\Delta_z(B(u)) = A(u) \otimes B(u-z) + B(u) \otimes D(u-z)$, rewritten via $B = k_1 E$ and $A = k_1 + F k_2 E$, yields (22.7) after extracting the k_1 factor. Equation (22.8) follows by the analogous computation on $C(u) = F(u) k_2(u)$. $\square$

Remark 22.13.5 (*Factorisation-algebraic origin of Δ_z*). The spectral parameter z is the relative position along $\mathbb{R}_t$: it is the topological interval coordinate of the $\text{SC}^{\text{ch}, \text{top}}$ -structure. The twisted coproduct Δ_z is the factorisation product of line operators at positions t_1 and $t_2 = t_1 + z$ on the topological interval. The formula $\Delta_z(T(u)) = T(u) \dot{\otimes} T(u-z)$ is the bar-coalgebra deconcatenation specialised to degree 2 in the ordered bar complex. At $z = 0$ the two insertion points collide and one recovers the ordinary (untwisted) Hopf coproduct.

PBW basis and Hilbert series

THEOREM 22.13.6 (*PBW theorem for $Y_{\hbar}(\mathfrak{sl}_2)$*). The ordered monomials

$$\{ f_{r_1} \cdots f_{r_a} \ h_{s_1} \cdots h_{s_b} \ e_{t_1} \cdots e_{t_c} \mid 0 \leq r_1 \leq \cdots \leq r_a, 0 \leq s_1 \leq \cdots \leq s_b, 0 \leq t_1 \leq \cdots \leq t_c \}$$

form a basis of $Y_{\hbar}(\mathfrak{sl}_2)$ over $\mathbb{C}$. The Hilbert series with respect to the grading $\deg(X_r) = r$ is

$$\text{HS}_{Y_{\hbar}(\mathfrak{sl}_2)}(q) = \prod_{d \geq 0} \frac{1}{(1 - q^d)^3}.$$

Proof. The PBW property follows from the Drinfeld relations (D1)–(D6) by a standard diamond lemma argument: the leading terms of (D2)–(D6) (in the degree-lexicographic order $f_{r_1} \cdots h_{s_1} \cdots e_{t_1} \cdots$) show that every out-of-order monomial reduces to a sum of ordered monomials of equal or lower total degree. The three families of generators $\{e_r\}_{r \geq 0}$, $\{f_r\}_{r \geq 0}$, $\{h_r\}_{r \geq 0}$ each contribute a factor of $\prod_{d \geq 0} (1 - q^d)^{-1}$ to the Hilbert series, giving the stated product formula. The PBW basis is compatible with the filtration $F_{\leq n} Y_{\hbar}(\mathfrak{sl}_2) = \langle X_{r_1} \cdots X_{r_k} \mid r_1 + \cdots + r_k \leq n \rangle$, and the associated graded is $\text{gr } Y_{\hbar}(\mathfrak{sl}_2) \simeq U(\mathfrak{sl}_2[t])$. $\square$

Classical limit: comparison with $U(\mathfrak{sl}_2[t])$

THEOREM 22.13.7 (*Classical limit*). At $\hbar = 0$, the Yangian $Y_{\hbar}(\mathfrak{sl}_2)$ degenerates to the universal enveloping algebra of the current Lie algebra $\mathfrak{sl}_2[t] = \mathfrak{sl}_2 \otimes \mathbb{C}[t]$. Explicitly:

- (i) Relations (D2)–(D3) at $\hbar = 0$ become $[H(u), E(v)] = 0 = [H(u), F(v)]$ after clearing denominators and passing to modes, yielding $[h_r, e_s] = 2e_{r+s}$, $[h_r, f_s] = -2f_{r+s}$ the current-algebra Lie brackets $[h \otimes t^r, e \otimes t^s] = 2(e \otimes t^{r+s})$.
- (ii) Relation (D4) at $\hbar = 0$ becomes $[E_r, F_s] = H_{r+s}$, i.e. $[e \otimes t^r, f \otimes t^s] = h \otimes t^{r+s}$.
- (iii) Relations (D5)–(D6) at $\hbar = 0$ become $[E(u), E(v)] = 0 = [F(u), F(v)]$ after clearing $(u-v)$ the Serre relation for $\mathfrak{sl}_2[t]$ (abelian root spaces).
- (iv) The twisted coproduct Δ_z at $\hbar = 0$ degenerates to the cocommutative coproduct $\Delta(X_r) = X_r \otimes 1 + 1 \otimes X_r$ of $U(\mathfrak{sl}_2[t])$.

The PBW filtration on $Y_{\hbar}(\mathfrak{sl}_2)$ has associated graded $\text{gr } Y_{\hbar}(\mathfrak{sl}_2) \cong U(\mathfrak{sl}_2[t])$, confirming that the Yangian is a filtered deformation of the current algebra, with deformation parameter $\hbar = 1/(k+2)$ sourced by the level of the affine input $V_k(\mathfrak{sl}_2)$.

Proof. Setting $\hbar = 0$ in relations (D1)–(D6) is immediate. For (i): (D2) becomes $[H(u), E(v)] = 0$ at $\hbar = 0$; expanding $H(u) = 1 + \hbar \sum H_r u^{-r-1}$ and taking the leading $\hbar$ -linear term recovers $[h_r, e_s] = 2e_{r+s}$. For (ii): (D4) is $\hbar$ -independent. For (iii): the right-hand side of (D5) vanishes at $\hbar = 0$, giving $[E(u), E(v)] = 0$. For (iv): the shift $u \mapsto u - z$ in the second tensor factor of Δ_z is the spectral-parameter manifestation of the coproduct; at $\hbar = 0$ the modes become primitive. The associated-graded statement follows from the PBW theorem (Theorem 22.13.6). $\square$

Remark 22.13.8 (*The deformation parameter and the level*). The identification $\hbar = 1/(k+2)$ has a precise bar-complex origin: the collision residue $r(z) = \hbar \Omega/z$ inherits $\hbar$ from the normalisation of the affine OPE $J^a(z) J^b(w) \sim k \kappa^{ab}/(z-w)^2 + f^{ab}_c J^c/(z-w)$, where the $d \log$ kernel absorbs one power and the remaining pole is rescaled by $1/(k + h^\vee)$ with $h^\vee = 2$ for $\mathfrak{sl}_2$. At the critical level $k = -h^\vee = -2$, the parameter $\hbar$ diverges and the Yangian construction degenerates: this is the ordered-bar reflection of the Sugawara obstruction at critical level.

22.14 THE DOUBLE BAR AND WHAT IT RECOVERS

The ordered Koszul dual of $\widehat{\mathfrak{g}}_k$ is $Y_{\hbar}(\mathfrak{g})$. What is the ordered Koszul dual of $Y_{\hbar}(\mathfrak{g})$?

If ordered Koszul duality were an involution (as the full $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ duality is (Theorem 22.14.2 below), then $\overline{B}^{\mathrm{ch},\mathrm{ord}}(Y_{\hbar}(\mathfrak{g}))$ would recover $\widehat{\mathfrak{g}}_k$. It does not.

The ordered double bar recovers $U(\mathfrak{g}[t])$ *without* the central extension. The level k is invisible because it enters the Yangian as $\hbar = 1/(k + h^\vee)$, not as an OPE pole: the spectral R -matrix $R(u) = 1 + \hbar \Omega/u + O(\hbar^2)$ has only a simple pole, so the $d \log$ propagator of the ordered bar extracts the Lie bracket of $\mathfrak{g}[t]$ and nothing more. The double pole that *creates* the central extension lives in the holomorphic OPE on $\mathrm{FM}_2(\mathbb{C})$ (the closed colour), and no iteration of the open bar can reach it.

THEOREM 22.14.1 (*Central extension is invisible to the ordered double bar*). Let $\mathfrak{g}$ be a simple Lie algebra and let $A = \widehat{\mathfrak{g}}_k$ at non-critical level. The ordered double Koszul dual satisfies

$$(A_{\mathrm{line}}^!)_{\mathrm{line}}^! \simeq U(\mathfrak{g}[t]), \quad \text{not } \widehat{\mathfrak{g}}_k.$$

Proof. The level k of $\widehat{\mathfrak{g}}_k$ enters the ordered Koszul dual $Y_{\hbar}(\mathfrak{g})$ as the scalar $\hbar = 1/(k + h^\vee)$. The holomorphic double pole $k \delta^{ab}/(z - w)^2$ (the source of the central term $k n \delta_{n+m,0}$ in the mode algebra) does not survive as a double pole in the spectral variable: the Yangian R -matrix $R(u) = 1 + \hbar r(u) + O(\hbar^2)$ has its singularity at $u = 0$ with a *simple* pole $r(u) = \Omega/u$, where $\Omega = \sum_a T^a \otimes T^a$ is the Casimir tensor.

The ordered bar differential of $Y_{\hbar}(\mathfrak{g})$ uses the propagator $d \log(u_i - u_j)$ on $\mathrm{Conf}_n^<(\mathbb{A}_u^1)$. By the $d \log$ absorption principle, a simple spectral pole yields the zeroth product $a_{(0)}b$; a double pole would yield a derivative term $a_{(1)}b$ carrying the central extension. But the spectral OPE has no double pole. Degree by degree:

Degree 1. Yangian generators E_n, F_n, H_n map to current modes J_n^a .

Degree 2. The spectral OPE $[E(u), F(v)] \sim \hbar/(u - v) \cdot (\dots)$ has only simple poles, so

$$d_{\mathrm{bar}}(s^{-1}E_n \otimes s^{-1}F_m) = s^{-1}[E_n, F_m] = s^{-1}H_{n+m},$$

with no central term. For the E – E component, the pole at $u - v = \hbar$ is shifted off the collision diagonal, giving $d_{\mathrm{res}}(s^{-1}E \otimes s^{-1}E) = 0$, i.e. $[e, e] = 0$ in $\mathfrak{g}[t]$.

Degree 3. $d^2 = 0$ reduces to the classical Yang–Baxter equation for $r(u) = \Omega/u$, which holds by the Jacobi identity for $\mathfrak{g}$.

Hence the bar differential recovers only the Lie bracket of $\mathfrak{g}[t]$, not the central extension. $\square$

The loss is not a failure of the machinery; it is a precise diagnosis of what each colour carries.

THEOREM 22.14.2 (*Two-colour double Koszul duality is involutive*). Let A be a strongly admissible E_∞ -chiral algebra on a curve X . The full $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ double Koszul duality satisfies $(A^!)^! \simeq A$, recovering all central extensions and higher-pole data.

Proof. The full duality operates on both components: the *chiral component* (symmetric bar $\overline{B}^\Sigma(A)$ on $\mathrm{Ran}(X)/\Sigma_n$, dualised by D_{Ran}) carries the holomorphic OPE including the double pole; the *coassociative component* (ordered bar $\overline{B}^{\mathrm{ch},\mathrm{ord}}(A)$ on $\mathrm{Conf}_n^<(\mathbb{R})$, dualised by linear duality) carries the spectral data. Verdier/Ran duality preserves the full pole structure, so the double pole survives. The bar–cobar involution $\Omega(\overline{B}^{\mathrm{ch}}(\Omega(\overline{B}^{\mathrm{ch}}(A)))) \simeq A$ (Hypothesis 22.2.3(I), applied twice) then recovers A in its entirety. For $\widehat{\mathfrak{g}}_k$: the chiral Verdier dual is $\widehat{\mathfrak{g}}_{-k-2h^\vee}$ (Feigin–Frenkel dual level), and the second application returns to $\widehat{\mathfrak{g}}_k$ with the central extension intact. $\square$

COROLLARY 22.14.3 (*Non-redundancy of the two colours*). For any E_∞ -chiral algebra A with non-trivial OPE poles, the open and closed bar complexes carry genuinely non-redundant information. Neither colour alone recovers A by iterating Koszul duality: the ordered double bar loses the central extension (Theorem 22.14.1), while the chiral symmetric bar does not determine the R -matrix monodromy for the ordered-to-unordered descent (Proposition 22.4.3).

Proof. The ordered colour alone is insufficient by Theorem 22.14.1: iterating the ordered bar-cobar construction forgets the double-pole central extension data. The symmetric chiral colour alone is also insufficient by Proposition 22.4.3: it retains the holomorphic OPE data but does not recover the ordered R -matrix monodromy needed for descent from the ordered to the unordered picture. These two failures are complementary, so the open and closed colours carry genuinely different information and both are needed to recover A . $\square$

Remark 22.14.4 (*The chiral-coassociative architecture at a glance*). The double-bar computation for $\widehat{\mathfrak{sl}}_{2,k}$ distills the architecture:

	Chiral (holomorphic)	Coassociative (topological)
Pole order	double: $k/(z-w)^2$	simple: $\hbar/(u-v)$
Extracted datum	central extension	Lie bracket of $\mathfrak{g}[t]$
Double KD output	$\widehat{\mathfrak{g}}_k$ (full)	$U(\mathfrak{g}[t])$ (no central ext.)

The two components of the E_1 -chiral bar carry genuinely non-redundant information. The coassociative component sees the Yangian; the chiral component sees the level. Neither alone recovers the algebra; the central extension is the datum that forces both components to be present.

22.15 THE VIRASORO ORDERED BAR COMPLEX AND THE GRAVITATIONAL YANGIAN

The affine Yangian $Y_\hbar(\mathfrak{sl}_2)$ has three independent generator families $E(u)$, $F(u)$, $H(u)$. The Virasoro algebra has one generator T . What happens to the Yangian when the input has a single generator of spin greater than 1?

The answer is forced by two structural features (a triple-pole collision residue and a single-generator mode collapse) whose interplay produces an object that is simultaneously trivial as a Lie algebra and infinitely non-formal as an A_∞ algebra. The Virasoro OPE is

$$T(z)T(w) \sim \frac{c/2}{(z-w)^4} + \frac{2T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w}.$$

Beat 1: the triple pole

The bar complex uses the propagator $d \log(z-w) = dz/(z-w)$, which absorbs one power of the pole in each OPE term. The quartic pole becomes a triple pole; the double pole becomes a simple pole; the simple pole is absorbed entirely and feeds the bar differential $d_{\overline{B}^{\text{ch}}} [s^{-1}T | s^{-1}T] = s^{-1}(T_{(0)}T) = s^{-1}(\partial T)$.

PROPOSITION 22.15.1 (*Virasoro collision residue*;). The collision residue r -matrix of Vir_c is

$$r^{\text{coll}}(z) = \frac{c/2}{z^3} \mathbf{1} \otimes \mathbf{1} + \frac{2T}{z} \otimes \mathbf{1}. \quad (22.9)$$

This is a **triple-pole** r -matrix: the leading singularity z^{-3} is unprecedented in the affine case, where $r_{\text{KM}}^{\text{coll}}(z) = k \Omega_{\mathfrak{g}}/z$ is a simple pole (Theorem 22.12.1). The two depth components (the central scalar $(c/2)/z^3$ and the field-valued $2T/z$) play entirely different roles: the central term controls curvature, while the field-valued term generates the non-associative cascade.

Proof. The Virasoro OPE has singular terms of orders 4, 2, and 1. Passing to the collision-residue kernel removes one pole order because the bar propagator contributes a $d \log$ factor, so these become poles of orders 3, 1, and 0. The regular part is absorbed into the ordinary bar differential $d_{\bar{B}^{\text{ch}}}$. The remaining singular pieces are exactly the two terms displayed in (22.9), with the cubic pole coming from the central term and the simple pole from the field T . $\square$

The collision residue satisfies the classical Yang–Baxter equation.

PROPOSITION 22.15.2 (*Virasoro CYBE*;). The collision residue (22.9) satisfies

$$[r^{12}(u), r^{13}(u+v)] + [r^{12}(u), r^{23}(v)] + [r^{13}(u+v), r^{23}(v)] = 0. \quad (22.10)$$

Proof. Write $r(z) = \frac{c/2}{z^3} \mathbf{1} \otimes \mathbf{1} + \frac{2T}{z} \mathbf{1} \otimes T$. The cubic central term commutes with every tensor factor, so it contributes nothing to the three commutators in (22.10). For the simple-pole part, the Laplace transform identifies the CYBE with the Jacobi identity for the Virasoro PVA bracket $\{T, \lambda T\} = \partial T + 2T\lambda + \frac{c}{12}\lambda^3$. The three commutators in the CYBE are precisely the three Jacobi terms, so their sum vanishes. $\square$

Beat 2: the collapse

Now the single-generator structure exerts its force.

THEOREM 22.15.3 (*Gravitational Yangian collapse*;). Let $c' = 26 - c$ denote the Koszul dual central charge. Define the level- r generators on $\text{Vir}_{c'}$ by

$$\mathsf{T}_n^{(r)} := \binom{n+r-1}{r} L_{-n-r}, \quad \Omega_r = \sum_{n \in \mathbb{Z}} \mathsf{T}_n^{(r)} \otimes L_n,$$

so that $r(z) = \sum_{r \geq 0} \Omega_r z^{-r-1}$. Then:

- (i) *Linear dependence.* For every $r \geq 1$ and $n \in \mathbb{Z}$, $\mathsf{T}_n^{(r)} = \binom{n+r-1}{r} L_{-n-r}$ is a scalar multiple of a single Virasoro mode. There is no independent Yangian partner at any level.
- (ii) *Lie-algebraic isomorphism.* $Y^{\text{dg}}(\text{Vir}_c) \cong \text{Vir}_{c'}$ as Lie algebras. The entire Yangian Lie structure collapses.
- (iii) *All-level bracket.*

$$[\mathsf{T}_m^{(r)}, \mathsf{T}_n^{(s)}] = \binom{m+r-1}{r} \binom{n+s-1}{s} [(n+s-m-r) L_{-m-n-r-s} - \frac{c'}{12} ((m+r)^3 - (m+r)) \delta_{m+n+r+s,0}],$$

which reduces to a single Virasoro commutator.

Proof. Part (i) is the entire argument: because T has conformal weight 2, the mode L_{-n-r} depends only on the sum $n+r$. The level index r splits this sum but adds no new degree of freedom. In the affine Yangian, level-1 generators (e_1, f_1, h_1) are linearly independent of (e_0, f_0, h_0) because $\dim \mathfrak{g} \geq 3$ generators of spin 1 each have an independent mode family. Here the single spin-2 generator forces all levels into the same

Virasoro mode lattice. Part (ii) follows: the generators $\{T_n^{(r)}\}_{n,r}$ span $\{L_m\}_{m \in \mathbb{Z}}$, which is Vir_c . Part (iii) is a direct computation using the Virasoro commutator $[L_{-m-r}, L_{-n-s}] = (n+s-m-r) L_{-m-n-r-s} + \frac{c'}{12}((m+r)^3 - (m+r)) \delta_{m+n+r+s,0}$. $\square$

The collapse is absolute: the gravitational Yangian has no independent higher-level data, no non-primitive coproduct, no Drinfeld partners. As a Lie algebra it is just Vir_{26-c} . But the story does not end here.

Beat 3: the infinite tower

Despite the Lie-algebraic triviality, the bar complex is infinitely non-formal. The triple pole forces non-vanishing A_∞ operations at every degree, through a cascade that cannot terminate.

THEOREM 22.15.4 (*Virasoro non-formality*;). For generic central charge c , the A_∞ operation m_k of the ordered bar complex $\overline{B}^{\text{ch}}(\text{Vir}_c)$ is nonzero for all $k \geq 3$. The Virasoro algebra is class **M** (infinite shadow depth).

Proof. The degree-3 associator is computed directly from the PVA λ -bracket. The Stasheff identity at degree 3 requires $m_3 = -A_3$ where

$$A_3(T, T, T; \lambda_{12}, \lambda_{23}) = -\{T_{\lambda_{23}}\{T_{\lambda_{12}}T\}\} = \frac{c}{12} \lambda_{23}^3 (2\lambda_{12} + \lambda_{23}) + (T\text{-dependent terms}).$$

The scalar contact term $\frac{c}{12} \lambda_{23}^3 (2\lambda_{12} + \lambda_{23})$ is nonzero for $c \neq 0$, and the T -dependent terms (from the double-pole coefficient $2T$) are nonzero for *all* c including $c = 0$. Hence $m_3 \neq 0$.

The Stasheff cascade is now forced. At degree $k + 1$, the identity $\sum_{i+j=k+1} m_i \circ m_j = 0$ produces a nonzero obstruction from compositions of lower-degree operations; the unique solution is $m_{k+1} \neq 0$. The triple pole ensures this cascade never stabilises: the pole depth 3 exceeds the formality threshold (pole depth 1), and each degree draws on the full pole structure to generate new non-associativity. $\square$

Remark 22.15.5 (*What non-formality is not*). Three distinct things are being kept apart here.

- (i) *Non-formality* ($m_k \neq 0$ for all k) is a property of the A_∞ -chiral structure on Vir_c transferred to bar cohomology: it says the transferred higher operations m_k are not formal. It does *not* say Vir_c is non-Koszul. Vir_c is chirally Koszul at every non-critical central charge: the bar cohomology $H^\bullet(\overline{B}^{\text{ch}}(\text{Vir}_c))$ is concentrated in bar degree 1 by PBW universality and single-generator freeness. Koszulness (bar concentration) and A_∞ formality (vanishing of transferred higher operations) are different properties. Virasoro is Koszul but A_∞ non-formal.
- (ii) E_1 *versus* E_∞ is the question of locality. Vir_c is and remains E_∞ -chiral: local, with Σ_n -equivariant factorization. The ordered bar complex applies the E_1 -Koszul duality *functor* to the E_∞ input; non-formality of the output does not make the input non-local. Having OPE poles never breaks E_∞ .
- (iii) *The R-matrix is derived*, not independent input: $R(z)$ is obtained as the monodromy of the Kohno connection built from the collision residue r^{coll} , and the d log absorption step sets the correct pole structure.

Curvature

PROPOSITION 22.15.6 (*Gravitational Yangian curvature*;). The curvature of the gravitational dg-shifted Yangian is

$$\kappa(Y^{\text{dg}}(\text{Vir}_c)) = \frac{26 - c}{2}.$$

Two central charges are distinguished:

- (i) *Critical string* ($c = 26$): $\kappa = 0$. The gravitational Yangian is flat; $F_g = 0$ for all $g \geq 1$. This is anomaly cancellation.
- (ii) *Koszul self-dual* ($c = 13$): $\kappa = 13/2$. The Koszul involution $c \mapsto 26 - c$ fixes $c = 13$, so $\text{Vir}_{13}^! = \text{Vir}_{13}$. The genus tower is invariant under $c \mapsto 26 - c$ (gravitational S-duality) with $F_g(\text{Vir}_{13}) = \frac{13}{2} \lambda_g^{\text{FP}}(\text{UNIFORM} - \text{WEIGHT}) \neq 0$.

Proof. Volume I Theorem D gives the Virasoro curvature formula $\kappa(\text{Vir}_c) = c/2$. By Theorem 22.15.3, the gravitational dg-shifted Yangian is identified with the Koszul dual Vir_{26-c} . Applying the same curvature formula to that dual central charge gives

$$\kappa(Y^{\text{dg}}(\text{Vir}_c)) = \kappa(\text{Vir}_{26-c}) = \frac{26-c}{2}.$$

Substituting $c = 26$ and $c = 13$ yields the critical and self-dual cases listed in the statement. $\square$

The gauge-gravity dichotomy

The three beats assemble into a single structural dichotomy.

COROLLARY 22.15.7 (*Gauge-gravity complexity dichotomy*;). The two standard HT families occupy opposite corners of the (A_∞, Δ) -complexity plane:

	A_∞ products m_k ($k \geq 3$)	coproduct Δ_z
Gauge (KM, class L)	$m_k = 0$ (formal)	nontrivial Yangian Δ_z
Gravity (Vir, class M)	$m_k \neq 0 \forall k$ (non-formal)	strictly primitive Δ_z

The dichotomy is controlled by two inputs:

- (1) *Pole order.* Double OPE pole $\Rightarrow$ simple collision residue $\Rightarrow$ class **L** $\Rightarrow$ formal. Quartic OPE pole $\Rightarrow$ triple collision residue $\Rightarrow$ class **M** $\Rightarrow$ non-formal.
- (2) *Generator count.* $\dim \mathfrak{g}$ generators of spin 1 $\Rightarrow$ independent Yangian partners $\Rightarrow$ nontrivial coproduct. One generator of spin 2 $\Rightarrow$ collapse (Theorem 22.15.3) $\Rightarrow$ primitive coproduct.

Drinfeld–Sokolov reduction transports class **L** to class **M**: the Sugawara construction manufactures the quartic pole from the affine double pole, and the resolvent tree formula $m_k^{\text{W}} = \sum_{\text{Catalan}} (m_2^{\text{aff}} \circ h_{\text{DS}})$ generates the infinite A_∞ tower from the single binary product.

Proof. The A_∞ column: class **L** formal by pole-order classification; class **M** non-formal by Theorem 22.15.4. The coproduct column: the Yangian coproduct is non-primitive for gauge theory (Theorem 22.16.1) and strictly primitive for gravity by Theorem 22.15.8. $\square$

Gravitational coproduct primitivity

The corollary's coproduct column rests on a structural vanishing that deserves its own statement. The DS-transferred coproduct on Vir_c has no non-primitive corrections at any degree; the mechanism is ghost-number filtration, not a cancellation.

THEOREM 22.15.8 (*Gravitational coproduct primitivity*;). Let Δ_z^{Vir} denote the coproduct on the Virasoro algebra obtained by Drinfeld–Sokolov reduction from the affine coproduct on $\widehat{\mathfrak{sl}}_2$. Then Δ_z^{Vir} is strictly primitive at all degrees:

$$(p \otimes p) \circ \Delta_z^{\text{Vir}}(T) = T \otimes 1 + 1 \otimes T,$$

where p is the projection to ghost number 0.

Proof. The BRST charge $h = c + \phi b$ carries ghost degree -1 . Every HPL tree correction to the coproduct at degree $r \geq 2$ passes through h -decorated internal edges, producing elements of ghost number $\neq 0$ on at least one tensor factor. Source trees (root on the left) contribute ghost $+1$; target trees (root on the right) contribute ghost -1 on one factor. In both cases, $p \otimes p$ kills the correction.

The vanishing is not an accident of low degree. The ghost-number filtration is an exact functor on the category of transferred operations, and DS reduction preserves the filtration strictly. The statement holds at all degrees simultaneously. $\square$

Remark 22.15.9 (*The (m, Δ) -complexity plane*). The contrast between product and coproduct complexity is absolute. The transferred product m_z^{Vir} is infinitely complicated: the full A_∞ tower is nonzero at all degrees (class **M**, shadow depth $r_{\max} = \infty$). The transferred coproduct is trivial. In the (m, Δ) -complexity plane, gravity sits at $(\infty, 0)$: infinite product complexity, zero coproduct complexity. Gauge theory (affine Kac–Moody) sits at $(3, \text{nonzero})$: finite product complexity (class **L**), nontrivial coproduct. The Sugawara embedding confirms this: the affine coproduct applied to the Sugawara stress tensor $T = \kappa^{ab} : J_a J_b : / (2(k + h^\vee))$ produces a nontrivial cross term

$$\Delta_z^{\text{KM}}(T) - T \otimes 1 - 1 \otimes T = \frac{\Omega}{(k + h^\vee)z}, \quad \Omega = \kappa^{ab} J_a \otimes J_b.$$

Primitivity is a genuine consequence of DS reduction, not a triviality of Virasoro. The physical content: gravity does not produce particles. It braids them, curves their propagators, and dresses them with an infinite tower of higher products, but the coproduct, which governs particle creation from the vacuum, is trivial. This is the coalgebraic shadow of the no-hair theorem: the gravitational sector has no nontrivial coalgebra structure at any degree.

Remark 22.15.10 (*Summary of the gravitational dg-shifted Yangian*). $Y^{\text{dg}}(\text{Vir}_c)$ is Vir_{26-c} equipped with: (a) the infinite A_∞ tower $\{m_k\}_{k \geq 3}$ (class **M**); (b) primitive coproduct $\Delta_z(x) = \tau_z(x) \otimes 1 + 1 \otimes x$; (c) triple-pole collision residue $r(z) = (c'/2)/z^3 + 2T/z$; (d) curvature $\kappa = (26 - c)/2$. The Lie-algebraic Yangian structure is trivial (all levels collapse); the entire nontrivial content resides in the A_∞ tower. The gravitational Yangian is a *curved A_∞ -deformation* of $U(\text{Vir}_{26-c})$, not a filtered deformation of $U(\text{Witt}[t])$.

22.16 THE UNIVERSAL KAC–MOODY YANGIAN THEOREM

The full nonabelian Kac–Moody family yields the definitive result. For every simple Lie algebra $\mathfrak{g}$ and non-critical level $k \neq -h^\vee$, the E_1 -chiral Koszul dual is the Yangian $Y_h(\mathfrak{g})$. This is the ordered analogue of Theorem G.7.1, which gives the symmetric Koszul duality $\widehat{\mathfrak{g}}_k^! \simeq \widehat{\mathfrak{g}}_{-k-2h^\vee}$.

All affine Kac–Moody algebras $\widehat{\mathfrak{g}}_k$ are E_∞ -chiral: they are local vertex algebras with Σ_n -equivariant factorization structure. The OPE poles do not break E_∞ -locality.

22.16.1 THE ORDERED BAR COMPLEX OF $\widehat{\mathfrak{g}}_k$

Fix a simple Lie algebra $\mathfrak{g}$ with invariant form $(\cdot, \cdot)$ normalised so that $(\theta|\theta) = 2$ for the highest root θ , dual Coxeter number $h^\vee$, and structure constants f^{ab}_c in an orthonormal basis $\{T^a\}_{a=1}^{\dim \mathfrak{g}}$. Let $\widehat{\mathfrak{g}}_k$ be the affine vertex algebra at level $k \neq -h^\vee$, with OPE

$$J^a(z) J^b(w) \sim \frac{k (T^a, T^b)}{(z-w)^2} + \frac{f^{ab}_c J^c(w)}{z-w}. \quad (22.11)$$

Write $\hbar = 1/(k + h^\vee)$ for the deformation parameter (well-defined away from critical level) and

$$\Omega = \sum_{a=1}^{\dim \mathfrak{g}} T^a \otimes T^a \in \mathfrak{g} \otimes \mathfrak{g}$$

for the quadratic Casimir tensor.

THEOREM 22.16.1 (*Universal Kac–Moody Yangian theorem*;). For every simple Lie algebra $\mathfrak{g}$ and non-critical level $k \neq -h^\vee$, the E_1 -chiral Koszul dual of the affine vertex algebra $\widehat{\mathfrak{g}}_k$ is the dg-shifted Yangian:

$$A_{\text{line}}^{\text{!}, \text{ord}}(\widehat{\mathfrak{g}}_k) \simeq Y_{\hbar}^{\text{dg}}(\mathfrak{g}) \simeq Y_{\hbar}(\mathfrak{g}), \quad \hbar = \frac{1}{k + h^\vee},$$

where the second equivalence is the spectral Drinfeld strictification (Theorem 22.17.8), which identifies the dg-shifted Yangian with the classical Yangian as strict associative algebras. The duality is:

- (1) functorial in $\mathfrak{g}$ (respects Lie algebra homomorphisms);
- (2) compatible with the symmetric Koszul duality $\widehat{\mathfrak{g}}_k^! \simeq \widehat{\mathfrak{g}}_{-k-2h^\vee}$ via R -twisted Σ_n -descent (Proposition 22.4.3);
- (3) valid for all nine infinite families and exceptional types (Table 22.1).

Proof. The proof has five steps.

Step 1: Collision residue. The OPE (22.11) has a double pole $k (T^a, T^b)/(z-w)^2$ and a simple pole $f^{ab}_c J^c(w)/(z-w)$. The bar kernel $d \log(z-w)$ absorbs one power, so the collision residue on $\text{Conf}_2^{\text{ord}}(\mathbb{C})$ is

$$r_{12}(z) = \frac{\hbar \Omega_{12}}{z} + (r_0)_{12}, \quad (22.12)$$

where $r_0 = \sum_{a,b,c} f^{ab}_c T^a \wedge T^b \otimes T_c$ encodes the Lie bracket and $\hbar \Omega/z$ is the spectral term from the double pole. Here $(r_0)_{12}$ acts in the $(1, 2)$ tensor slots.

Step 2: Bar differential at degree 2. The ordered bar differential on $\overline{B}_2^{\text{ch}, \text{ord}}(\widehat{\mathfrak{g}}_k)$ extracts the Lie bracket from the simple-pole collision:

$$d_{\overline{B}^{\text{ch}}} [s^{-1} J^a | s^{-1} J^b] = f^{ab}_c [s^{-1} J^c]. \quad (22.13)$$

This is the Lie bracket $[T^a, T^b] = f^{ab}_c T^c$ of $\mathfrak{g}$. At degree 2, the ordered bar complex reproduces the Chevalley–Eilenberg complex of $\mathfrak{g}$. The double-pole term $k (T^a, T^b)/(z-w)^2$ contributes through the

collision residue $\hbar \Omega/z$ to the R -matrix, not to the bar differential (this is the ordered/symmetric distinction: in the symmetric bar complex, the same data appears in the bar differential as the curvature $m_0 = \frac{k+h^\vee}{2h^\vee} \kappa$).

Step 3: $d^2 = 0$ at degree 3 is the CYBE. The bar differential satisfies $d^2 = 0$ on the ordered bar complex. At degree 3, this condition applied to $[s^{-1}J^a \mid s^{-1}J^b \mid s^{-1}J^c]$ is equivalent to the *classical Yang–Baxter equation* for $r(z) = \hbar \Omega/z$:

$$[r_{12}(z_1 - z_2), r_{13}(z_1 - z_3)] + [r_{12}(z_1 - z_2), r_{23}(z_2 - z_3)] + [r_{13}(z_1 - z_3), r_{23}(z_2 - z_3)] = 0.$$

Substituting $r_{ij}(z) = \hbar \Omega_{ij}/z$, the three terms become proportional to $f^{a[b}{}_e f^{c]e}{}_d$, and the vanishing is exactly the Jacobi identity for $\mathfrak{g}$. Thus $d^2 = 0$ holds unconditionally for every simple $\mathfrak{g}$.

Step 4: Complete strictification. The spectral Drinfeld class $[\delta] \in H^2(\mathfrak{g}, \mathfrak{g} \otimes \mathfrak{g})$ measures the obstruction to strictifying the A_∞ -Yangian to a strict associative algebra. For every simple Lie algebra $\mathfrak{g}$, the root spaces are one-dimensional (root-space one-dimensionality), so the relevant H^2 group decomposes into root sectors: each sector is one-dimensional, and the Jacobi identity forces the cocycle $[\delta]$ to be a coboundary in every sector. The class therefore vanishes:

$$[\delta] = 0 \quad \text{for all simple } \mathfrak{g}.$$

This is the strictification mechanism: the Yangian $Y_\hbar(\mathfrak{g})$ is a *strict* associative algebra, not merely an A_∞ -algebra.

Step 5: Identification of the Koszul dual. The cohomology $H^\bullet(\overline{B}^{\text{ch,ord}}(\widehat{\mathfrak{g}}_k))$ with the dual multiplication (from dualising the deconcatenation coproduct) is the RTT presentation of the Yangian $Y_\hbar(\mathfrak{g})$: the degree-1 generators are the currents $\{T_n^a\}_{a,n}$, the degree-2 relations are the RTT relations $R(u - v) T_1(u) T_2(v) = T_2(v) T_1(u) R(u - v)$ with R -matrix $R(u) = 1 + \hbar \Omega/u$, and the strictification of Step 4 ensures no higher A_∞ corrections. By the Drinfeld theorem, this is $Y_\hbar(\mathfrak{g})$. $\square$

22.16.2 DATA FOR ALL SIMPLE TYPES

In every case the curvature of the E_1 -chiral Koszul dual is

$$\kappa(Y_\hbar(\mathfrak{g})) = -\kappa(\widehat{\mathfrak{g}}_k) = -\frac{\dim(\mathfrak{g}) \cdot (k + h^\vee)}{2h^\vee},$$

the negation of the affine curvature. The KM complementarity identity $\kappa(\widehat{\mathfrak{g}}_k) + \kappa(Y_\hbar(\mathfrak{g})) = 0$ holds specifically for Kac–Moody and free-field families and does *not* generalise: for Virasoro one has $\kappa(\text{Vir}_c) + \kappa(\text{Vir}_{26-c}) = 13$, and for $\mathcal{W}_3$ one has $\kappa(\mathcal{W}_3^k) + \kappa(\mathcal{W}_3^{k'}) = 250/3$ (cf. and Theorem D of Volume I).

Remark 22.16.2 (Casimir tensor for each type). In the fundamental representation, the Casimir tensor $\Omega \in \mathfrak{g} \otimes \mathfrak{g}$ acts as:

- (a) *Type A_n .* $\Omega = P - \frac{1}{n+1} I \otimes I$, where $P \in \text{End}(\mathbb{C}^{n+1} \otimes \mathbb{C}^{n+1})$ is the permutation operator.
- (b) *Types B_n, D_n .* $\Omega = P - K$, where $K_{ij,kl} = \delta_{ik'} \delta_{jl'}$ is the contraction with the invariant bilinear form (using the index convention $i' = 2n + 2 - i$ for B_n , $i' = 2n + 1 - i$ for D_n).
- (c) *Type C_n .* $\Omega = P - K$, where $K_{ij,kl} = J_{ik} J_{jl}$ involves the symplectic form J .
- (d) *Exceptional types.* Ω is determined by the structure constants $f^{ab}{}_c$ via $\Omega = \sum_a T^a \otimes T^a$ in any orthonormal basis; explicit matrix forms follow from the Chevalley basis.

Table 22.1: Ordered Koszul duality data for the simple Kac–Moody family. All entries are unconditional ().

Type	$\mathfrak{g}$	$\dim \mathfrak{g}$	$h^\vee$	Fund. repr. dim	$\hbar$	$\kappa(Y_{\hbar}(\mathfrak{g}))$
A_n	$\mathfrak{sl}_{n+1}$	$n^2 + 2n$	$n + 1$	$n + 1$	$\frac{1}{k+n+1}$	$-\frac{(n^2+2n)(k+n+1)}{2(n+1)}$
B_n	$\mathfrak{so}_{2n+1}$	$n(2n + 1)$	$2n - 1$	$2n + 1$	$\frac{1}{k+2n-1}$	$-\frac{n(2n+1)(k+2n-1)}{2(2n-1)}$
C_n	$\mathfrak{sp}_{2n}$	$n(2n + 1)$	$n + 1$	$2n$	$\frac{1}{k+n+1}$	$-\frac{n(2n+1)(k+n+1)}{2(n+1)}$
D_n	$\mathfrak{so}_{2n}$	$n(2n - 1)$	$2n - 2$	$2n$	$\frac{1}{k+2n-2}$	$-\frac{n(2n-1)(k+2n-2)}{2(2n-2)}$

F_4	$\mathfrak{f}_4$	52	9	26	$\frac{1}{k+9}$	$-\frac{52(k+9)}{18}$
G_2	$\mathfrak{g}_2$	14	4	7	$\frac{1}{k+4}$	$-\frac{14(k+4)}{8}$

Remark 22.16.3 (Relation to Drinfeld–Kohno and quantum groups). The Kohno connection (22.1) for $\widehat{\mathfrak{g}}_k$ takes the form $\nabla = d - \hbar \sum_{i < j} \Omega_{ij} dz_{ij}/z_{ij}$, which is the Knizhnik–Zamolodchikov connection at level k . Its monodromy representation $\pi_1(\text{Conf}_n(\mathbb{C})) \rightarrow \text{GL}(\mathfrak{g}^{\otimes n})$ factors through the Yangian via the Drinfeld–Kohno theorem: the monodromy of the KZ connection at $\hbar = 1/(k + h^\vee)$ coincides with the R -matrix of $Y_{\hbar}(\mathfrak{g})$ acting on evaluation modules. The ordered bar complex provides the chain-level refinement of this classical result.

Remark 22.16.4 (The pole-order dichotomy). The Kac–Moody OPE has a double pole and a simple pole. The $d \log$ kernel absorbs one power, leaving a collision residue with a simple pole $\hbar \Omega/z$ (the spectral term) and a constant r_0 (the Lie bracket term). This places all $\widehat{\mathfrak{g}}_k$ in class L (double-pole OPE, simple-pole collision residue, finite shadow depth). By contrast, the Virasoro OPE has a quartic pole, giving a triple-pole collision residue and class M (infinite shadow depth). Under DS reduction $\widehat{\mathfrak{g}}_k \rightarrow \mathcal{W}_k(\mathfrak{g})$, the pole-order escalation transports class L to class M via Sugawara.

Remark 22.16.5 (The Kac–Moody frontier). Theorem 22.16.1 covers all simple Lie algebras. The genuine frontier is Kac–Moody algebras $\widehat{\mathfrak{g}}_k$ for $\mathfrak{g}$ a Kac–Moody Lie algebra (not finite-dimensional simple): for affine or indefinite Kac–Moody algebras, root multiplicities can exceed one, the root-space one-dimensionality argument of Step 4 fails, and the strictification mechanism requires new input.

22.17 SPECTRAL DRINFELD STRICTIFICATION

The ordered bar complex of a dg-shifted Yangian carries a filtered A_∞ structure. The question of whether this A_∞ structure can be straightened to a genuine associative structure with spectral parameter is controlled by a cohomological obstruction: the *spectral Drinfeld class*. This obstruction vanishes for all simple Lie algebras.

22.17.1 THE OBSTRUCTION CLASS

Definition 22.17.1 (Spectral Drinfeld class at filtration p). Let A be a filtered dg-shifted Yangian carrying a spectral quasi-factorization datum with quasi-associator

$$\Phi(w, z) = 1 + \phi_p(w, z) \pmod{F^{p+1}},$$

where ϕ_p is the first nontrivial term at filtration p . The spectral cochain complex is defined by

$$C_{\text{spec}}^2(A) = \{g(u) \in A^{\widehat{\otimes}^2}\}, \quad C_{\text{spec}}^3(A) = \{\phi(w, z) \in A^{\widehat{\otimes}^3}\},$$

with linearized spectral differential

$$(\delta g)(w, z) = 1 \otimes g(z) + (\text{id} \otimes \Delta_z)g(w) - (\Delta_w \otimes \text{id})g(z) - g(w) \otimes 1.$$

The *spectral Drinfeld class at filtration p* is

$$\mathfrak{D}_{\text{spec}}(A, \Omega)|_{F^p} := [\phi_p] \in H_{\text{spec}}^3(\text{gr}^p A).$$

Remark 22.17.2 (Interpretation). The spectral Drinfeld class measures the failure of the A_∞ bar-complex structure to strictify to a genuine associative product with spectral parameter. At each filtration $p \geq 2$, the pentagon relation on the quasi-associator linearizes: ϕ_p is a 3-cocycle, a spectral twist shifts it by a coboundary, and the class $[\phi_p] \in H_{\text{spec}}^3(\text{gr}^p A)$ is the intrinsic obstruction. If $[\phi_p] = 0$ for all $p \geq 2$, an iterative filtered twist produces $\Phi^G = 1$, and the quasi-factorization datum strictifies to an honest spectral factorization R -matrix.

22.17.2 ROOT-SPACE ONE-DIMENSIONALITY

The key structural input is a classical theorem about the root structure of simple Lie algebras: every root space is one-dimensional. This forces the spectral Drinfeld class, which is valued in root spaces, to be a scalar, and a scalar is determined by a single equation.

THEOREM 22.17.3 (Root-space one-dimensionality;). Let $\mathfrak{g}$ be a simple Lie algebra. For any subset $S = \{\alpha_1, \dots, \alpha_n\}$ of simple roots such that $\alpha = \sum_{i=1}^n \alpha_i$ is a root of $\mathfrak{g}$, the multilinear degree- n space

$$\text{span}\{\text{Lie monomials in } E_{\alpha_1}, \dots, E_{\alpha_n} \text{ using each exactly once}\} \subseteq \mathfrak{g}_\alpha$$

is one-dimensional.

Proof. Every multilinear Lie monomial in $E_{\alpha_1}, \dots, E_{\alpha_n}$ has weight $\alpha_1 + \dots + \alpha_n = \alpha$ (since each bracket adds the weights of its arguments). Therefore all such monomials lie in the root space $\mathfrak{g}_\alpha$. In a simple Lie algebra, every root has multiplicity one: $\dim \mathfrak{g}_\alpha = 1$. Hence the multilinear space is at most one-dimensional.

It remains to verify that at least one multilinear monomial is nonzero. Since α is a root and the simple roots α_i are linearly independent, there exists an ordering $\alpha_{i_1}, \dots, \alpha_{i_n}$ and a sequence of partial sums $\beta_k = \alpha_{i_1} + \dots + \alpha_{i_k}$ such that each β_k is a root (this follows from the connectedness of the support of α in the Dynkin diagram and the standard theory of root strings). The iterated bracket $[E_{\alpha_{i_1}}, [E_{\alpha_{i_2}}, \dots, E_{\alpha_{i_n}}] \dots]$ is then nonzero (each intermediate bracket lands in a nonzero root space). $\square$

22.17.3 THE JACOBI COLLAPSE LEMMA

When root spaces are one-dimensional, multilinear Lie monomials in root vectors are necessarily proportional: the target space has no room for independent contributions. The mechanism by which the free Lie algebra's higher-dimensional multilinear spaces collapse to one dimension inside $\mathfrak{g}$ is the Jacobi identity.

The simplest nontrivial case is the D_4 star: four simple roots $\alpha_1, \alpha_2, \alpha_3, \alpha_c$ with α_c adjacent to each of $\alpha_1, \alpha_2, \alpha_3$, and the α_i mutually non-adjacent. In the free Lie algebra modulo non-adjacency commutation, the multilinear degree-4 space is two-dimensional. In $\mathfrak{g}$, the Jacobi identity collapses it to one.

LEMMA 22.17.4 (*Jacobi collapse for star sectors*;). Let X_1, X_c, X_2, X_3 be root vectors in a Lie algebra $\mathfrak{g}$ with $[X_1, X_2] = [X_1, X_3] = [X_2, X_3] = 0$ (the D_4 -star commutation relations). Define

$$A = [[X_2, [X_1, X_c]], X_3], \quad B = [[X_3, [X_1, X_c]], X_2].$$

Then $A = B$.

Proof. Apply the Jacobi identity to (X_2, X_c, X_3) :

$$[X_2, [X_c, X_3]] + [X_c, [X_3, X_2]] + [X_3, [X_2, X_c]] = 0.$$

Since $[X_2, X_3] = 0$, the middle term vanishes, giving

$$[X_2, [X_c, X_3]] = [X_3, [X_c, X_2]]. \quad (22.14)$$

Now expand A and B using Jacobi and $[X_1, X_2] = [X_1, X_3] = 0$:

$$\begin{aligned} A &= [[X_2, [X_1, X_c]], X_3] = [X_2, [[X_1, X_c], X_3]] - [[X_1, X_c], [X_2, X_3]] \\ &= [X_2, [[X_1, X_c], X_3]] \quad (\text{since } [X_2, X_3] = 0) \\ &= [X_2, [X_1, [X_c, X_3]]] - [X_2, [X_c, [X_1, X_3]]] \\ &= [X_2, [X_1, [X_c, X_3]]] \quad (\text{since } [X_1, X_3] = 0) \\ &= [[X_2, X_1], [X_c, X_3]] + [X_1, [X_2, [X_c, X_3]]] \\ &= [X_1, [X_2, [X_c, X_3]]] \quad (\text{since } [X_1, X_2] = 0). \end{aligned}$$

The identical computation with $2 \leftrightarrow 3$ gives $B = [X_1, [X_3, [X_c, X_2]]]$. By (22.14), $[X_2, [X_c, X_3]] = [X_3, [X_c, X_2]]$, hence $A = B$. $\square$

Remark 22.17.5 (Root multiplicity one as structural inevitability). The Jacobi collapse lemma is not a clever computation that happens to kill the obstruction. The point is that the obstruction *has nowhere to live*.

The spectral Drinfeld class at filtration n , restricted to the root sector $\alpha = \sum \alpha_i$, is a cohomology class valued in $\mathfrak{g}_\alpha$. Root multiplicity one says $\dim \mathfrak{g}_\alpha = 1$. A cohomology class valued in a one-dimensional space is a scalar. A scalar is determined by a single equation. The coproduct rigidity provides that equation.

The free Lie algebra on the simple root vectors, modulo non-adjacency commutation, may have higher-dimensional multilinear spaces (the D_4 star has $\dim = 2$). But in $\mathfrak{g}$ the Jacobi identity collapses them (Lemma 22.17.4). This collapse is not an accident: it is the shadow of root multiplicity one, which is itself a theorem about the representation theory of $\mathfrak{sl}_2$ -triples.

22.17.4 THE BETA-INTEGRAL COEFFICIENT

The BCH expansion of $\log(e^{X_1} \cdots e^{X_n})$ produces the universal coefficient at each filtration. This coefficient is determined by the Dynkin projection.

THEOREM 22.17.6 (*Dynkin coefficient via the beta integral*;). Let $X_1, \dots, X_n$ satisfy the path commutation relations $[X_i, X_j] = 0$ for $|i - j| \geq 2$. Then the multilinear $X_1 \cdots X_n$ -part of the ordered Baker–Campbell–Hausdorff product is

$$\text{mult}_{X_1 \cdots X_n} \log(e^{X_1} e^{X_2} \cdots e^{X_n}) = \frac{1}{n} [X_1, [X_2, \dots, [X_{n-1}, X_n] \cdots]],$$

where the coefficient $1/n$ arises from the beta integral

$$\frac{1}{n} = \int_0^1 (1-t)^{n-1} dt.$$

This is the unique coefficient forced by the BCH formula: the Dynkin projection $D_n = \frac{1}{n} \ell_n$ applied to the ordered concatenation $X_1 \otimes \cdots \otimes X_n$.

Proof. The multilinear part is $c_n \cdot [X_1, [X_2, \dots, X_n] \cdots]$ for a unique scalar c_n (the multilinear Lie space is one-dimensional by root-space one-dimensionality in $\mathfrak{g}$, or by the path one-dimensionality theorem in the free Lie algebra quotient). We determine c_n by extracting the coefficient of the concatenation monomial $X_1 \cdot X_2 \cdots X_n$ in the universal enveloping algebra.

Step 1: Coefficient in the Lie bracket. In the universal enveloping algebra, the right-normed bracket $[X_1, [X_2, \dots, [X_{n-1}, X_n] \cdots]]$ has leading term $X_1 X_2 \cdots X_n$ with coefficient $+1$.

Step 2: Coefficient in the BCH logarithm. The multilinear part of $e^{X_1} \cdots e^{X_n}$ in the free associative algebra is $X_1 \cdots X_n$. The coefficient of $X_1 \cdots X_n$ in $\log(e^{X_1} \cdots e^{X_n})$, computed via $\log(1 + A) = \sum_{k \geq 1} (-1)^{k+1} A^k / k$, counts compositions of n into k parts:

$$\text{coeff of } X_1 \cdots X_n \text{ in } \log(P) = \sum_{k=1}^n \frac{(-1)^{k+1}}{k} \binom{n-1}{k-1}.$$

Step 3: The beta integral.

$$\begin{aligned} \sum_{k=1}^n \frac{(-1)^{k+1}}{k} \binom{n-1}{k-1} &= \sum_{j=0}^{n-1} \frac{(-1)^j}{j+1} \binom{n-1}{j} = \sum_{j=0}^{n-1} \binom{n-1}{j} (-1)^j \int_0^1 t^j dt \\ &= \int_0^1 \sum_{j=0}^{n-1} \binom{n-1}{j} (-t)^j dt = \int_0^1 (1-t)^{n-1} dt = \frac{1}{n}. \end{aligned}$$

Combining Steps 1–3: $c_n \cdot 1 = \frac{1}{n}$, hence $c_n = \frac{1}{n}$. □

Remark 22.17.7 (*The Dynkin projection as coassociative counit*). The coefficient $1/n$ is the Dynkin projection $D_n: T^n(V) \rightarrow \text{Lie}^n(V)$, $D_n = \frac{1}{n} \ell_n$, applied to the ordered concatenation. The bar-cobar counit $\varepsilon: \Omega(\overline{B}^{\text{ch}}(\mathcal{A})) \rightarrow \mathcal{A}$ extracts the chiral algebra from its bar complex (a chiral operation on $\text{FM}_k(\mathbb{C})$). The Dynkin projection extracts the Lie element from the tensor algebra (a coassociative operation on $\text{Conf}_n(\mathbb{R})$). Both are extraction maps from a cofree object to the generating algebra, controlled by the same combinatorial identity: the logarithm of the ordered exponential. The coefficient $1/n$ is the quantitative expression of how much Lie content survives the ordered tensor product, the same content that the bar-cobar adjunction computes in the chiral setting.

22.17.5 COMPLETE STRICTIFICATION

THEOREM 22.17.8 (*Complete strictification for all simple Lie algebras;*). Let $\mathfrak{g}$ be a simple Lie algebra of any type. The spectral Drinfeld class vanishes at every filtration:

$$\mathfrak{D}_{\text{spec}}(A, \Omega)|_{F^p} = 0 \quad \text{for all } p \geq 2.$$

In particular, whenever a residue-bounded complete dg-shifted Yangian over $\mathfrak{g}$ carries a spectral quasi-factorization datum, that datum strictifies to an honest spectral factorization realization. The dg-shifted Yangian $Y_h^{\text{dg}}(\mathfrak{g})$ carries a strict filtered algebra structure.

Proof. The proof proceeds by analysing the spectral Drinfeld class sector by sector. At filtration p , each root sector of type $\alpha = \sum_{i=1}^p \alpha_i$ (where the α_i are simple roots) contributes independently.

Case 1: α is not a root. If $\alpha = \sum \alpha_i$ is not a root of $\mathfrak{g}$, then the root space $\mathfrak{g}_\alpha = 0$ and every multilinear Lie monomial in $\{E_{\alpha_i}\}$ vanishes. The sector contributes nothing.

Case 2: α is a root (path-type sectors). The spectral Drinfeld class restricted to the root sector lives in $\mathfrak{g}_\alpha$. By Theorem 22.17.3, $\dim \mathfrak{g}_\alpha = 1$. The multilinear BCH computation (Theorem 22.17.6) gives a unique coefficient $1/p$ for the product side. The coproduct rigidity gives a unique equation for the coproduct side. Since both sides are scalars in the same one-dimensional space, equality reduces to a single identity (the same identity that holds at filtrations 2 and 3) and the obstruction class vanishes.

Case 3: Non-path sectors (e.g., the D_4 star). Root-space one-dimensionality (Theorem 22.17.3) forces the multilinear BCH contribution to be a scalar multiple of the unique generator of $\mathfrak{g}_\alpha$. The Jacobi collapse lemma (Lemma 22.17.4) ensures that the two-dimensional free Lie space collapses to one dimension in $\mathfrak{g}$, so the only surviving contribution is the iterated bracket $[E_{\alpha_1}, [E_{\alpha_2}, \dots]]$, whose coefficient in the BCH expansion is $1/p$ by the Dynkin formula.

The inductive strictification. Therefore no root sector at any filtration carries an independent obstruction class. The spectral Drinfeld class vanishes at every filtration. Starting from any spectral quasi-factorization datum, a filtered twist kills the first nontrivial quasi-associator term at each filtration. Iterating filtration by filtration produces a twist with trivial quasi-associator, hence an honest spectral factorization realization. $\square$

Remark 22.17.9 (*The role of root multiplicity one*). The theorem has the form of a *root-multiplicity-one rigidity principle*: the spectral Drinfeld obstruction to strictifying a dg-shifted Yangian vanishes because every root-sector multilinear space is one-dimensional.

The bar complex $\overline{B}^{\text{ord}}(\mathcal{A})$ is an E_1 coassociative coalgebra; the $\text{SC}^{\text{ch}, \text{top}}$ datum emerges at the level of the chiral derived center, as the pair $(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \mathcal{A})$ (Theorem 22.10.1). The complete strictification theorem says that, once the spectral quasi-factorization package has been constructed, the passage from quasi to strict is not an additional datum but an automatic consequence of the root structure. Just as the Decomposition Theorem (purity of IC complexes) makes the Hecke algebra arise inevitably from the geometry of G/B , root multiplicity one makes the strictification step arise inevitably from the Lie theory of $\mathfrak{g}$.

Remark 22.17.10 (*What fails for Kac–Moody algebras with root multiplicities > 1*). For Kac–Moody algebras whose root lattice contains roots with multiplicity > 1 (e.g., imaginary roots of indefinite Kac–Moody algebras), root-space one-dimensionality fails. The Jacobi collapse mechanism no longer forces multilinear

Lie monomials to be proportional, and the spectral Drinfeld obstruction class can live in a space of dimension > 1 . In such cases, the coproduct rigidity provides fewer equations than unknowns, and genuine obstructions could survive.

The frontier admits a precise stratification: the obstruction vanishes in all root sectors where root multiplicity one holds (all roots of simple Lie algebras, real roots of affine Lie algebras), and the remaining sectors are exactly those with higher multiplicity.

For untwisted affine Lie algebras $\widehat{\mathfrak{g}}$, the real roots $\alpha + n\delta$ have multiplicity 1 (so the theorem applies verbatim), while the imaginary roots $n\delta$ have multiplicity $\ell = \text{rank}(\mathfrak{g})$. The imaginary sectors are abelian (elements within a single $\mathfrak{g}_{n\delta}$ commute), and a Cartan gauge-twist argument should absorb the defect. The mixed real-plus-imaginary sectors require a separate analysis. Complete strictification for affine types therefore remains conjectural pending the detailed imaginary-sector computation.

22.18 WORKED EXAMPLE: $\mathfrak{sl}_3$ AT LEVEL k

Theorem 22.16.1 applies to every simple Lie algebra. For $\mathfrak{g} = \mathfrak{sl}_3$ in explicit matrix-unit coordinates, the rank-2 phenomena invisible in the rank-1 ($\mathfrak{sl}_2$) case: adjacent-root triangle sectors, the coefficient $\frac{1}{2}$, the Serre relations from root-space vanishing, and the 9×9 R -matrix.

22.18.1 ROOT SYSTEM AND MATRIX-UNIT NOTATION

The Lie algebra $\mathfrak{sl}_3$ has root system $\Phi = \{\pm\alpha_1, \pm\alpha_2, \pm(\alpha_1 + \alpha_2)\}$ of type A_2 , with simple roots α_1, α_2 and Cartan matrix

$$A = \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}.$$

In the $\mathfrak{gl}_3$ matrix-unit basis we set

$$e_1 = E_{12}, \quad e_2 = E_{23}, \quad e_{12} = [e_1, e_2] = E_{13},$$

$$f_1 = E_{21}, \quad f_2 = E_{32}, \quad f_{12} = [f_2, f_1] = E_{31},$$

and $h_1 = E_{11} - E_{22}$, $h_2 = E_{22} - E_{33}$. The composite root generators satisfy

$$[e_1, e_2] = e_{12}, \quad [f_2, f_1] = f_{12}, \quad [f_1, f_2] = -f_{12}.$$

The affine vertex algebra $V_k(\mathfrak{sl}_3)$ has OPE

$$J^a(z) J^b(w) \sim \frac{k \kappa(a, b)}{(z - w)^2} + \frac{[a, b](w)}{z - w}$$

where κ is the Killing form normalised so that $\kappa(e_i, f_i) = 1$ and $\kappa(e_{12}, f_{12}) = 1$.

22.18.2 DEGREE-1 GENERATORS: THE DRINFELD CURRENTS

The ordered bar complex $\overline{B}^{\text{ch ord}}_\bullet(V_k(\mathfrak{sl}_3))$ has degree-1 generators $s^{-1}e_1, s^{-1}e_2, s^{-1}e_{12}, s^{-1}f_1, s^{-1}f_2, s^{-1}f_{12}, s^{-1}h_1, s^{-1}h_2$. The corresponding bar cohomology classes organise into Drinfeld generating func-

tions for $Y_{\hbar}(\mathfrak{sl}_3)$ with $\hbar = 1/(k+3)$:

$$\begin{aligned} E_i(u) &= \sum_{r \geq 0} E_i^{(r)} u^{-r-1}, \quad i = 1, 2, \\ F_i(u) &= \sum_{r \geq 0} F_i^{(r)} u^{-r-1}, \\ H_i(u) &= 1 + \sum_{r \geq 0} H_i^{(r)} u^{-r-1}, \end{aligned}$$

where $u = 1/z$ is the spectral parameter. The zeroth modes $E_i^{(0)}, F_i^{(0)}, H_i^{(0)}$ generate a copy of $U(\mathfrak{sl}_3)$ inside $Y_{\hbar}(\mathfrak{sl}_3)$.

22.18.3 DEGREE-2 RELATIONS: CARTAN MATRIX AND YANGIAN DEFORMATION

The bar differential (22.13) specialises to

$$\begin{aligned} d_{\overline{B}}^{\text{ch}}(s^{-1}h_i \otimes s^{-1}e_j) &= A_{ij} s^{-1}e_j, \\ d_{\overline{B}}^{\text{ch}}(s^{-1}e_i \otimes s^{-1}f_j) &= \delta_{ij} s^{-1}h_i, \\ d_{\overline{B}}^{\text{ch}}(s^{-1}e_1 \otimes s^{-1}e_2) &= s^{-1}e_{12}, \\ d_{\overline{B}}^{\text{ch}}(s^{-1}f_2 \otimes s^{-1}f_1) &= s^{-1}f_{12}. \end{aligned}$$

The first two lines reproduce the Cartan relations $[H_i, E_j] = A_{ij}E_j$ and $[E_i, F_j] = \delta_{ij}H_i$ at leading order in the spectral parameter. The last two express the composite root as a bar boundary. The Yangian deformation appears at the next spectral order:

$$[H_i(u), E_j(v)] = \frac{A_{ij}}{u-v} E_j(v) + (\text{regular}), \quad [E_i(u), F_j(v)] = \frac{\delta_{ij}}{u-v} H_i(v) + (\text{regular}).$$

22.18.4 DEGREE-3 TRIANGLE SECTORS

This is the first genuinely rank-2 sector: the composite root $\alpha_1 + \alpha_2$ produces degree-3 bar elements that have no $\mathfrak{sl}_2$ analogue.

Definition 22.18.1 (Triangle sectors for $\mathfrak{sl}_3$). The degree-3 ordered bar complex $\overline{B}_3^{\text{chord}}(V_k(\mathfrak{sl}_3))$ contains four *triangle sectors*, indexed by the composite root $\alpha_1 + \alpha_2$ and the two orderings of simple lowering (respectively raising) operators:

$$\begin{aligned} T_{12}^L &= E_{13}^{(1)} E_{21}^{(2)} E_{32}^{(3)}, & T_{21}^L &= E_{13}^{(1)} E_{32}^{(2)} E_{21}^{(3)}, \\ T_{12}^R &= E_{12}^{(1)} E_{23}^{(2)} E_{31}^{(3)}, & T_{21}^R &= E_{23}^{(1)} E_{12}^{(2)} E_{31}^{(3)}. \end{aligned}$$

The left triangles have the composite raising operator $e_{12} = E_{13}$ in the first tensor factor and the two simple lowering operators split across factors 2 and 3. The right triangles have the two simple raising operators in factors 1 and 2 and the composite lowering operator $f_{12} = E_{31}$ in factor 3.

THEOREM 22.18.2 (*Triangle coefficient for $\mathfrak{sl}_3$*). Let the two-body spectral functions be given by the rational ansatz $\rho_{\alpha}(u) = c_{\alpha}/u$, and define the triangle transport coefficient λ by

$$\Pi_{\langle T_{12}^L, T_{21}^L \rangle}((\text{id} \otimes \Delta_z) X_{\alpha_1 + \alpha_2}^{12}(w)) = \lambda(\rho_1(w)\rho_2(w+z) T_{12}^L - \rho_2(w)\rho_1(w+z) T_{21}^L).$$

Then the triangle coefficient is

$$\lambda = \frac{c_1 c_2}{2 c_{12}} = \frac{1}{2} = \int_0^1 (1-t) dt,$$

where the last equality identifies the coefficient as the $n = 2$ Euler beta integral $B(1, 2) = \int_0^1 (1-t)^{2-1} dt = 1/2$. In the normalised case $c_1 = c_2 = c_{12} = 1$, the coefficient is $\frac{1}{2}$ for both left and right triangles and both orderings: $\lambda_{12}^L = \lambda_{21}^L = \lambda_{12}^R = \lambda_{21}^R = \frac{1}{2}$.

Proof. The product side of the filtration-2 hexagon defect equation projects to the triangle sectors by commutator extraction. The only terms that contribute are

$$[E_1^{(1)} F_1^{(2)}, E_2^{(1)} F_2^{(3)}] = E_{12}^{(1)} F_1^{(2)} F_2^{(3)}$$

and

$$[E_2^{(1)} F_2^{(2)}, E_1^{(1)} F_1^{(3)}] = -E_{12}^{(1)} F_2^{(2)} F_1^{(3)},$$

where the signs arise from $[e_1, e_2] = e_{12}$ and $[e_2, e_1] = -e_{12}$. The logarithm of the ordered product of two-body exponentials gives

$$\Pi_{\langle T_{12}^L, T_{21}^L \rangle} \frac{1}{2} [S_{12}(w), S_{13}(w+z)] = \frac{1}{2} \rho_1(w) \rho_2(w+z) T_{12}^L - \frac{1}{2} \rho_2(w) \rho_1(w+z) T_{21}^L.$$

On the coproduct side, $X_{\alpha_1+\alpha_2}$ is the unique composite root generator that can land in the triangle sector. The twisted coproduct on $X_{\alpha_1+\alpha_2}^{12}(w)$ projects to the triangle sector with transport coefficient λ . Equating the two sides and substituting the rational ansatz $\rho_\alpha(u) = c_\alpha/u$ gives

$$\frac{c_{12}}{w} \cdot \frac{\lambda}{w+z} = \frac{1}{2} \cdot \frac{c_1}{w} \cdot \frac{c_2}{w+z},$$

whence $\lambda = c_1 c_2 / (2 c_{12})$. In the normalised case this is $1/2$. The integral representation follows from $B(1, 2) = \int_0^1 (1-t) dt = 1/2$. $\square$

Remark 22.18.3 (The triangle coefficient as BCH coefficient). The coefficient $1/2$ is the $n = 2$ instance of the universal n -gon coefficient $1/n$ proved in Vol II (the n -gon localisation formula). At $n = 2$ the ordered BCH expansion $\log(e^X e^Y) = X + Y + \frac{1}{2}[X, Y] + \cdots$ has $\frac{1}{2}$ as the coefficient of the first commutator term. This is not a coincidence: the triangle sector is the first commutator sector in the ordered bar complex. The integral $\int_0^1 (1-t)^{n-1} dt = 1/n$ provides a uniform derivation for all n , replacing case-by-case Baker–Campbell–Hausdorff algebra.

22.18.5 SERRE RELATIONS FROM ROOT-SPACE VANISHING

PROPOSITION 22.18.4 (*Serre relations from root-space vanishing*). The Serre relations of $Y_h(\mathfrak{sl}_3)$ arise from degree-3 bar cohomology by root-space obstruction. Specifically:

- (i) $2\alpha_1 + \alpha_2 \notin \Phi(\mathfrak{sl}_3)$, so $(\mathfrak{sl}_3)_{2\alpha_1+\alpha_2} = 0$, which forces $[e_1, [e_1, e_2]] = 0$.
- (ii) $\alpha_1 + 2\alpha_2 \notin \Phi(\mathfrak{sl}_3)$, so $(\mathfrak{sl}_3)_{\alpha_1+2\alpha_2} = 0$, which forces $[e_2, [e_2, e_1]] = 0$.

In the ordered bar complex, these correspond to the vanishing of the degree-3 bar differential on the would-be generators $s^{-1}e_1 \otimes s^{-1}e_1 \otimes s^{-1}e_2$ and $s^{-1}e_2 \otimes s^{-1}e_2 \otimes s^{-1}e_1$: the target root spaces are empty, so the bar differential has trivial image and the corresponding bar cohomology classes are zero. The spectral-parameter deformation promotes these to the Yangian Serre relations:

$$\text{Sym}_{u_1, u_2} [E_i(u_1), [E_i(u_2), E_j(v)]] = 0, \quad A_{ij} = -1.$$

Proof. Consider the degree-3 bar element $s^{-1}e_1 \otimes s^{-1}e_1 \otimes s^{-1}e_2$. The bar differential evaluates the nested commutator $[e_1, [e_1, e_2]] = [e_1, e_{12}]$. But $e_1 \in (\mathfrak{sl}_3)_{\alpha_1}$ and $e_{12} \in (\mathfrak{sl}_3)_{\alpha_1 + \alpha_2}$, so the commutator would live in $(\mathfrak{sl}_3)_{2\alpha_1 + \alpha_2}$. Since $2\alpha_1 + \alpha_2 \notin \Phi(\mathfrak{sl}_3)$ (the root system of A_2 contains only roots of height ≤ 2), this root space is zero, hence $[e_1, e_{12}] = 0$. The identical argument with $\alpha_1 \leftrightarrow \alpha_2$ gives $[e_2, e_{21}] = [e_2, [e_2, e_1]] = 0$.

For the Yangian deformation: the spectral OPE $E_i(u)E_i(v)$ has a pole shifted to $u - v = \hbar$ (off the collision diagonal), so the collision residue vanishes and $d_{\text{res}}(s^{-1}E_i \otimes s^{-1}E_i) = 0$. The degree-3 bar cocycle condition $d^2 = 0$ then forces the symmetrised nested commutator to vanish, giving the Yangian Serre relation. $\square$

22.18.6 THE RTT PRESENTATION AND THE 9×9 R-MATRIX

THEOREM 22.18.5 (*RTT presentation for $Y_{\hbar}(\mathfrak{sl}_3)$ from the ordered bar complex*). Let $V = \mathbb{C}^3$ be the defining representation of $\mathfrak{sl}_3$ and define the transfer matrix

$$T(u) = \sum_{a,b=1}^3 e_{ab} \otimes t^{ab}(u) \in \text{End}(V) \otimes Y_{\hbar}(\mathfrak{sl}_3)[[u^{-1}]],$$

where $t^{ab}(u)$ are the degree-1 bar cohomology generating functions. Then the consistency of the degree-3 ordered bar complex $\overline{B}_3^{\text{ch ord}}$ gives the RTT relation

$$R(u-v) T_1(u) T_2(v) = T_2(v) T_1(u) R(u-v), \quad (22.15)$$

where $R(u) \in \text{End}(V \otimes V)$ is the rational Yang R -matrix

$$R(u) = 1 + \frac{\hbar \Omega}{u} + O(u^{-2}), \quad \Omega = \sum_{a,b=1}^3 e_{ab} \otimes e_{ba},$$

acting on $V \otimes V \cong \mathbb{C}^9$. Here Ω is the $\mathfrak{sl}_3$ -Casimir in the tensor square of the defining representation (Remark 22.16.2(a) with $n = 2$), and e_{ab} are the standard matrix units of $\mathfrak{gl}_3$.

Proof. This is the A_2 specialisation of Theorem 22.16.1. The R -matrix arises from the monodromy of the flat connection $\nabla = d - r(z) dz$ on the ordered configuration space $C_2^<(\mathbb{C})$, where $r(z) = \hbar \Omega / z$ is the classical r -matrix (22.12) (with the $d \log$ kernel absorbing one pole order). The RTT relation (22.15) is equivalent to $d^2 = 0$ on $\overline{B}_3^{\text{ch ord}}$: the three-fold bar consistency intertwines two orderings of the first two tensor factors via the R -matrix and inserts a bar cohomology class in the third slot. The Yang–Baxter equation

$$R_{12}(u-v) R_{13}(u) R_{23}(v) = R_{23}(v) R_{13}(u) R_{12}(u-v)$$

follows from $d^3 = 0$ on $\overline{B}_4^{\text{ch ord}}$ and is verified directly for $R(u) = 1 + \hbar \Omega / u$ using the $\mathfrak{sl}_3$ Jacobi identity in the tensor cube $V^{\otimes 3} \cong \mathbb{C}^{27}$. $\square$

Remark 22.18.6 (The 9×9 versus 4×4 R -matrix). For $\mathfrak{sl}_2$ the R -matrix acts on $\mathbb{C}^2 \otimes \mathbb{C}^2 \cong \mathbb{C}^4$. For $\mathfrak{sl}_3$ it acts on $\mathbb{C}^3 \otimes \mathbb{C}^3 \cong \mathbb{C}^9$. The decomposition $\mathbb{C}^9 \cong \mathbf{6} \oplus \mathbf{3}$ (symmetric and exterior squares) is an eigenspace decomposition for the permutation $P = \sum e_{ab} \otimes e_{ba}$: eigenvalue $+1$ on $\text{Sym}^2(V)$ and -1 on $\wedge^2(V)$. The R -matrix $R(u) = 1 + \hbar P/u$ therefore has eigenvalues $1 + \hbar/u$ and $1 - \hbar/u$ on these two subspaces. The four triangle sectors $T_{12}^L, T_{21}^L, T_{12}^R, T_{21}^R$ are the components of the degree-3 bar complex that detect the off-diagonal $(\alpha_1 + \alpha_2)$ block of this R -matrix.

22.18.7 STRICTIFICATION FOR $\mathfrak{sl}_3$

THEOREM 22.18.7 (*Vanishing of the spectral Drinfeld class for $\mathfrak{sl}_3$*). The spectral Drinfeld class $[\delta] \in H^2(\mathfrak{sl}_3, \text{End}(\mathfrak{sl}_3 \otimes \mathfrak{sl}_3))$ vanishes. Concretely:

- (i) At filtration 1 (Cartan sector), the defect is identically zero because the Cartan matrix A_{ij} has integer entries and the rational ansatz is already exact.
- (ii) At filtration 2 (triangle sector), the obstruction lives in the two-dimensional space spanned by T_{12}^L and T_{21}^L . The triangle coefficient $\lambda = 1/2$ satisfies the rigidity equations of Theorem 22.18.2, so the defect vanishes.
- (iii) At filtration ≥ 3 , the Serre relation $[e_1, [e_1, e_2]] = 0$ ensures vanishing target. Root-space one-dimensionality ($\dim(\mathfrak{sl}_3)_\alpha = 1$ for all $\alpha \in \Phi$) forces the remaining cochains to be coboundaries via the Jacobi collapse mechanism (Step 4 of Theorem 22.16.1).

Therefore $[\delta] = 0$ at every filtration, and $Y_\hbar(\mathfrak{sl}_3)$ is a strict associative algebra.

Proof. This is Step 4 of Theorem 22.16.1 specialised to A_2 . The filtration-by-filtration verification above records what the general root-space one-dimensionality argument looks like when all root spaces are enumerated: Φ has exactly 6 roots, all of multiplicity one. $\square$

Remark 22.18.8 (Contrast with root multiplicities > 1). The vanishing of $[\delta]$ uses $\dim(\mathfrak{sl}_3)_\alpha = 1$ in an essential way. For Kac–Moody algebras with root multiplicities > 1 (e.g. the Monster Lie algebra), the endomorphism space at a root of multiplicity m is $\text{End}(\mathbb{C}^m)$, and the Jacobi collapse argument fails: the obstruction cochain has non-scalar entries that need not be coboundaries.

22.19 HIGHER-RANK PATTERN: THE $\mathfrak{sl}_4$ ROOT QUADRILATERAL

For $\mathfrak{sl}_4$ the Dynkin diagram is the path $\alpha_1 - \alpha_2 - \alpha_3$ of type A_3 , with positive roots

$$\Phi^+ = \{\alpha_1, \alpha_2, \alpha_3, \alpha_1 + \alpha_2, \alpha_2 + \alpha_3, \alpha_1 + \alpha_2 + \alpha_3\}.$$

In matrix-unit notation: $e_1 = E_{12}, e_2 = E_{23}, e_3 = E_{34}, e_{12} = E_{13}, e_{23} = E_{24}, e_{123} = E_{14}$.

Definition 22.19.1 (*Quadrilateral sectors*). The degree-4 ordered bar complex exhibits *quadrilateral sectors* associated to the maximal composite root $\alpha_1 + \alpha_2 + \alpha_3$. The left quadrilateral vector is

$$Q_{123}^L = E_{14}^{(1)} E_{21}^{(2)} E_{32}^{(3)} E_{43}^{(4)},$$

with permuted orderings of the simple lowering operators in factors 2, 3, 4.

THEOREM 22.19.2 (*Quadrilateral coefficient for $\mathfrak{sl}_4$*). Under the normalised rational ansatz, the quadrilateral transport coefficient is

$$\frac{1}{3} = \int_0^1 (1-t)^2 dt = B(1, 3),$$

the $n = 3$ instance of the universal n -gon coefficient $1/n$.

Proof. By the same method as Theorem 22.18.2, the product side of the filtration-3 hexagon defect gives

$$\frac{1}{3} [X_1, [X_2, X_3]],$$

where the coefficient $1/3$ arises from the Dynkin path BCH formula: $\log(e^{X_1}e^{X_2}e^{X_3})$ restricted to the multilinear part of the path $\alpha_1 \sim \alpha_2 \sim \alpha_3$ gives $\frac{1}{3}[X_1, [X_2, X_3]]$ (using $[X_1, X_3] = 0$ since α_1 and α_3 are non-adjacent). The integral representation is $\int_0^1 (1-t)^2 dt = \frac{1}{3}$.

On the coproduct side, $X_{\alpha_1+\alpha_2+\alpha_3}$ is the unique height-3 generator whose twisted coproduct projects to the quadrilateral sector. Equating coefficients gives the claim.

The Serre relations for $\mathfrak{sl}_4$ provide further constraints: $(\text{ad } e_i)^{1-A_{ij}}(e_j) = 0$ with $A_{ij} = -1$ for adjacent i, j and $A_{13} = 0$. The last condition gives $[e_1, e_3] = 0$: non-adjacent simple roots commute.

The strictification obstruction vanishes for $\mathfrak{sl}_4$ by root-space one-dimensionality (every root of A_3 has multiplicity 1), exactly as for $\mathfrak{sl}_3$. $\square$

REMARK 22.19.3 (*The beta-integral staircase*). The pattern of n -gon coefficients

$$\frac{1}{n} = \int_0^1 (1-t)^{n-1} dt = B(1, n), \quad n = 2, 3, 4, \dots,$$

gives a staircase indexed by Dynkin path length:

$\mathfrak{sl}_N$	$N = 2$	$N = 3$	$N = 4$	$N = 5$
path length n	1	2	3	4
coefficient	1	1/2	1/3	1/4

At $n = 1$ (the $\mathfrak{sl}_2$ case), there is no triangle sector and the coefficient is 1: this is the degree-2 bar differential, which is the Lie bracket itself. The genuine rank-2 phenomenon begins at $n = 2$ with the coefficient $1/2$. Each step up the rank ladder introduces one additional nested commutator and one additional power of $(1-t)$ in the integrand. The beta integral provides a single uniform computation that replaces all the case-by-case Baker–Campbell–Hausdorff algebra.

For general simple $\mathfrak{g}$, the maximal Dynkin path length is the rank r , and the deepest n -gon coefficient is $1/r$. The strictification obstruction vanishes for all simple Lie algebras by root-space one-dimensionality (every root in a finite root system has multiplicity 1), confirming Theorem 22.16.1.

22.19.1 EXPLICIT COMPUTATIONS AND R -MATRICES: TYPES B_2, C_2, G_2

Table 22.1 records summary data for all types. We work out the three rank-2 families beyond type A , exhibiting root data, R -matrices in the fundamental representation, Serre relations, and strictification.

THEOREM 22.19.4 (*Ordered bar complexes and Yangian R -matrices for rank-2 non- A types;*). For each of the rank-2 types below, the collision residue is $r(z) = \hbar \Omega / z$ with $\hbar = 1/(k+h^\vee)$, root-space one-dimensionality forces complete strictification, and the RTT relation $R_{12}(u-v) T_1(u) T_2(v) = T_2(v) T_1(u) R_{12}(u-v)$ generates the Yangian.

Type B_2 ($\mathfrak{so}_5$, $h^\vee = 3$, $V = \mathbb{C}^5$). Cartan matrix $\begin{pmatrix} 2 & -1 \\ -2 & 2 \end{pmatrix}$; positive roots $\alpha_1, \alpha_2, \alpha_1+\alpha_2, \alpha_1+2\alpha_2$; max height 3. The Casimir image on $V \otimes V$ is $\Omega_V = P - K$, where K is the trace contraction. The Zamolodchikov–Fateev R -matrix is

$$R(u) = u \cdot \text{id} + P - \frac{Q}{u + \varkappa}, \quad \varkappa = \frac{N-2}{2} = \frac{3}{2}, \quad (22.16)$$

with eigenvalues $u+1$ on $S_0^2 V \cong \mathbf{14}$, $u-1$ on $\Lambda^2 V \cong \mathbf{10}$, and $(u^2 + \frac{5}{2}u - \frac{7}{2})/(u + \frac{3}{2})$ on $\mathbf{1}$. Serre: $[e_2, [e_2, [e_2, e_1]]] = 0$ from $(\mathfrak{so}_5)_{3\alpha_2+\alpha_1} = 0$.

Type C_2 ($\mathfrak{sp}_4$, $h^\vee = 3$, $V = \mathbb{C}^4$). Cartan matrix $\begin{pmatrix} 2 & -2 \\ -1 & 2 \end{pmatrix}$; positive roots $\alpha_1, \alpha_2, \alpha_1+\alpha_2, 2\alpha_1+\alpha_2$; max height 3. The Casimir image uses the symplectic form $J: \Omega_V = P - K_J$, with $(K_J)_{ij,kl} = J_{il} J_{jk}$. The symplectic R -matrix is

$$R(u) = u \cdot \text{id} + P + \frac{K}{u - \varkappa}, \quad \varkappa = n+1 = 3,$$

with eigenvalues $u+1$ on $\text{Sym}^2 V \cong \mathbf{10}$, $u-1$ on $\Lambda_0^2 V \cong \mathbf{5}$, and $(u^2 - 4u - 1)/(u - 3)$ on $\mathbf{1}$. The sign of the contraction pole is *opposite* to type B : this is the R -matrix–level manifestation of Langlands duality $B_n \leftrightarrow C_n$. Serre: $[e_1, [e_1, [e_1, e_2]]] = 0$ from $(\mathfrak{sp}_4)_{3\alpha_1+\alpha_2} = 0$.

Type G_2 ($\mathfrak{g}_2$, $h^\vee = 4$, $V = \mathbb{C}^7$). Cartan matrix $\begin{pmatrix} 2 & -1 \\ -3 & 2 \end{pmatrix}$; positive roots $\alpha_1, \alpha_2, \alpha_1+\alpha_2, 2\alpha_1+\alpha_2, 3\alpha_1+\alpha_2, 3\alpha_1+2\alpha_2$; max height 5. The tensor product $V \otimes V \cong \mathbf{1} \oplus \mathbf{7} \oplus \mathbf{14} \oplus \mathbf{27}$ decomposes into four G_2 -irreducibles with Casimir eigenvalues $c_1 = 0$, $c_7 = 1/4$, $c_{14} = 1/2$, $c_{27} = 5/12$. The R -matrix involves four equivariant projectors:

$$R(u) = \sum_{\lambda \in \{1,7,14,27\}} f_\lambda(u) \cdot \Pi_\lambda, \quad (22.17)$$

with $f_{27} = u+1$, $f_{14} = u-1$, $f_7 = (u+1)(u-2)/(u+2)$, $f_1 = (u+1)(u-4)/(u+4)$. The poles at $u = -2$ and $u = -4$ correspond to the two primitive G_2 -invariant tensors beyond id and P . The Serre relations follow from root-space vanishing: $[e_2, [e_2, e_1]] = 0$ since $\alpha_1+2\alpha_2 \notin \Phi(G_2)$; $[e_1, [e_1, [e_1, [e_1, e_2]]]] = 0$ since $4\alpha_1+\alpha_2 \notin \Phi(G_2)$. The Jacobi collapse lemma handles the degree-5 star-sector at the longest root $3\alpha_1+2\alpha_2$.

Proof. All collision residues and root-space one-dimensionality follow from Theorem 22.16.1. The R -matrices are the unique $\mathfrak{g}$ -invariant rational YBE solutions with classical limit $R(u) = u \cdot \text{id} + \hbar \Omega_V / u + O(u^{-2})$: for types B/C , the Brauer algebra relations ($P^2 = \text{id}$, $Q^2 = NQ$ or $K^2 = -2nK$) determine all coefficients; for G_2 , $\dim \text{End}_{G_2}(V \otimes V) = 4$ and the YBE plus unitarity $R(u)R_{21}(-u) \propto \text{id}$ fix the eigenvalues uniquely. Serre relations and strictification are verified by direct root-space analysis. $\square$

Remark 22.19.5 (*Comparison across rank-2 types*).

Type	$h^\vee$	$\dim V_{\text{fund}}$	$ \Phi^+ $	max height	R -matrix structure
A_2	3	3	3	2	P only
B_2	3	5	4	3	P, Q
C_2	3	4	4	3	P, K_J
G_2	4	7	6	5	four projectors

The R -matrix complexity increases with $|\text{Irr}(V_{\text{fund}} \otimes V_{\text{fund}})|$: type A has 2 summands, types B/C have 3, G_2 has 4. The Langlands duality $B_2^\vee = C_2$ interchanges $Q \leftrightarrow K_J$ and reverses the contraction-pole sign. The G_2 representation $V = \mathbb{C}^7$ is the imaginary octonions; the four-projector R -matrix encodes octonionic structure constants.

The preceding sections develop the ordered bar complex at genus zero. Wrapping the topological direction $\mathbb{R}$ into S^1 lifts the theory to genus one.

22.20 THE ANNULAR BAR COMPLEX AND GENUS-ONE STRUCTURE

The strip ordered bar complex $\overline{B}^{\text{ch,ord}}(\mathcal{A})$ on $\text{FM}_k(\mathbb{C}) \times \text{Conf}_k^<(\mathbb{R})$ computes genus-zero data: the topological direction is $\mathbb{R}$, an interval, and the resulting chain complex classifies the genus-zero E_1 -chiral Koszul dual. Replacing the strip $\mathbb{R}$ by the circle $S^1 = \mathbb{R}/\mathbb{Z}$ wraps the topological direction and produces a genus-one analogue: the *annular bar complex*. The wrapping converts the two-sided cobar complex into a coHochschild complex, and the resulting object computes $\text{HH}_\bullet^{\text{ch}}(\mathcal{A})$, connecting the ordered sector to the modular operad at genus 1.

22.20.1 DEFINITION OF THE ANNULAR BAR COMPLEX

Definition 22.20.1 (Annular bar complex). Let $\mathcal{A}$ be a strongly admissible augmented E_1 -chiral algebra and $C = \overline{B}^{\text{ch,ord}}(\mathcal{A})$ its ordered bar coalgebra, with C_Δ the diagonal bicomodule (Theorem 22.7.4). The *annular bar complex* is the chain complex

$$B_\bullet^{\text{ann}}(\mathcal{A}) := C_\bullet(\overline{\text{FM}}_{r,s}^{\text{ann}}; \omega_{\text{bar}}) \cong \bigoplus_{n \geq 0} \text{cyc}^n(C, C_\Delta),$$

where $\text{cyc}^n(C, C_\Delta) := C_\Delta \widehat{\otimes}_C C^{\widehat{\otimes} n}$ is the *cyclic cotensor*: the completed tensor product that cyclically identifies the last right C -coaction with the first left C -coaction, reflecting the periodicity of the circle.

The annular configuration space $\overline{\text{FM}}_{r,s}^{\text{ann}}$ parametrises r holomorphic marked points on $\mathbb{C}$ and s ordered marked points on S^1 , with the Fulton–MacPherson compactification in the holomorphic direction. It is the geometric carrier for the genus-one ordered sector: the strip $\text{FM}_k(\mathbb{C}) \times \text{Conf}_k^<(\mathbb{R})$ wraps to $\text{FM}_k(\mathbb{C}) \times \text{Conf}_k^{\text{cyc}}(S^1)$, where $\text{Conf}_k^{\text{cyc}}(S^1)$ denotes cyclically ordered configurations on the circle. The compactification $\overline{\text{FM}}_{r,s}^{\text{ann}}$ is a manifold with corners whose codimension-one boundary strata encode the four components of the annular differential below.

22.20.2 THE ANNULAR BAR DIFFERENTIAL

THEOREM 22.20.2 (*Annular bar differential*;). The differential on $B_\bullet^{\text{ann}}(\mathcal{A})$ decomposes as

$$d^{\text{ann}} = d_{\text{int}} + d_{\text{res}} + d_\Delta + d_{\text{wrap}},$$

where:

- (a) d_{int} : internal differential on each tensor factor (the intrinsic differential of $\mathcal{A}$).
- (b) d_{res} : collision residue differential arising from OPE residues at interior collisions in the holomorphic direction (identical to the strip bar differential).

- (c) d_Δ : comultiplication differential at non-wrapping boundary collisions, the coface maps δ_i for $1 \leq i \leq n-1$ that split a tensor factor via the ordered coproduct.
- (d) d_{wrap} : the wrap-around differential at the seam of the annulus, given by

$$d_{\text{wrap}}\langle a_1 | \cdots | a_n \rangle = \sum_{(a_n)} (-1)^\epsilon \langle a_1 | \cdots | a_{n-1} | a'_n | a''_n \rangle + \sum_{(a_1)} (-1)^{\epsilon'} \langle a'_1 | a''_1 | a_2 | \cdots | a_n \rangle,$$

where the sums are over the ordered coproduct $\Delta(a_n) = \sum a'_n \otimes a''_n$ and $\Delta(a_1) = \sum a'_1 \otimes a''_1$, and the signs ϵ, ϵ' are the Koszul signs dictated by the suspended grading $|s^{-1}a| = |a| - 1$.

The identity $(d^{\text{ann}})^2 = 0$ follows from $\partial^2 = 0$ on the manifold with corners $\overline{\text{FM}}_{r,s}^{\text{ann}}$: each boundary face of codimension 2 appears as the common boundary of exactly two codimension-1 faces, with opposite orientations.

Proof. The proof parallels that of the strip bar differential (Construction 22.II.9). The codimension-1 boundary strata of $\overline{\text{FM}}_{r,s}^{\text{ann}}$ are of four types:

- (i) an internal bubble separates at a single tensor factor (producing d_{int});
- (ii) two or more holomorphic points collide away from the seam (producing d_{res});
- (iii) two consecutive topological points collide away from the seam, splitting a tensor factor via the ordered coproduct (producing d_Δ);
- (iv) a topological point crosses the seam $0 \sim 1$ of S^1 , forcing the first or last tensor factor to split and re-enter at the opposite end (producing d_{wrap}).

The identity $(d^{\text{ann}})^2 = 0$ is the algebraic manifestation of $\partial^2 = 0$: every codimension-2 face of $\overline{\text{FM}}_{r,s}^{\text{ann}}$ is a common boundary of exactly two codimension-1 faces, and the orientations cancel pairwise. $\square$

Remark 22.20.3 (The wrap-around differential as the genus-one novelty). The wrap-around differential d_{wrap} is the only component without a strip analogue. Algebraically, it provides the coface maps δ_0 and δ_n that close the two-sided cobar complex into the coHochschild complex: without it the complex computes $\text{Cotor}^{C^e}(C_\Delta, C_\Delta)$; with it, the result is the self-cotrace $C_\Delta \square_{C^e}^L C_\Delta \simeq \text{coHH}_\bullet^{\text{ch}}(C, C_\Delta)$.

22.20.3 ANNULAR CHIRAL HOCHSCHILD IDENTIFICATION

THEOREM 22.20.4 (*Annular bar complex computes chiral Hochschild homology*;). Let $\mathcal{A}$ be a strongly admissible E_1 -chiral algebra with ordered bar coalgebra $C = \overline{B}^{\text{ch,ord}}(\mathcal{A})$ and diagonal bicomodule C_Δ . There is a canonical quasi-isomorphism

$$B_\bullet^{\text{ann}}(\mathcal{A}) \simeq \text{coHH}_\bullet^{\text{ch}}(C, C_\Delta) \simeq \text{HH}_\bullet^{\text{ch}}(\mathcal{A}),$$

where the second equivalence is Theorem 22.8.1.

Proof. By Definition 22.20.I, the annular bar complex is the cyclic cotensor $\bigoplus_{n \geq 0} \text{cyc}^n(C, C_\Delta)$. The coHochschild complex of a coalgebra C with coefficients in a bicomodule M is the standard cochain complex

$$\text{coHH}_\bullet^{\text{ch}}(C, M) = \bigoplus_{n \geq 0} M \widehat{\otimes}_C C^{\widehat{\otimes} n}$$

with differential assembled from the coface maps $\delta_0, \dots, \delta_n$. For $M = C_\Delta$, this is precisely the annular bar complex: the coface maps $\delta_1, \dots, \delta_{n-1}$ produce d_Δ (non-wrapping boundary collisions), and the coface maps δ_0 and δ_n produce d_{wrap} (the wrap-around at the seam). The internal differential d_{int} and collision residue d_{res} are carried along as the internal structure of each tensor factor.

The second equivalence is Theorem 22.8.1, which identifies $\text{coHH}_\bullet^{\text{ch}}(C, C_\Delta) \simeq \text{HH}_\bullet^{\text{ch}}(\mathcal{A})$ via the bimodule/bicomodule equivalence of Theorem 22.7.3. $\square$

22.20.4 CONNECTION TO THE MODULAR OPERAD AT GENUS 1

Remark 22.20.5 (The annular bar complex and the modular E_1 -chiral structure). The annular bar complex provides the ordered sector's contribution to the genus-1 modular E_1 -chiral operad. The passage from strip to annulus ($\mathbb{R} \rightsquigarrow S^1$) is the topological-direction analogue of the holomorphic passage from $\mathbb{C}$ to the elliptic curve E_τ : both wrap an infinite direction into a compact one, and both introduce monodromy.

In the modular operad framework:

- (i) The strip bar complex $\overline{B}^{\text{ch,ord}}(\mathcal{A})$ is the genus-0 open sector, computing the E_1 Koszul dual.
- (ii) The annular bar complex $B_\bullet^{\text{ann}}(\mathcal{A})$ is the genus-1 open sector, computing chiral Hochschild homology.
- (iii) The genus-1 closed sector carries the curvature $d^2 = \kappa(\mathcal{A}) \cdot \omega_1$ from the Hodge bundle (Vol I, Theorem D).
- (iv) The annular closure of Conjecture 22.30.3(4) is the geometric realisation of the isomorphism $B_\bullet^{\text{ann}} \simeq \text{coHH}_\bullet^{\text{ch}}(C)$ at the configuration-space level.

The open trace formalism (Theorem 22.9.5) at genus 1 factors through the annular bar complex: the de-categorified trace $\text{tr}: K_0(C_{\text{line}}) \rightarrow \text{HH}_0^{\text{ch}}(\mathcal{A})$ computes characters of line operators by wrapping them around the annulus.

22.20.5 CURVATURE-BRAIDING DICHOTOMY AT GENUS 1

At genus 0, the curvature $\kappa(\mathcal{A})$ (measuring the failure of formality, i.e. $d^2 = \kappa \cdot \omega_g$ in the curved bar complex) and the spectral R -matrix $R(z)$ (measuring the braiding monodromy on the ordered configuration space) are independent structures: the curvature is controlled by the chiral differential, the braiding by the coassociative coproduct. At genus 1, however, they meet: the spectral braiding must be defined on the elliptic curve E_τ , and the quasi-periodicity of the elliptic propagator forces the two structures to interact. The nature of this interaction is controlled entirely by the lowest-pole coefficient c_0 of the λ -bracket.

Remark 22.20.6 (Convention for this subsection). Throughout this subsection and through Definition 22.23.2 we use the *raw* λ -bracket expansion $\{a_\lambda b\} = \sum_{n \geq 0} c_n(a, b) \lambda^n$ (so c_n is the n -th OPE mode coefficient $a_{(n)}b$) and parameterise the genus-0 classical r -matrix by $r(z) = \sum c_n/z^{n+1}$. This differs from the d log-absorbed collision-residue convention used in Theorem 22.12.3, in the Virasoro collision-residue proposition below, and in Theorem 22.16.1, where the simple-pole coefficient of r^{coll} corresponds to $a_{(1)}b$ rather than $a_{(0)}b$. The two conventions are related by the shift $n \mapsto n-1$ in the pole index. Within the present subsection we keep the raw convention because it aligns with the standard genus-1 dichotomy (Heisenberg decoupled because $c_0 = a_{(0)}b = 0$, affine entangled because $c_0 = f^{ab}{}_c J^c \neq 0$).

THEOREM 22.20.7 (*Curvature–braiding dichotomy at genus 1;*). Let $\mathcal{A}$ be a logarithmic E_1 -chiral algebra and write the (-1) -shifted λ -bracket on cohomology as

$$\{a_\lambda b\} = c_0(a, b) + c_1(a, b) \lambda + c_2(a, b) \lambda^2 + \cdots,$$

so that the genus-0 classical r -matrix has the Laurent expansion

$$r(z) = \frac{c_0}{z} + \frac{c_1}{z^2} + \frac{c_2}{z^3} + \cdots \quad (\text{formal, } z \rightarrow \infty).$$

At genus 1, the classical r -matrix on E_τ is obtained by replacing each rational function $1/z^{n+1}$ ($n \geq 0$) by its unique elliptic counterpart with the same local singularity at $z = 0$:

$$r^{E_\tau}(z) = c_0 \cdot \zeta(z|\tau) + \sum_{n \geq 1} \frac{(-1)^{n-1}}{n!} c_n \cdot \wp^{(n-1)}(z|\tau), \quad (22.18)$$

where $\wp^{(0)} := \wp$, and $\zeta(z|\tau)$, $\wp(z|\tau)$ are the Weierstrass zeta and $\wp$ -functions with periods 1, τ . The first three terms are $c_0 \zeta + c_1 \wp - \frac{1}{2} c_2 \wp' + \cdots$; the prefactors $(-1)^{n-1}/n!$ come from the Laurent expansion $\wp^{(m)}(z) = (-1)^m (m+1)!/z^{m+2} + O(1)$ setting $m = n-1$. Then:

(a) (Quasi-periodicity.) The B -cycle monodromy of r^{E_τ} is

$$r^{E_\tau}(z + \tau) - r^{E_\tau}(z) = 2\eta_\tau \cdot c_0,$$

where $\eta_\tau = \zeta(\tau/2|\tau)$ is the quasi-period. The A -cycle monodromy is $2\eta_1 \cdot c_0$.

(b) (Decoupling: Cartan type.) If $c_0 = 0$ (equivalently, $\{a_0 b\} = 0$ for all $a, b \in H^\bullet(\mathcal{A}, Q)$), then $r^{E_\tau}(z)$ is a meromorphic function on E_τ (doubly periodic). The spectral braiding is independent of the B -cycle monodromy that sources the curvature $\kappa(\mathcal{A}) \cdot \omega_1$. The genus-1 E_1 -chiral bar complex splits:

$$\overline{B}^{\text{ch, ord}}(\mathcal{A})^{(1)} \simeq (\text{curved chiral differential}) \times (\text{flat coassociative coproduct with meromorphic braiding}).$$

(c) (Entanglement: Yangian type.) If $c_0 \neq 0$, then $r^{E_\tau}(z)$ is quasi-periodic with non-trivial B -cycle monodromy $2\eta_\tau \cdot c_0$. The spectral braiding is a section of a flat connection on the universal cover of E_τ with holonomy c_0 , and the genus-1 E_1 -chiral bar complex does *not* split. The braiding and the curvature share a common geometric source: the B -cycle monodromy of the Weierstrass zeta function.

Proof. **Step 1** (Elliptic propagator). At genus 0, the holomorphic propagator is $K^{\mathbb{C}}(z) = dz/z$ (the $d \log$ kernel). At genus 1, on the elliptic curve E_τ , the unique meromorphic one-form with a simple pole at $z = 0$ and prescribed quasi-periodicity is $K^{E_\tau}(z) = \zeta(z|\tau) dz$. This has the same local singularity $\zeta(z|\tau) = 1/z + O(z)$ near $z = 0$ but acquires the quasi-periodicity $\zeta(z+1|\tau) = \zeta(z|\tau) + 2\eta_1$ and $\zeta(z+\tau|\tau) = \zeta(z|\tau) + 2\eta_\tau$.

Step 2 (Expansion of the elliptic r -matrix). The genus-0 r -matrix $r(z) = \sum_{n \geq 0} c_n/z^{n+1}$ arises from pairing the propagator dz/z with the λ -bracket coefficients. At genus 1, each rational function $1/z^{n+1}$ is replaced by its unique elliptic counterpart: $1/z \mapsto \zeta(z|\tau)$ and $1/z^{n+1} \mapsto \frac{(-1)^{n-1}}{n!} \wp^{(n-1)}(z|\tau)$ for $n \geq 1$, with $\wp^{(0)} := \wp$. These are the unique functions on $\mathbb{C} \setminus (\mathbb{Z} + \mathbb{Z}\tau)$ that match $1/z^{n+1} + O(z)$ near $z = 0$

and are doubly periodic for $n \geq 1$ (or quasi-periodic for $n = 0$). The prefactor comes from the Laurent expansion $\wp^{(m)}(z) = (-1)^m(m+1)!/z^{m+2} + O(1)$ specialised to $m = n - 1$. This yields formula (22.18).

Step 3 (Dichotomy). The quasi-periodicity is inherited entirely from $\zeta(z|\tau)$, since $\wp$ and all its derivatives are doubly periodic. Therefore the B -cycle monodromy of r^{E_τ} is $2\eta_\tau \cdot c_0$, proving (a). When $c_0 = 0$, the ζ -term is absent and r^{E_τ} is meromorphic on E_τ , hence the spectral braiding defined by the annular bar differential decouples from the curved chiral differential. When $c_0 \neq 0$, the non-trivial monodromy forces the braiding to be a section of a flat connection with holonomy $\exp(2\pi i \cdot c_0)$, and this flat connection is the same geometric object whose B -cycle monodromy controls the curvature $\kappa(\mathcal{A}) \cdot \omega_1$. $\square$

Remark 22.20.8 (Classification by pole structure). The dichotomy partitions all E_∞ -chiral algebras (i.e. all vertex algebras, which are local and Σ_n -equivariant) into two classes at genus 1:

Class	c_0	Monodromy	Example
Cartan (decoupled)	$= 0$	trivial	Heisenberg $\mathcal{H}_k$, free fermion
Yangian (entangled)	$\neq 0$	$2\eta_\tau \cdot c_0$	$\widehat{\mathfrak{g}}_k$ ($\mathfrak{g}$ simple), Virasoro

For the Heisenberg algebra $\mathcal{H}_k$, the OPE $J(z)J(w) \sim k/(z-w)^2$ has $c_0 = \{J_{(0)}J\} = 0$ (no simple pole in the λ -bracket: the lowest nonvanishing coefficient is $c_1 = k$). The genus-1 r -matrix is $r^{E_\tau}(z) = k \cdot \wp(z|\tau)$, which is doubly periodic. For $\widehat{\mathfrak{sl}}_2$ at level k , the OPE $J^a(z)J^b(w) \sim k \kappa^{ab}/(z-w)^2 + f^{ab}_c J^c(w)/(z-w)$ has $c_0 = f^{ab}_c J^c \neq 0$, and the genus-1 structure is genuinely entangled.

22.21 QUANTUM GROUPS FROM GENUS-1 MONODROMY

The preceding sections develop the ordered bar complex and its R -matrix on the genus-zero configuration space $\text{Conf}_n(\mathbb{C})$. At genus 1 the configuration space is replaced by $\text{Conf}_n(E_\tau)$, where $E_\tau = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ is the elliptic curve with modulus τ . The fundamental group of $\text{Conf}_n(E_\tau)$ is richer than the pure braid group P_n : it contains two additional generators (the A -cycle and B -cycle monodromies), and their interaction with the braid generators produces the quantum group $U_q(\mathfrak{g})$ from the Yangian $Y_h(\mathfrak{g})$.

The genus-1 lift for the affine lineage $V^k(\mathfrak{g})$ combines the Drinfeld–Kohno theorem with the one-loop collapse mechanism established in Volume II, giving a rigorous passage from the KZ connection to the KZB connection and thence to the quantum group.

22.21.1 THE KZ CONNECTION ON ORDERED CONFIGURATIONS

The genus-0 starting point is as follows. Let $\mathfrak{g}$ be a simple Lie algebra and $k \in \mathbb{C} \setminus \{-h^\vee\}$ generic. Choose an orthonormal basis $\{I^a\}$ for $\mathfrak{g}$ with respect to the Killing form normalised so that $\text{tr}(I^a I^b) = \delta^{ab}$. The Casimir tensor is $\Omega = \sum_a I^a \otimes I^a \in \mathfrak{g} \otimes \mathfrak{g}$.

Definition 22.21.1 (KZ connection). On the trivial bundle over $\text{Conf}_n(\mathbb{C})$ with fibre $V_1 \otimes \cdots \otimes V_n$ (finite-dimensional $\mathfrak{g}$ -modules), the *Knizhnik–Zamolodchikov connection* is

$$\nabla_{\text{KZ}} = d - \frac{\hbar}{2\pi i} \sum_{1 \leq i < j \leq n} \Omega_{ij} d(z_i - z_j)/(z_i - z_j), \quad (22.19)$$

where $\hbar = \pi i/(k + h^\vee)$ and Ω_{ij} denotes the Casimir acting in the (i, j) tensor slots.

Remark 22.21.2. The connection (22.19) is a special case of the Kohn connection (22.1): for the affine algebra $V^k(\mathfrak{g})$, the collision residue $r_{ij}(z)$ extracted by the $d \log$ kernel (cf. the kernel absorbs one pole) is $r_{ij}(z) = (\hbar/2\pi i) \Omega_{ij}/z$, which has the expected simple pole. The one-loop collapse mechanism from Volume II ensures that the higher A_∞ operations m_k ($k \geq 3$) do not contribute on evaluation modules, so the full superconnection reduces to the KZ connection. The flatness $\nabla_{\text{KZ}}^2 = 0$ follows from $[\Omega_{ij}, \Omega_{ik} + \Omega_{jk}] = 0$, which is the $\mathfrak{g}$ -equivariance of the Casimir.

22.21.2 GENUS-0 MONODROMY: THE R -MATRIX

At genus 0, the fundamental group $\pi_1(\text{Conf}_n(\mathbb{C}))$ is the pure braid group P_n . The monodromy of ∇_{KZ} around the generator γ_{ij} (in which z_i circles z_j) gives the R -matrix:

$$R_{ij} = \text{Mon}_{\gamma_{ij}}(\nabla_{\text{KZ}}) = \mathcal{P} \exp\left(\frac{\hbar}{2\pi i} \oint_{\gamma_{ij}} \Omega_{ij} d(z_i - z_j)/(z_i - z_j)\right) = e^{\hbar \Omega_{ij}}.$$

This is the *A-cycle monodromy*: it encodes how parallel transport twists when one point winds around another on the genus-0 surface. The Yang–Baxter equation $R_{12} R_{13} R_{23} = R_{23} R_{13} R_{12}$ follows from flatness (eq. (22.2) and its exponentiated form), as proved in Proposition 22.4.3.

22.21.3 THE KZB CONNECTION ON THE ELLIPTIC CURVE

At genus 1 the base curve is E_τ and the configuration space $\text{Conf}_n(E_\tau)$ has fundamental group containing two distinguished classes of generators beyond the braid generators: the *A-cycle* (a point traverses the real period 1) and the *B-cycle* (a point traverses the imaginary period τ). The KZ connection must be replaced by the *Knizhnik–Zamolodchikov–Bernard* (KZB) connection, which encodes the genus-1 monodromy of conformal blocks.

Definition 22.21.3 (KZB connection). On the trivial bundle over $\text{Conf}_n(E_\tau)$ with fibre $V_1 \otimes \cdots \otimes V_n$, the *KZB connection* is

$$\nabla_{\text{KZB}} = d - \frac{\hbar}{2\pi i} \sum_{1 \leq i < j \leq n} \Omega_{ij} \wp_1(z_i - z_j, \tau) dz_{ij} - \frac{\hbar}{2\pi i} \sum_{i=1}^n D_i d\tau, \quad (22.20)$$

where $\wp_1(z, \tau) = \partial_z \log \theta_1(z, \tau)$ is the logarithmic derivative of the Jacobi theta function (the elliptic analogue of $1/z$), $z_{ij} = z_i - z_j$, and D_i is the modular Hamiltonian

$$D_i = \sum_{j \neq i} (\wp(z_{ij}, \tau) \Omega_{ij} + \text{lower order}),$$

with $\wp(z, \tau) = -\partial_z \wp_1(z, \tau)$ the Weierstrass $\wp$ -function.

Remark 22.21.4. The KZB connection is a genus-1 deformation of the KZ connection. In the degeneration limit $\tau \rightarrow i\infty$ (the nodal rational curve), $\wp_1(z, \tau) \rightarrow \pi \cot(\pi z) \rightarrow 1/z + O(z)$, and the KZB connection degenerates to the KZ connection. The $d\tau$ term, absent at genus 0, records the dependence of conformal blocks on the modulus τ and is the source of the modular anomaly: it measures the failure of conformal blocks to form a flat bundle over the moduli space $\mathcal{M}_{1,n}$.

Remark 22.21.5 (Bar-complex origin). In the E_1 -chiral framework, the KZB connection arises from the ordered bar complex on the elliptic curve E_τ equipped with its logarithmic chiral coassociative structure. The collision residue on $\text{Conf}_n^{\text{ord}}(E_\tau)$ is $r_{ij}^{E_\tau}(z) = (\hbar/2\pi i) \Omega_{ij} \wp_1(z, \tau)$, which replaces the genus-0 collision

residue $r_{ij} = (\hbar/2\pi i) \Omega_{ij}/z$ by its elliptic regularisation. The additional $d\tau$ connection component encodes the curvature $\kappa(A) \cdot \omega_1$ from the Hodge bundle on $\overline{\mathcal{M}}_{1,n}$: the curved bar structure $d^2 = \kappa(A) \cdot \omega_1$ at genus 1 is precisely the non-flatness of the naive genus-0 connection, corrected by the Bernard term $D_i d\tau$.

22.21.4 *B*-CYCLE MONODROMY AND THE QUANTUM GROUP PARAMETER

The decisive new phenomenon at genus 1 is the *B*-cycle monodromy.

THEOREM 22.21.6 (*Quantum group from B-cycle monodromy*;). Let $\mathfrak{g}$ be a simple Lie algebra and $k \in \mathbb{C} \setminus \{-h^\vee\}$ generic. Consider the KZB monodromy representation

$$\rho_n^{\text{KZB}} : \pi_1(\text{Conf}_n(E_\tau)) \longrightarrow \text{GL}(V_1 \otimes \cdots \otimes V_n).$$

- (i) ***A*-cycle monodromy.** The monodromy around the *A*-cycle generator α_i (in which $z_i \mapsto z_i + 1$, all other points fixed) gives the *R*-matrix:

$$\rho_n^{\text{KZB}}(\alpha_i) = R_i(z),$$

which is the spectral *R*-matrix of Construction 22.4.2, now defined via the elliptic collision residue.

- (ii) ***B*-cycle monodromy.** The monodromy around the *B*-cycle generator β_i (in which $z_i \mapsto z_i + \tau$, all other points fixed) produces the quantum group parameter:

$$\rho_n^{\text{KZB}}(\beta_i) = q^{H_i} \cdot (\text{braiding corrections}),$$

where

$$q = e^{2\pi i \hbar} = e^{2\pi^2 i / (k + h^\vee)}$$

and H_i is the Cartan action in the *i*-th tensor slot.

- (iii) **Quantum group structure.** The combined *A*-cycle and *B*-cycle monodromies, together with the braid monodromies, generate a representation of the quantum group $U_q(\mathfrak{g})$ on $V_1 \otimes \cdots \otimes V_n$ at the parameter $q = e^{2\pi i \hbar}$.

Proof. (i) is immediate from the fact that *A*-cycle monodromy around $z_i \mapsto z_i + 1$ corresponds to the quasi-periodicity of $\wp_1(z, \tau)$ along the real period, which introduces the same braid-type contribution as at genus 0.

(ii). The *B*-cycle monodromy arises from $z_i \mapsto z_i + \tau$. The quasi-periodicity of the Jacobi theta function gives $\wp_1(z + \tau, \tau) = \wp_1(z, \tau) - 2\pi i$, so the connection form acquires a constant shift $-2\pi i \cdot (\hbar/2\pi i) \Omega_{ij} = -\hbar \Omega_{ij}$ from each pair. The parallel transport along the *B*-cycle path $z_i \mapsto z_i + t\tau$ ($t \in [0, 1]$) includes both the dz contribution (from the connection one-form) and the $d\tau$ contribution (from the modular Hamiltonian D_i). On evaluation modules, the one-loop collapse ensures that only the leading Casimir term contributes, and the result is

$$\rho_n^{\text{KZB}}(\beta_i) = \exp(2\pi i \hbar \cdot H_i + \text{off-diagonal}),$$

where H_i is the Cartan element acting in the *i*-th slot. The exponential $e^{2\pi i \hbar} = q$ extracts the quantum group parameter. The “braiding corrections” are conjugations by *R*-matrices arising from the interaction of the *B*-cycle path with the other points; they are controlled by the mixed *A*-*B* relations in $\pi_1(\text{Conf}_n(E_\tau))$.

(iii). The Drinfeld–Kohno theorem (genus-1 version, see the discussion below) proves that the monodromy representation of the KZB connection factors through $U_q(\mathfrak{g})$. The A -cycle monodromies give the R -matrix (the braiding in $\text{Rep}_q(\mathfrak{g})$), the B -cycle monodromies give the Cartan elements (the q^H operators), and together with the braid monodromies they generate the full quantum group action. $\square$

Remark 22.21.7 (Physical origin of q). The parameter $q = e^{2\pi i \hbar} = e^{2\pi^2 i / (k + h^\vee)}$ has a transparent origin in the holomorphic-topological framework. At genus 0, the bar complex on $\text{FM}_n(\mathbb{C}) \times \text{Conf}_n(\mathbb{R})$ produces the Yangian $Y_{\hbar}(\mathfrak{g})$, a deformation over the formal parameter $\hbar = \pi i / (k + h^\vee)$. At genus 1, the B -cycle monodromy exponentiates the additive parameter $\hbar$ into the multiplicative parameter $q = e^{2\pi i \hbar}$: the passage from the additive formal group $\widehat{\mathbb{G}}_a$ to the multiplicative formal group $\widehat{\mathbb{G}}_m$ is the passage from the Yangian to the quantum group. The elliptic curve E_τ provides the geometric mechanism: its B -cycle is the Wick-rotated time circle in the holomorphic-topological theory, and the monodromy around it converts the infinitesimal deformation parameter into a finite one.

Observation 22.21.8 (Sesquilinearity forces the additive formal group). The spectral parameter λ in the λ -bracket $\{a_\lambda b\}$ carries the additive formal group law $F(\lambda, \mu) = \lambda + \mu$. Sesquilinearity $\{\partial a_\lambda b\} = -\lambda \{a_\lambda b\}$ identifies λ as the Fourier dual of translation; the Fourier dual of the additive group is the additive group. A multiplicative law $F(\lambda, \mu) = \lambda + \mu + \lambda\mu$ would require $\{\partial a_\lambda b\} = -(1 + \lambda)\{a_\lambda b\} \cdot \log(1 + \lambda)/\lambda$, which is not polynomial in λ .

Observation 22.21.9 (Endomorphism ring of $\widehat{\mathbb{G}}_a$ and the Wick rotation). Over any $\mathbb{C}$ -algebra R , $\text{End}(\widehat{\mathbb{G}}_{a/R}) = R$: every element $\alpha \in R$ defines an endomorphism $[\alpha]: x \mapsto \alpha x$, and these exhaust all endomorphisms since $\widehat{\mathbb{G}}_a$ has no nonlinear endomorphisms in characteristic zero. In particular, $[i] \in \text{End}(\widehat{\mathbb{G}}_{a/\mathbb{C}})$: the Wick rotation $\lambda \mapsto i\lambda$ (equivalently $t \mapsto it$ in the topological direction of $\mathbb{C}_z \times \mathbb{R}_t$) is an automorphism of the spectral-parameter formal group.

Remark 22.21.10 (Spectralization contracts the endomorphism ring). Over $\mathbb{F}_p$, the additive formal group has height ∞ ($[p](x) = px = 0$), not height 1. Upon spectralization (passing from chain complexes to spectra, replacing $\widehat{\mathbb{G}}_a$ by a formal group of finite height), the endomorphism ring contracts:

$$\begin{aligned} \widehat{\mathbb{G}}_a &: \text{End} = \mathbb{C} && (\text{height } \infty \text{ over } \mathbb{F}_p) \\ \widehat{\mathbb{G}}_m &: \text{End} = \mathbb{Z}_p && (\text{height } 1) \\ \widehat{E}_\tau &: \text{End} = \text{order in } \mathbb{Q}(\sqrt{-d}) && (\text{height } \leq 2) \end{aligned}$$

The ring $\mathbb{Z}_p$ does not contain i for $p \neq 2$ unless $p \equiv 1 \pmod{4}$, and even then $i \in \mathbb{Z}_p$ is a p -adic integer, not the complex Wick rotation. For a generic elliptic curve, $\text{End}(\widehat{E}_\tau) = \mathbb{Z}$, which excludes $[i]$ entirely.

The sole exception is the CM curve E_i with j -invariant $j = 1728$: here $\text{End}(\widehat{E}_i) \supseteq \mathbb{Z}[i]$, so $[i]$ is an endomorphism. This is the unique elliptic curve over $\mathbb{C}$ (up to isomorphism) whose formal group admits a Wick rotation: an arithmetic accident, not a structural feature.

The bar-cobar theory of this monograph is a theory of chain complexes over $\mathbb{C}$. Every chain complex is an $H\mathbb{C}$ -module, hence rational, hence chromatic height 0. The endomorphism ring $\text{End}(\widehat{\mathbb{G}}_a) = \mathbb{C}$ reflects this: the theory admits all constant endomorphisms, including $[i]$. Positive chromatic height enters only after spectralization, which contracts the endomorphism ring from $\mathbb{C}$ to an arithmetic object ($\mathbb{Z}_p$ or an order in a quadratic field) and generically excludes the Wick rotation (cf. the chromatic/shadow discussion in Chapter K.7.1).

22.21.5 THE DRINFELD–KOHNO THEOREM

The identification of the KZ/KZB monodromy with the quantum group action is the content of the Drinfeld–Kohno theorem and its generalisations.

THEOREM 22.21.11 (*Drinfeld–Kohno; for the affine lineage*). Let $\mathfrak{g}$ be a simple Lie algebra, $k \in \mathbb{C} \setminus \{-h^\vee\}$ generic, and $V_1, \dots, V_n$ finite-dimensional $\mathfrak{g}$ -modules.

- (i) **Genus 0.** The monodromy representation of the KZ connection (22.19) on $\text{Conf}_n(\mathbb{C})$ is isomorphic to the braid group representation obtained from the braided monoidal structure of $\text{Rep}_q(\mathfrak{g})$ via the universal R -matrix of $U_q(\mathfrak{g})$:

$$\rho_n^{\text{KZ}} \simeq \rho_n^{U_q(\mathfrak{g})}.$$

- (ii) **Genus 1.** The monodromy representation of the KZB connection (22.20) on $\text{Conf}_n(E_\tau)$ factors through $U_q(\mathfrak{g})$ and recovers the full quantum group action (including the q^H operators from B -cycle monodromy) on the tensor product $V_1 \otimes \dots \otimes V_n$.

Proof. (i) is the classical Drinfeld–Kohno theorem. The proof proceeds in three steps.

Step 1: Drinfeld associator. Drinfeld constructs a formal series $\Phi \in U(\mathfrak{g})^{\otimes 3}[[\hbar]]$ satisfying the pentagon and hexagon equations, using iterated integrals of $d \log(z_i - z_j)$ on $\text{Conf}_3(\mathbb{C})$. This associator converts the infinitesimal braid relations (the CYBE) into the finite braid relations (the YBE), providing an equivalence of braided monoidal categories between the representation category of the Drinfeld–Kohno Lie algebra $\mathfrak{t}_n$ (with its KZ braiding) and $\text{Rep}_q(\mathfrak{g})$ (with its universal R -matrix braiding).

Step 2: One-loop collapse. For the affine algebra $V^k(\mathfrak{g})$, the one-loop exactness of the BV-BRST differential (Theorem ?? of Volume II) ensures that the higher A_∞ operations m_k ($k \geq 3$) vanish on evaluation modules. The full superconnection on the bar complex therefore collapses to the KZ connection, and the bar-complex monodromy ρ_n^{HT} equals ρ_n^{KZ} (the one-loop collapse statement of Volume II).

Step 3: Identification. Combining Steps 1 and 2, the bar-complex monodromy for the affine lineage equals the quantum-group braid representation: $\rho_n^{\text{HT}} = \rho_n^{\text{KZ}} \simeq \rho_n^{U_q(\mathfrak{g})}$.

(ii) follows from the genus-1 generalisation of the Drinfeld–Kohno theorem (Etingof–Schiffmann, Calaque–Enriquez–Etingof): the KZB monodromy representation on $\text{Conf}_n(E_\tau)$ factors through $U_q(\mathfrak{g})$, with the B -cycle monodromy providing the q^H operators. The one-loop collapse for the affine lineage ensures that the bar-complex monodromy on $\text{Conf}_n(E_\tau)$ equals the KZB monodromy, and the identification follows. $\square$

22.21.6 THE GENUS-1 DEFORMATION: FROM YANGIAN TO QUANTUM GROUP

The passage from genus 0 to genus 1 can be summarised as a deformation of the Yangian $Y_\hbar(\mathfrak{g})$ to the quantum group $U_q(\mathfrak{g})$.

THEOREM 22.21.12 (*Yangian–quantum group deformation for the affine lineage*). Let $\mathfrak{g}$ be a simple Lie algebra and $k \in \mathbb{C} \setminus \{-h^\vee\}$ generic.

- (i) At genus 0, the ordered bar complex of $V^k(\mathfrak{g})$ on $\text{FM}_n(\mathbb{C}) \times \text{Conf}_n(\mathbb{R})$ produces the Yangian $Y_\hbar(\mathfrak{g})$ as the line-operator algebra, with $\hbar = \pi i / (k + h^\vee)$.
- (ii) At genus 1, the ordered bar complex on $E_\tau \times \mathbb{R}$ produces the quantum group $U_q(\mathfrak{g})$ as the line-operator algebra, with $q = e^{2\pi i \hbar}$.

- (iii) The degeneration $\tau \rightarrow i\infty$ (pinching the B -cycle) recovers the Yangian from the quantum group: $\lim_{\tau \rightarrow i\infty} U_q(\mathfrak{g}) = Y_{\hbar}(\mathfrak{g})$, in the sense that the KZB connection degenerates to the KZ connection and the B -cycle monodromy becomes trivial.
- (iv) The quantum group parameter $q = e^{2\pi i \hbar}$ is the exponential of the Yangian parameter $\hbar$ under the exponential map $\widehat{\mathbf{G}}_a \rightarrow \widehat{\mathbf{G}}_m$ provided by the B -cycle of E_{τ} .

Proof. Part (i) is the content of the genus-0 programme: the bar differential on $\mathrm{FM}_n(\mathbb{C})$ encodes the chiral OPE, the E_1 coproduct on $\mathrm{Conf}_n(\mathbb{R})$ encodes the associative composition, and the resulting algebra is the Yangian (see the holographic dictionary of Volume II, Corollary K.7.1).

Part (ii) combines Theorem 22.21.6 with the Drinfeld–Kohno theorem (Theorem 22.21.11(ii)): the full monodromy of the KZB connection generates $U_q(\mathfrak{g})$.

Part (iii) follows from the degeneration $\wp_1(z, \tau) \rightarrow 1/z + O(z)$ as $\tau \rightarrow i\infty$: the KZB connection degenerates to KZ, the B -cycle shrinks to a point, and the q^H monodromy becomes trivial.

Part (iv) is a restatement: $q = e^{2\pi i \hbar}$ is the exponential of $\hbar$ multiplied by $2\pi i$, and the B -cycle monodromy is the geometric mechanism that implements this exponentiation. $\square$

Conjecture 22.21.13 (Yangian–quantum group deformation beyond the affine lineage). The Yangian–quantum group deformation of Theorem 22.21.12 extends to non-affine chiral algebras: for any modular Koszul algebra $\mathcal{A}$ on $E_{\tau} \times \mathbb{R}$, the genus-1 ordered bar complex produces a quantum-group-type algebra deforming the genus-0 Yangian-type algebra, with the B -cycle monodromy implementing the exponential map $\hbar \mapsto q = e^{2\pi i \hbar}$.

22.21.7 THE $\mathfrak{sl}_2$ CASE AND ROOTS OF UNITY

For $\mathfrak{g} = \mathfrak{sl}_2$, the quantum group parameter specialises to a root of unity at integer level.

COROLLARY 22.21.14 ($U_q(\mathfrak{sl}_2)$ at roots of unity from affine $\mathfrak{sl}_2$;). For $\mathfrak{g} = \mathfrak{sl}_2$ at positive integer level $k \in \mathbb{Z}_{>0}$:

- (i) The quantum group parameter is $q = e^{2\pi^2 i/(k+2)}$, and $q^{2(k+2)} = 1$.
- (ii) The quantum group $U_q(\mathfrak{sl}_2)$ at this root of unity has a finite-dimensional quotient with $k + 1$ irreducible modules $V_0, V_1, \dots, V_k$ of dimensions $1, 2, \dots, k + 1$.
- (iii) These $k + 1$ modules are in bijection with the integrable highest-weight modules of $\widehat{\mathfrak{sl}}_2$ at level k . The truncation of the representation category is the genus-1 avatar of the level- k WZW fusion category.

Proof. Part (i): $h^{\vee} = 2$ for $\mathfrak{sl}_2$, so $\hbar = \pi i/(k + 2)$ and $q = e^{2\pi i \hbar} = e^{2\pi^2 i/(k+2)}$. For the root-of-unity property: $q^{2(k+2)} = e^{2 \cdot 2\pi^2 i} = 1$.

Part (ii) is a classical result: at q a root of unity, the quantum group $U_q(\mathfrak{sl}_2)$ has a large centre generated by E^{k+2} , F^{k+2} , and $K^{2(k+2)}$, and the quotient by this centre has finitely many simple modules.

Part (iii) is the Kazhdan–Lusztig equivalence: $\mathcal{O}_k^{\mathrm{int}}(\widehat{\mathfrak{sl}}_2) \simeq \mathrm{Rep}_q(\mathfrak{sl}_2)^{\mathrm{fin}}$. $\square$

22.21.8 THE JONES POLYNOMIAL FROM GENUS-1 MONODROMY

The Jones polynomial emerges as a topological invariant from the genus-1 monodromy applied to the bar complex.

THEOREM 22.21.15 (*Jones polynomial from genus-1 bar-complex monodromy*;). For $\mathfrak{g} = \mathfrak{sl}_2$ at level $k \in \mathbb{Z}_{>0}$, let K be a framed knot presented as the closure of a braid $\beta \in B_n$. Then:

- (i) The bar complex of $V^k(\mathfrak{sl}_2)$, viewed as a logarithmic $\mathrm{SC}^{ch,top}$ -algebra, produces the braid group representation $\rho_n^{\mathrm{HT}} = \rho_n^{\mathrm{KZ}}$ on tensor powers of the fundamental representation V .
- (ii) By the Drinfeld–Kohno theorem (Theorem 22.21.11), this representation factors through $U_q(\mathfrak{sl}_2)$ at $q = e^{2\pi^2 i/(k+2)}$.
- (iii) The Jones polynomial is recovered by the quantum trace:

$$J_K(q) = \mathrm{tr}_q(\rho_n^{\mathrm{HT}}(\beta)) = \mathrm{tr}(q^{2\rho} \cdot \rho_n^{\mathrm{KZ}}(\beta)),$$

where ρ is the half-sum of positive roots ($\rho = 1/2$ for $\mathfrak{sl}_2$) and tr_q is the categorical trace in the ribbon category $\mathrm{Rep}_q(\mathfrak{sl}_2)$.

- (iv) The integration domain is $\mathrm{FM}_n(\mathbb{C}) \times \mathrm{Conf}_n(\mathbb{R})$: the $\mathrm{FM}_n(\mathbb{C})$ factor carries the bar differential encoding the chiral OPE, and the $\mathrm{Conf}_n(\mathbb{R})$ factor carries the E_1 coproduct implementing the topological interval-cutting. The Jones polynomial is a holomorphic-topological invariant: the holomorphic direction produces the braiding, and the topological direction produces the monoidal structure.

Proof. Parts (i)–(ii) combine the Volume II one-loop collapse statement (the bar-complex monodromy equals the KZ monodromy for the affine lineage) with Theorem 22.21.11(i) (the KZ monodromy equals the quantum group braid representation).

Part (iii) is the Reshetikhin–Turaev construction: $\mathrm{Rep}_q(\mathfrak{sl}_2)$ is a ribbon category (the ribbon element is $v = K^{-1}u$ where $K = q^H$ and $u = \sum S(b_i)a_i$), and the quantum trace $\mathrm{tr}_q = \mathrm{tr}(q^{2\rho} \cdot)$ implements the Markov closure converting a braid representation into a framed link invariant. Since $\rho_n^{\mathrm{HT}} = \rho_n^{\mathrm{KZ}} \simeq \rho_n^{U_q}$, the quantum trace applied to the bar-complex monodromy equals the Jones polynomial.

Part (iv) is a restatement of the E_1 -chiral factorisation structure: the bar complex lives on the product of holomorphic and topological configuration spaces, and the Jones polynomial is the output of applying the Reshetikhin–Turaev functor to the monodromy of the connection defined on this product. $\square$

Remark 22.21.16 (*The three levels of the construction*). The passage from chiral algebra to knot invariant has three levels, each proved:

Level	Object	Output
Genus 0, ordered bar	KZ connection	Yangian $Y_h(\mathfrak{g})$
Genus 1, B -cycle monodromy	KZB connection	Quantum group $U_q(\mathfrak{g})$
Markov closure	Quantum trace	Jones polynomial $J_K(q)$

Each level is proved for the affine lineage by the one-loop collapse mechanism. Beyond the affine lineage (for $\mathcal{W}$ -algebras obtained by Drinfeld–Sokolov reduction, where higher A_∞ operations contribute), the correspondence between bar-complex monodromy and quantum group representations remains conjectural.

22.21.9 SCOPE AND FRONTIER

Remark 22.21.17 (Status). The results of this section are proved for the *affine lineage*: $V^k(\mathfrak{g})$ for simple $\mathfrak{g}$ at generic level k , acting on finite-dimensional evaluation modules. The proof mechanism is the one-loop collapse mechanism from Volume II, which reduces the full bar-complex superconnection to the KZ/KZB connection, and the Drinfeld–Kohno theorem (classical at genus 0, Etingof–Schiffmann/Calaque–Enriquez–Etingof at genus 1), which identifies the KZ/KZB monodromy with the quantum group representation.

Beyond the affine lineage, two frontiers are open:

- (a) *$\mathcal{W}$ -algebras.* For $\mathcal{W}$ -algebras obtained by Drinfeld–Sokolov reduction, the higher A_∞ operations m_k ($k \geq 3$) do not vanish: the one-loop collapse mechanism breaks. The full superconnection contributes to the monodromy, and the genus-1 deformation should produce a *deformed quantum group* or *quantum $\mathcal{W}$ -algebra*. This is the content of Conjecture K.7.1 in Volume II.
- (b) *Higher genus.* At genus $g \geq 2$, the configuration space $\text{Conf}_n(\Sigma_g)$ has $2g$ distinguished cycle classes, and the monodromy acquires $2g$ additional generators. The curvature $\kappa(A) \cdot \omega_g$ from the Hodge bundle on $\overline{\mathcal{M}}_{g,n}$ provides genus-by-genus corrections. The algebraic object controlling the monodromy at genus g should be a *higher-genus quantum group* or *mapping-class-group representation* generalising the braid-group representations at genus 0 and 1.

22.21.10 THE ORDERED TRIDEGREE DECOMPOSITION

The symmetric bar complex carries a natural bidegree (g, n) with g the genus and n the degree. The ordered bar complex refines this to a *tridegree* that records the depth of consecutive collisions in the Fulton–MacPherson compactification.

Definition 22.21.18 (Ordered tridegree). Let A be a strongly admissible associative chiral algebra and $\overline{B}^{\text{ch,ord}}(A)$ its ordered bar complex. The *ordered tridegree* of a bar element $\alpha \in \overline{B}^{\text{ch,ord}}(A)$ is the triple $(g, n, d)^{E_1}$ where:

- (i) $g \geq 0$ is the genus (the number of handles of the underlying curve);
- (ii) $n \geq 1$ is the degree (the number of bar slots);
- (iii) $d \geq 0$ is the *ordered collision depth*: the codimension of the planted-forest boundary stratum of $\overline{\text{FM}}_n^{\text{ord}}(\mathbb{C})$ at which α is supported.

At degree n , the ordered compactification $\overline{\text{FM}}_n^{\text{ord}}(\mathbb{C})$ has exactly $n-1$ codimension-one boundary divisors $D_{i,i+1}$, $1 \leq i \leq n-1$, corresponding to consecutive collisions $z_i \rightarrow z_{i+1}$. The depth d counts the codimension in this boundary stratification: $d = 0$ is the interior (no collision), and the maximal depth at degree n is $d = n-1$ (complete consecutive collapse). In the unordered FM compactification, degree n has $\binom{n}{2}$ codimension-one divisors; the restriction to $n-1$ consecutive divisors is the geometric signature of the E_1 -structure.

THEOREM 22.21.19 (Ordered depth spectrum). Let A be a strongly admissible associative chiral algebra whose OPE has pole orders $\{p_1, \dots, p_s\}$ (i.e., $a_{(n)}b \neq 0$ precisely for $n \in \{p_1-1, \dots, p_s-1\}$, with the convention that $a_{(n)}b$ contributes a pole of order $n+1$). Then the depth spectrum at genus 0, degree 2 is

$$\text{Spec}(d^{E_1}; A)|_{(0,2)} = \{ \max(p-1, 0) : p \text{ is a pole order of the OPE of } A \}.$$

The following table records the depth spectrum for the standard examples:

Algebra	OPE poles	Depth spectrum
Heisenberg H_k	$\{2\}$	$\{0, 1\}$
Affine $V^k(\mathfrak{g})$	$\{1, 2\}$	$\{0, 1\}$
Virasoro Vir_c	$\{1, 2, 4\}$	$\{0, 1, 3\}$

The depth spectrum of the Virasoro algebra exhibits a gap at $d = 2$, reflecting the absence of a cubic pole in the Virasoro OPE $T(z)T(w) \sim (c/2)(z-w)^{-4} + 2T(w)(z-w)^{-2} + \partial T(w)(z-w)^{-1}$.

Proof. At degree 2, the ordered bar differential acts by extracting the collision residue at the unique divisor $D_{1,2} = \{z_1 = z_2\}$ via the ordered logarithmic propagator $\eta = d \log(z_1 - z_2)$. A pole of order p in the OPE contributes a term $c_{IJ;p-1}^K (z_1 - z_2)^{-p}$ to the structure constants. The $d \log$ kernel absorbs one power of the pole (the collision residue $r(z)$ has pole orders one less than the OPE), producing a residue of order $p - 1$ in the collision variable. This residue is supported on the codimension- $(p-1)$ boundary stratum of $\overline{\text{FM}}_2^{\text{ord}}(\mathbb{C})$, hence contributes at depth $d = p - 1$. The zeroth product $a_{(0)}b$ (pole of order 1) contributes at depth $d = 0$, living in the interior.

For the Virasoro algebra: the quartic pole gives depth $d = 3$, the double pole gives depth $d = 1$, and the simple pole gives depth $d = 0$. The cubic pole is absent, so $d = 2$ does not appear. $\square$

THEOREM 22.21.20 (Ordered AOS reduction). The ordered AOS relations (the identities imposed on the bar differential $d_{\overline{B}^{\text{ch,ord}}}$ by the condition $d^2 = 0$ on $\overline{\text{FM}}_k^{\text{ord}}(\mathbb{C})$) are the Stasheff associahedron identities. Concretely: at degree k , the boundary of $\overline{\text{FM}}_k^{\text{ord}}(\mathbb{C})$ has exactly $k-1$ codimension-one faces $D_{i,i+1}$ ($1 \leq i \leq k-1$), each corresponding to the consecutive collision $z_i \rightarrow z_{i+1}$. The condition

$$d^2 = 0 \iff \sum_{\substack{1 \leq i < j \leq k-1 \\ j=i+1}} d_{i,i+1} \circ d_{j,j+1} + \sum_{i=1}^{k-1} d_{i,i+1} \circ d_{\text{int}} = 0$$

is associativity: the A_∞ Stasheff relations $\sum_{r+s+t=n} m_{r+1+t} \circ (\text{id}^{\otimes r} \otimes m_s \otimes \text{id}^{\otimes t}) = 0$.

In the unordered FM compactification, $d^2 = 0$ encodes the Jacobi identity (the Arnold relation among $\binom{k}{2}$ divisors contributes the antisymmetry). In the ordered compactification, the Arnold relation is geometrically redundant: there are no non-consecutive divisors $D_{i,j}$ with $j > i + 1$, so no three-term antisymmetry relation can form.

Proof. By Stokes' theorem on $\overline{\text{FM}}_k^{\text{ord}}(\mathbb{C})$, the condition $d^2 = 0$ is equivalent to the vanishing of the boundary integral $\int_{\partial \overline{\text{FM}}_k^{\text{ord}}} \eta = 0$ for the bar propagator form η . The boundary decomposes as

$$\partial \overline{\text{FM}}_k^{\text{ord}}(\mathbb{C}) = \bigcup_{i=1}^{k-1} D_{i,i+1},$$

a union of $k-1$ consecutive-collision divisors. Each divisor $D_{i,i+1}$ is isomorphic to $\overline{\text{FM}}_{k-1}^{\text{ord}}(\mathbb{C})$ (the two colliding points are replaced by their merged image). The boundary integral along $D_{i,i+1}$ computes the composition $d_{i,i+1} \circ d$, and the total relation $\sum_{i=1}^{k-1} d_{i,i+1} \circ d = 0$ is the k -th Stasheff identity.

In the unordered setting, $\overline{\text{FM}}_k(\mathbb{C})$ has $\binom{k}{2}$ codimension-one divisors $D_{i,j}$ for all $i < j$, and Stokes yields $\binom{k}{2}$ terms: the Jacobi/Arnold relations. The ordered restriction to $k-1$ consecutive divisors eliminates all non-adjacent collision terms. The Arnold relation $\omega_{ij} \wedge \omega_{jk} + \omega_{jk} \wedge \omega_{ki} + \omega_{ki} \wedge \omega_{ij} = 0$ cannot be stated

when ω_{ik} does not exist as a generator (the non-consecutive divisor $D_{i,k}$ is absent), so it is geometrically vacuous in the ordered compactification. $\square$

PROPOSITION 22.21.21 (*Averaging and surplus*). The averaging map $\text{av}: \overline{B}^{\text{ch,ord}}(A) \rightarrow \overline{B}^{\text{ch}}(A)$ intertwines the ordered tridegree with the symmetric bidegree via

$$\text{av}: \overline{B}^{\text{ch,ord}}(A)_{(g,n,d)} \longrightarrow \overline{B}^{\text{ch}}(A)_{(g,n,d')} \quad \text{with } d' \geq d.$$

The depth can only increase under averaging: symmetrisation may identify an ordered element supported at depth d with symmetric elements supported at deeper strata. At genus 0 and fixed degree n , the kernel $\ker(\text{av}|_{(0,n)})$ is generated by the R -matrix monodromy data of Proposition 22.4.3. For E_∞ -chiral algebras without OPE poles (the pole-free subclass), the R -matrix is the Koszul sign $R(z) = \tau$, the averaging map is the naive Σ_n -quotient, and $\ker(\text{av}) = 0$.

Proof. The averaging map is the composition $\overline{B}^{\text{ch,ord}}(A)_n \xrightarrow{\Sigma_n\text{-orbit}} \overline{B}^{\text{ch}}(A)_n$, twisted by the R -matrix as in Proposition 22.4.3: the Σ_n -action on the ordered bar uses the R -matrix monodromy $R_{i,i+1}(z_i - z_{i+1})$ at each adjacent transposition. An element α of depth d is supported on a stratum $\partial_F \overline{\text{FM}}_n^{\text{ord}}(\mathbb{C})$ of codimension d . Under symmetrisation, the orbit $\Sigma_n \cdot \alpha$ may map to strata of the unordered compactification at codimension $d' \geq d$, since the $\binom{n}{2}$ divisors of the unordered space refine the $n-1$ ordered divisors.

For the kernel: $\text{av}(\alpha) = 0$ if and only if $\sum_{\sigma \in \Sigma_n} (R \cdot \sigma) \cdot \alpha = 0$, which is precisely the condition that α lies in the R -twisted augmentation ideal of the group algebra $\mathbb{C}[\Sigma_n]$. When $R(z) = \tau$ (pole-free E_∞ case), this reduces to $\sum_{\sigma} \text{sgn}(\sigma) \cdot \sigma(\alpha) = 0$, which vanishes only for the zero element in the symmetric quotient, giving $\ker(\text{av}) = 0$. $\square$

Remark 22.21.22 (*Physical meaning: the soft graviton hierarchy*). The ordered tridegree $(g, n, d)^{E_1}$ organises the soft graviton hierarchy of the gravity part of Volume II. The correspondence is: soft order p of a graviton theorem corresponds to degree $r = p+2$ in the bar complex. The depth d records *which OPE pole is responsible*: a soft theorem at order p receives contributions from all poles whose depth $d = \max(p'-1, 0)$ satisfies $d \leq r-1$.

For the Virasoro algebra, the depth-3 component (from the quartic pole, i.e. the central charge c) is the generator of the obstruction cascade. The Stasheff identity at degree 4 propagates the depth-3 contribution to m_4 ; at degree 5 it forces m_5 ; and so on in perpetuity. The gap at depth 2 in the Virasoro spectrum (Theorem 22.21.19) is the geometric expression of the absence of a cubic pole, equivalently the vanishing of the L_n -eigenvalue at the wrong parity: $[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}m(m^2-1)\delta_{m+n,0}$ jumps from the linear term ($d=1$) to the cubic term ($d=3$) with no quadratic intermediate.

Remark 22.21.23 (*Motivic interpretation of the tridegree*). The ordered tridegree refines the motivic content identified in Remark 22.4.7. The averaging map $\text{av}: \overline{B}^{\text{ch,ord}}(A) \rightarrow \overline{B}^{\text{ch}}(A)$ is a motivic projection in the following precise sense: the ordered bar complex at depth d computes periods of the mixed Hodge structure on $\overline{\text{FM}}_n^{\text{ord}}(\mathbb{C})$ that are supported on strata of codimension d .

Concretely, the three cases are:

- (i) *Depth* $d = 0$ (interior): the periods are polynomial in $2\pi i$ and the collision residues. At degree 2, these are the rational multiples of the OPE structure constants.
- (ii) *Depth* $d \geq 1$ (boundary strata): the periods are iterated integrals of the KZ connection along paths in $\text{Conf}_n^{\text{ord}}(\mathbb{C})$. At degree 3 and depth 1, the Drinfeld associator Φ_{KZ} contributes multiple zeta values $\zeta(2), \zeta(3), \dots$, periods of mixed Tate motives over $\mathbb{Z}$.

- (iii) *The symmetric image*: the averaging map av kills all motivic content. The symmetric bar invariants (curvature κ , complementarity class C , shadow tower Q) are rational numbers, periods of the trivial motive $\mathbb{Q}(0)$.

The ordered surplus $\ker(\text{av})$ is therefore the entire mixed Tate content of the configuration-space integrals. The tridegree decomposition stratifies this content: the depth d component carries mixed Tate motives of weight $\leq d$, and the motivic weight filtration on $\ker(\text{av})$ is induced by the depth filtration on the ordered bar complex. This is the precise sense in which the ordered bar complex is arithmetically richer than the symmetric bar complex: it remembers the multiple zeta values that the symmetric projection forgets.

working at the categorical rather than algebraic level. Concretely, the Drinfeld centre $\mathcal{Z}(Y_h(\mathfrak{sl}_2)^{\text{ch-mod}})$ should recover the quantum group category $\text{Rep}_q(\mathfrak{sl}_2)$ at $q = e^{2\pi i/(k+2)}$. This identification is the subject of the DK-5 programme; see [52I, §6] for the current status in type A.

The low-degree Yangian computations and the corresponding conjectural ordered-centre bounds concern the kernel of the averaging map on the ordered chiral centre, a cohomological object. The following proposition establishes the underlying representation-theoretic input: the dimension of $\ker(\text{av}_n)$ on the bare tensor power $V^{\otimes n}$, before passing to bar-complex cohomology.

PROPOSITION 22.21.24 (*Kernel of the Reynolds projector: general simple Lie algebras*). Let $\mathfrak{g}$ be any simple Lie algebra over C , let V be any finite-dimensional representation of $\mathfrak{g}$ with $d = \dim V$, and let $\text{av}_n: V^{\otimes n} \rightarrow (V^{\otimes n})_{\Sigma_n}$ denote the Reynolds averaging map (projection onto the Σ_n -coinvariant quotient). Then

$$\dim \ker(\text{av}_n|_{V^{\otimes n}}) = d^n - \binom{n+d-1}{d-1}.$$

The formula depends only on $d = \dim V$, not on $\mathfrak{g}$ or on the $\mathfrak{g}$ -module structure of V .

Special cases. For $\mathfrak{g} = \mathfrak{sl}_2$ with the fundamental representation $V = C^2$: $\dim \ker(\text{av}_n) = 2^n - (n+1)$. For any $\mathfrak{g}$ with d -dimensional representation V , at $n = 2$: $\dim \ker(\text{av}_2) = d^2 - d(d+1)/2 = d(d-1)/2 = \dim \wedge^2 V$.

Proof. The Reynolds projector $\text{av}_n = \frac{1}{n!} \sum_{\sigma \in \Sigma_n} \sigma$ acts on $V^{\otimes n}$ by permuting tensor factors. Its image is the Σ_n -invariant subspace $\text{Sym}^n(V)$, regardless of any Lie algebra structure on V . The dimension $\dim \text{Sym}^n(V) = \binom{n+d-1}{d-1}$ (the number of degree- n monomials in d variables) depends only on $d = \dim V$, as the stars-and-bars argument uses no algebraic structure beyond the vector space. Since $\dim V^{\otimes n} = d^n$, the kernel has dimension $d^n - \binom{n+d-1}{d-1}$.

When $\mathfrak{g} = \mathfrak{gl}_r$ with $V = C^r$, Schur–Weyl duality refines this to an isotypic decomposition. The tensor power decomposes into $(\Sigma_n, \mathfrak{gl}_r)$ -bimodules:

$$V^{\otimes n} \cong \bigoplus_{\lambda \vdash n, \ell(\lambda) \leq r} S_\lambda \otimes V_\lambda(\mathfrak{gl}_r),$$

where λ runs over partitions of n with at most r rows, S_λ is the corresponding Specht module of Σ_n , and $V_\lambda(\mathfrak{gl}_r)$ is the irreducible $\mathfrak{gl}_r$ -representation of highest weight λ . The projector av_n selects the trivial isotypic component $S_{(n)} = C$ and annihilates every S_λ with $\lambda \neq (n)$. The image is

$$\text{im}(\text{av}_n) \cong S_{(n)} \otimes V_{(n)}(\mathfrak{gl}_r) = \text{Sym}^n(C^r),$$

and the kernel decomposes by isotypic components:

$$\ker(\text{av}_n) \cong \bigoplus_{\substack{\lambda \vdash n \\ \ell(\lambda) \leq r, \lambda \neq (n)}} S_\lambda \otimes V_\lambda(\mathfrak{gl}_r).$$

For a general simple $\mathfrak{g}$ acting on V , the Schur–Weyl decomposition involves the commutant algebra $\text{End}_{\mathfrak{g}}(V^{\otimes n})$ rather than the group algebra of $\text{GL}(V)$, and the individual summands carry different $\mathfrak{g}$ -representations with different dimensions. The total kernel dimension, however, depends only on $\dim \text{Sym}^n(V) = \binom{n+d-1}{d-1}$, which is determined by d alone. $\square$

Remark 22.21.25 (Explicit values and conjectural ordered-centre bounds). Table 22.2 records the kernel dimensions at low degrees for the fundamental representations of $\mathfrak{sl}_2$ through $\mathfrak{sl}_5$ (of dimensions $d = 2, 3, 4, 5$), together with the fundamental representations of $\mathfrak{so}_5$ ($d = 5$) and G_2 ($d = 7$). Since the formula depends only on $d = \dim V$, the rows for $\mathfrak{sl}_5$ and $\mathfrak{so}_5$ are identical. These are representation-theoretic upper bounds on the dimensions of the corresponding components of the ordered chiral centre in the conjectural ordered-centre kernel: $\ker(\text{av}_n)$ on the ordered chiral centre is a subquotient of $\ker(\text{av}_n|_{V^{\otimes n}})$, obtained by passing to bar-complex cohomology (only the cocycles in the non-trivial Σ_n -isotypics survive). At degree 2 for $\mathfrak{sl}_2$: the full 1-dimensional kernel $\bigwedge^2 V = \mathbb{C}$ survives in the classical Yangian computation. At degree $n \geq 3$, the kernel on the chiral centre is in general strictly smaller than the representation-theoretic bound $d^n - \binom{n+d-1}{d-1}$.

	$n = 2$	$n = 3$	$n = 4$	$n = 5$	$n = 6$
$\mathfrak{sl}_2$ ($d=2$)	1	4	11	26	57
$\mathfrak{sl}_3$ ($d=3$)	3	17	66	222	701
$\mathfrak{sl}_4$ ($d=4$)	6	44	221	968	4,012
$\mathfrak{sl}_5, \mathfrak{so}_5$ ($d=5$)	10	90	555	2,999	15,415
G_2 fund. ($d=7$)	21	259	2,191	16,345	116,725
<i>Formula</i>	$d^n - \binom{n+d-1}{d-1}$				

Table 22.2: Dimension of $\ker(\text{av}_n|_{V^{\otimes n}})$ for a d -dimensional representation V at degrees $n = 2, \dots, 6$ (Proposition 22.21.24). The formula depends only on $d = \dim V$.

22.2.2 BACKGROUND: CHIRAL ALGEBRAS AND THE E_1/E_∞ HIERARCHY

Remark 22.22.1 (The averaging kernel at genus 1: quasi-modular anomaly and Hodge curvature). Proposition 22.21.21 characterises $\ker(\text{av})$ at genus 0: it is generated by the R -matrix monodromy, carrying the full mixed Tate content of the configuration-space integrals. At genus 1, a new mechanism enters.

The genus-1 bar propagator on E_τ involves the Weierstrass $\wp$ -function and its derivatives (weight 1 after d log absorption; cf. Theorem 22.23.1). The Laurent expansion of $\wp$ near $z = 0$ generates a fan of Eisenstein corrections $G_{2k}(\tau)$, of which G_2 is distinguished: it is quasi-modular, not modular. Under $\gamma = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \text{SL}(2, \mathbb{Z})$,

$$G_2(\gamma \cdot \tau) = (c\tau + d)^2 G_2(\tau) - 2\pi i c(c\tau + d).$$

The anomalous term $-2\pi i c(c\tau + d)$ is the shadow of the Legendre relation $\eta_1 \tau - \eta_\tau = \pi i$ and is the source of the bar curvature $d^2 = \kappa(\mathcal{A}) \cdot \omega_1$ on $\overline{\mathcal{M}}_{1,n}$ (Theorem D, Remark 22.23.3).

The passage to the non-holomorphic completion $\widehat{G}_2(\tau) = G_2(\tau) - \pi/\text{Im } \tau$ restores modularity: $\widehat{G}_2$ transforms as a true weight-2 modular form. The difference $G_2 - \widehat{G}_2 = \pi/\text{Im } \tau$ is the anomaly that the symmetric bar complex absorbs into $\kappa(\mathcal{A}) \cdot \omega_1$. In the ordered bar complex, this anomaly is visible as explicit quasi-modular coefficients in the elliptic r -matrix; the averaging map av projects these coefficients to their modular completions, absorbing the anomaly into the Hodge curvature of the chiral differential.

This suggests the following structural picture for $\ker(\text{av})$ at genus 1.

- (i) *Rational component* (inherited from genus 0): the R -matrix monodromy on $\text{Conf}_n^{\text{ord}}(E_\tau)$ contributes elements to $\ker(\text{av})$ by the same mechanism as Proposition 22.21.21. These carry the elliptic multiple zeta values of Enriquez.
- (ii) *Quasi-modular component* (new at genus 1): the G_2 -anomaly terms in the ordered elliptic r -matrix are annihilated by av , since the symmetric bar complex sees only the completed $\widehat{G}_2$. The resulting kernel elements are weighted by $\kappa(\mathcal{A})$: when $\kappa(\mathcal{A}) = 0$ (uncurved, e.g. affine Kac–Moody at critical level $k = -h^\vee$), the curvature $d^2 = 0$ and the quasi-modular anomaly contributes nothing to the bar differential, so the kernel reduces to the genus-0 rational component. When $\kappa(\mathcal{A}) \neq 0$, the anomaly is nontrivial and scales linearly with $\kappa(\mathcal{A})$.
- (iii) *Interaction*: the two components are not independent. The genus-1 free energy $F_1 = \kappa(\mathcal{A})/24$ measures the leading Hodge class λ_1 on $\overline{\mathcal{M}}_{1,1}$. The $1/24$ is the residue of the η -function ($\eta(\tau) = q^{1/24} \prod_{n \geq 1} (1 - q^n)$), which is itself the square root of $1/G_2$ at leading order. The rational and quasi-modular components of $\ker(\text{av})$ are entangled through this η -function bridge: the ordered bar complex sees the full q -expansion of the propagator $E_2^*(\tau)/12$ (quasi-modular, weight 2), while the symmetric bar complex retains only the scalar $\kappa(\mathcal{A})/24$ after integration over $\overline{\mathcal{M}}_{1,1}$.

The genus-0 kernel $\ker(\text{av}|_{(0,n)})$ is a representation of the Grothendieck–Teichmüller group $\widehat{GT}$ (Remark 22.4.7). At genus 1, the conjectural extension is that $\ker(\text{av}|_{(1,n)})$ carries an action of the *elliptic* Grothendieck–Teichmüller group $\widehat{GT}^{\text{ell}}$ of Enriquez, with the quasi-modular anomaly defining the cocycle by which $\widehat{GT}^{\text{ell}}$ extends $\widehat{GT}$. The curvature $\kappa(\mathcal{A}) \cdot \omega_1$ enters as the scalar by which this cocycle acts on the chiral differential: $\widehat{GT}^{\text{ell}}$ permutes the quasi-modular completions of the elliptic associators, and the failure of the completion to commute with the $\widehat{GT}$ -action is measured by $\kappa(\mathcal{A})$.

22.23 CURVATURE–BRAIDING ENTANGLEMENT AT GENUS ONE

The dichotomy of §22.20 partitions chiral algebras according to whether curvature and braiding decouple at genus 1. The sharp form of this dichotomy isolates the mechanism that forces entanglement and identifies the central open question to which the entire annular bar theory points.

THEOREM 22.23.1 (*Elliptic spectral dichotomy, genus-1 specialisation*;). Let $\mathcal{A}$ be a logarithmic E_1 -chiral algebra with (-1) -shifted λ -bracket $\{a \lambda b\} = \sum_{n \geq 0} c_n(a, b) \lambda^n$ on $H^\bullet(\mathcal{A}, Q)$. At genus 1, the ordered r -matrix on the elliptic curve $E_\tau = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ takes the form

$$r_1(z; \tau) = c_0 \cdot \zeta(z | \tau) + \sum_{n \geq 1} \frac{(-1)^{n-1}}{n!} c_n \cdot \wp^{(n-1)}(z | \tau),$$

with $\wp^{(0)} := \wp$, where ζ and $\wp$ are the Weierstrass functions with periods $(1, \tau)$. The first two explicit terms are $c_0 \zeta + c_1 \wp$; the next is $-\frac{1}{2} c_2 \wp'$. The coefficient $c_0 = a_{(0)} b$ is the Coisson bracket (zeroth

product) and $c_1 = a_{(1)}b$ is the conformal pairing. The convention is the raw λ -bracket convention of Remark 22.20.6 (shifted by one from the d log-absorbed collision-residue convention).

The B -cycle monodromy is

$$r_1(z + \tau; \tau) - r_1(z; \tau) = 2\eta_\tau \cdot c_0, \quad (22.21)$$

with $\eta_\tau = \zeta(\frac{\tau}{2} | \tau)$ the quasi-period. The A -cycle monodromy is $2\eta_1 \cdot c_0$, where $\eta_1 = \zeta(\frac{1}{2} | \tau)$. The Legendre relation $\eta_1 \tau - \eta_\tau = \pi i$ constrains the two monodromies.

Proof. By Theorem 22.20.7, the genus-1 r -matrix is obtained from the genus-0 Laurent expansion $r(z) = \sum c_n/z^{n+1}$ by replacing each rational function $1/z^{n+1}$ with its unique elliptic counterpart on E_τ : $1/z \mapsto \zeta(z | \tau)$ for $n = 0$, and $1/z^{n+1} \mapsto \frac{(-1)^{n-1}}{n!} \wp^{(n-1)}(z | \tau)$ for $n \geq 1$, with $\wp^{(0)} := \wp$. These are uniquely determined by matching the local singularity $1/z^{n+1} + O(z)$ near $z = 0$ and requiring double periodicity for $n \geq 1$ (or quasi-periodicity for $n = 0$). The monodromy (22.21) follows from $\zeta(z + \tau | \tau) = \zeta(z | \tau) + 2\eta_\tau$ and the double periodicity of $\wp$ and all its derivatives. $\square$

Definition 22.23.2 (Decoupled vs. entangled genus-1 structure). Let $\mathcal{A}$ be a logarithmic E_1 -chiral algebra with $r_1(z; \tau)$ as in Theorem 22.23.1.

- (i) $\mathcal{A}$ is *decoupled at genus 1* if $c_0 = 0$: the Coisson bracket vanishes, r_1 is doubly periodic on E_τ , and the curvature $\kappa(\mathcal{A}) \cdot \omega_1$ and the spectral braiding are independent structures belonging to different components of the E_1 -chiral coalgebra.
- (ii) $\mathcal{A}$ is *entangled at genus 1* if $c_0 \neq 0$: r_1 is quasi-periodic with B -cycle monodromy $2\eta_\tau \cdot c_0$, and the braiding and the curvature share a common geometric source, the quasi-periodicity of the Weierstrass zeta function, which is the same mechanism that produces $\kappa(\mathcal{A}) \cdot \omega_1$ from the Hodge bundle on $\overline{\mathcal{M}}_{1,n}$.

Algebra	c_0	Status	Mechanism
Heisenberg $\mathcal{H}_k$	0	Decoupled	No simple pole; $r_1 = k \wp(z \tau)$
Free fermion ψ	0	Decoupled	$\{-_{(0)}-\} = 0$; $r_1 = \wp(z \tau)$
Lattice V_Λ (abelian)	0	Decoupled	Abelian Lie bracket
Affine $\widehat{\mathfrak{g}}_k$	$\neq 0$	Entangled	$c_0 = f^{ab}_c J^c$; KZB monodromy
Virasoro Vir_c	$\neq 0$	Entangled	$c_0 = 2T$; $r_1 = \frac{c}{2} \wp'(z) + 2T \zeta(z)$
$\mathcal{W}_N$ ($N \geq 2$)	$\neq 0$	Entangled	DS reduction inherits $c_0 \neq 0$ from $\widehat{\mathfrak{sl}}_N$

Remark 22.23.3 (The Eisenstein fan). The Laurent expansion of $\wp$ and its derivatives near $z = 0$ on E_τ takes the form

$$\wp^{(n)}(z | \tau) = \frac{(-1)^n (n+1)!}{z^{n+2}} + \sum_{k \geq 1} \frac{(2k+n+1)!}{(2k)! (n+1)!} G_{2k+n+2}(\tau) z^{2k},$$

where $G_{2k}(\tau) = \sum'_{(m,n) \in \mathbb{Z}^2} (m\tau + n)^{-2k}$ are the Eisenstein series. Each OPE pole of order $2k$ in the λ -bracket thus generates a $G_{2k}(\tau)$ correction to the elliptic r -matrix, producing a fan of modular corrections indexed by the pole spectrum.

The G_2 correction occupies a distinguished position: it is *quasi-modular*, transforming under $\mathrm{SL}(2, \mathbb{Z})$ with the anomalous shift

$$G_2(-1/\tau) = \tau^2 G_2(\tau) - 2\pi i \tau.$$

This anomaly is the shadow of the Legendre relation $\eta_1 \tau - \eta_\tau = \pi i$, and it manifests in the bar complex as the curvature $d^2 = \kappa(\mathcal{A}) \cdot \omega_1$ of the curved A_∞ -chiral structure at genus 1. More precisely: the non-holomorphic completion $\widehat{G}_2(\tau) = G_2(\tau) - \pi/\mathrm{Im} \tau$ is modular, and the passage from G_2 to $\widehat{G}_2$ is the modular gauge transformation that renders the chiral differential well-defined on $\overline{\mathcal{M}}_{1,n}$. Whether the analogous completion can be performed simultaneously on the coassociative coproduct (disentangling the braiding from the curvature when $c_0 \neq 0$) is the subject of the following question.

Question 22.23.4 (The central genus-1 frontier). Does the genus-1 coupling between the bar curvature $d^2 = \kappa(\mathcal{A}) \cdot \omega_1$ and the spectral braiding monodromy $2\eta_\tau \cdot c_0$ represent genuine entanglement of the chiral and coassociative structures, or can a modular gauge twist $r_1(z; \tau) \mapsto r_1(z; \tau) + \phi(z; \tau)$ disentangle them?

More precisely: for $\mathcal{A}$ with $c_0 \neq 0$, does there exist a doubly-periodic correction $\phi(z; \tau)$, meromorphic in z and modular in τ , such that

$$\widetilde{r}_1(z; \tau) := r_1(z; \tau) + \phi(z; \tau)$$

is doubly periodic in z and the annular bar differential d^{ann} computed from $\widetilde{r}_1$ remains a differential ($d^{\mathrm{ann}} \circ d^{\mathrm{ann}} = \kappa \cdot \omega_1$, not something worse)?

The obstruction lies in the Legendre relation. The quasi-period η_τ satisfies $\eta_1 \tau - \eta_\tau = \pi i$, which constrains the A - and B -cycle monodromies simultaneously. Any correction ϕ that kills the B -cycle monodromy $2\eta_\tau \cdot c_0$ must introduce an A -cycle defect of magnitude $2\pi i \cdot c_0/\tau$, and this defect couples to the modular parameter through the $\mathrm{SL}(2, \mathbb{Z})$ action. The question reduces to whether the resulting cocycle in $H^1(\mathrm{SL}(2, \mathbb{Z}), \mathcal{O}^{\mathrm{mer}}(E_\tau) \otimes \mathrm{End}(\mathcal{A}))$ is trivial.

For $c_0 = 0$ the answer is trivially yes: no correction is needed. For $c_0 \neq 0$, the Eisenstein fan suggests the answer is no: the G_2 quasi-modularity anomaly is intrinsic, and the entanglement between the chiral differential and the coassociative coproduct at genus 1 is a genuine feature of the theory, not a coordinate artifact. But a proof (or a counterexample at some specific algebra) remains open.

The main line of computations treats the families that drive the theory. The remaining standard families (free fields and lattice algebras) provide complementary tests.

22.24 THE $\beta\gamma$ AND bc ORDERED BAR COMPLEXES

The $\beta\gamma$ system $\mathcal{F}_{\beta\gamma}$ has generators β, γ of conformal weights $(1, 0)$ with $\beta(z) \gamma(w) \sim 1/(z-w)$. The bc ghost system $\mathcal{F}_{bc}$ has generators b, c of weights $(\lambda, 1-\lambda)$ with $b(z) c(w) \sim 1/(z-w)$. Both are E_∞ -chiral (tier (ii): vertex algebras with poles).

THEOREM 22.24.1 (Free-field ordered bar complexes;). Let $\mathcal{F}$ denote either $\mathcal{F}_{\beta\gamma}$ or $\mathcal{F}_{bc}$, with generators a, a' and OPE $a(z) a'(w) \sim 1/(z-w)$.

(a) *Collision residue.* The d log kernel absorbs the simple OPE pole leaving the nilpotent kernel

$$\Theta := a \otimes a' - a' \otimes a, \quad \Theta^2 = 0.$$

(b) *Bar differential.* Every adjacent collision inserts $a_{(0)}a' = \pm 1$, which the augmentation kills. Hence $d = 0$ in the reduced complex.

(c) *R-matrix.* The connection $\nabla = d - \Theta d(z_1 - z_2)/(z_1 - z_2)$ on $\text{Conf}_2^{\text{ord}}(\mathbb{C})$ has monodromy

$$R = \exp(2\pi i \Theta) = \text{id} + 2\pi i \Theta,$$

terminating at linear order because $\Theta^2 = 0$.

(d) *Koszul duals.* Duality exchanges statistics:

$$\mathcal{F}_{\beta\gamma}^{!,\text{ord}} \simeq \bigwedge^\bullet (s\beta^* \oplus s\gamma^*), \quad \mathcal{F}_{bc}^{!,\text{ord}} \simeq \text{Sym}^\bullet (s b^* \oplus s c^*).$$

Both are class C with shadow depth $r_{\max} = 4$ (Volume I, Theorem E.2.9), and $K(bc_\lambda) = c_{bc}(\lambda) + c_{\beta\gamma}(\lambda) = 0$.

Proof. Nilpotency: $\Theta^2 = 0$ because $a_{(0)}a' = 1$ is scalar (central), so expanding $(a \otimes a' - a' \otimes a)^2$ and using $a'_{(0)}a = -1$ gives cancellation. Bar differential: in the reduced complex every collision residue ± 1 lies in $\mathbb{C} \cdot 1$, which the augmentation kills. Monodromy: the parallel transport $T(u, u_0) = \text{id} + \Theta \log((u+x-y)/(u_0+x-y))$ terminates at linear order; the $d \log$ loop integral contributes $2\pi i$. Koszul dual: the antisymmetric $\Theta_{\beta\gamma}$ (bosonic generators) dualizes to $\wedge$; Θ_{bc} (fermionic generators) dualizes to Sym . $\square$

Remark 22.24.2 (Contrast with Heisenberg). The Heisenberg R-matrix $R(z) = \exp(k\hbar/z)$ (Theorem 22.12.3) is an infinite power series; the free-field R-matrix terminates at linear order. This dichotomy reflects the pole-order classification: double pole with scalar residue (class G) vs. simple pole with nilpotent residue (class C).

THEOREM 22.24.3 (*Wakimoto bar complex descent*;). For $\mathfrak{g}$ simple of rank r and $k \neq -h^\vee$, the Wakimoto module $\mathcal{M}_{\text{Wak}} = \bigotimes_{\alpha \in \Delta_+} (\beta\gamma)_\alpha \otimes \mathcal{H}_{\mathfrak{h}}$ satisfies

$$H^\bullet(\overline{B}^{\text{ch}}(\mathcal{M}_{\text{Wak}}, d_{\overline{B}^{\text{ch}}} + Q_{\text{DS}}) \simeq \overline{B}^{\text{ch}}(\widehat{\mathfrak{g}}_k),$$

and at the Koszul dual level, $Y_h^{\text{dg}}(\mathfrak{g}) \simeq H^\bullet(\bigotimes_\alpha \mathcal{F}_{\beta\gamma,\alpha}^{!,\text{ord}} \otimes Y(\mathfrak{u}(1))^{\otimes r}, Q_{\text{DS}}^!)$.

Proof. Q_{DS} commutes with $d_{\overline{B}^{\text{ch}}}$, so a spectral sequence with $E_1 = H^\bullet(\overline{B}^{\text{ch}}(\mathcal{M}_{\text{Wak}}, d_{\overline{B}^{\text{ch}}})$ and $d_1 = Q_{\text{DS}}$ converges to $\overline{B}^{\text{ch}}(\widehat{\mathfrak{g}}_k)$ (Volume I, Theorem E.7.1). Theorem 22.30.7 ensures Koszul duality and DS commute. $\square$

Remark 22.24.4 (The Wakimoto escalation). Shadow depth escalates through the Wakimoto chain: $\mathcal{H}_k \otimes \beta\gamma^{\otimes |\Delta_+|}$ (depths 2, 4) $\xrightarrow{Q_{\text{DS}}} \widehat{\mathfrak{g}}_k$ (depth 3) $\xrightarrow{Q_{\text{DS}}} \text{Vir}_c$ (depth ∞). The second reduction manufactures the quartic pole via Sugawara, escalating from class L to class M.

22.25 LATTICE VERTEX ALGEBRAS

Let Λ be an even lattice of rank d with bilinear form $\langle \cdot, \cdot \rangle$ and let $\varepsilon: \Lambda \times \Lambda \rightarrow \mathbb{C}^\times$ be a normalized bimultiplicative 2-cocycle. The lattice vertex algebra V_Λ^ε has vertex operators $Y(e^\alpha, z)$ for $\alpha \in \Lambda$ with OPE

$$Y(e^\alpha, z)Y(e^\beta, w) \sim \varepsilon(\alpha, \beta)(z-w)^{\langle \alpha, \beta \rangle} Y(e^{\alpha+\beta}, w) + \cdots \quad (22.22)$$

The E_1/E_∞ character of V_Λ^ε depends on the symmetry of the cocycle, as established in §B.11 of the lattice foundations chapter.

System	R -matrix	Depth	Class	$A_{\text{line}}^{\text{l,ord}}$	E_{∞}
$\mathcal{H}_k$	$e^{k\hbar/z}$ (scalar)	2	G	$\mathbb{C}[h_0, h_1, \dots]$	✓
$\beta\gamma$	$\text{id} + 2\pi i \Theta$ (nilpotent)	4	C	$\wedge^*(\beta^*, \gamma^*)$	✓
bc	$\text{id} + 2\pi i \Theta_{bc}$ (nilpotent)	4	C	$\text{Sym}^*(b^*, c^*)$	✓
$\widehat{\mathfrak{g}}_k$	$\exp(\hbar \Omega/z)$	3	L	$Y_{\hbar}(\mathfrak{g})$	✓
Vir_c	[triple pole]	∞	M	$Y^{\text{dg}}(\text{Vir})$	✓

Table 22.3: Ordered bar complex data for the standard families. All entries are E_{∞} -chiral; the R -matrix is derived from the local OPE in every case.

22.25.0.1 Symmetric cocycle: E_{∞} -chiral

THEOREM 22.25.1 (*Ordered bar complex with symmetric cocycle;*). Let ε be a symmetric cocycle satisfying the Borchers symmetry $\varepsilon(\alpha, \beta) = (-1)^{\langle \alpha, \beta \rangle} \varepsilon(\beta, \alpha)$. Then $V_{\Lambda}^{\varepsilon}$ is E_{∞} -chiral, and the ordered bar complex $\overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon})$ has:

- (1) **Collision residue.** The collision residue kernel on the diagonal α -sector is:

$$r(z) = \frac{1}{z} \sum_{\alpha \in \Lambda} \langle \alpha, \alpha \rangle (e^{\alpha} \otimes e^{-\alpha}). \quad (22.23)$$

This is the *diagonal* residue: only the Heisenberg-type contributions $\alpha \otimes (-\alpha)$ survive, weighted by the norm $\langle \alpha, \alpha \rangle$.

- (2) **R-matrix.** Since ε is symmetric, the R -matrix is determined by the local OPE (tier (ii) of the three-tier picture). The ordered-to-unordered descent $\overline{B}^{\text{ch}} \rightarrow \overline{\mathbf{B}}$ is the R -matrix-twisted Σ_n -quotient, with twist $R(z)$ derived from the OPE monodromy:

$$R_{\alpha, \beta}(z) = (-1)^{\langle \alpha, \beta \rangle} e^{\pi i \langle \alpha, \beta \rangle},$$

the standard lattice braiding phase. This is *not* independent input: it is the monodromy of the flat connection on $\text{Conf}_2(\mathbb{C})$ determined by the OPE poles, confirming the E_{∞} character.

Proof. The OPE $Y(e^{\alpha}, z) Y(e^{\beta}, w) \sim \varepsilon(\alpha, \beta)(z-w)^{\langle \alpha, \beta \rangle} Y(e^{\alpha+\beta}, w) + \dots$ has a pole of order $-\langle \alpha, \beta \rangle$ at $z = w$. After $d \log$ absorption, the collision residue extracts the order-1 coefficient: $\text{Res}_{z=w} [(z-w)^{-m} d \log(z-w)] = \delta_{m,1}$. For the diagonal sector $\beta = -\alpha$, the pole order is $-\langle \alpha, -\alpha \rangle = \langle \alpha, \alpha \rangle$, which is always even for an even lattice. The non-diagonal residue at order 1 gives (22.23).

For the R -matrix: the connection is $\nabla = d - r(z) d(z_1 - z_2)$, and the monodromy around $z_1 = z_2$ is $\exp(2\pi i \cdot r)$. On the lattice sector (e^{α}, e^{β}) , this is $(-1)^{\langle \alpha, \beta \rangle} e^{\pi i \langle \alpha, \beta \rangle}$, matching the standard lattice braiding. The Borchers symmetry of ε ensures this monodromy is *derived from* the local OPE, confirming E_{∞} . $\square$

22.25.0.2 Non-symmetric cocycle: genuinely E_1 -chiral

THEOREM 22.25.2 (*Ordered bar complex with non-symmetric cocycle;*). Let ε be a non-symmetric cocycle: there exist $\alpha, \beta \in \Lambda$ with $\varepsilon(\alpha, \beta)/\varepsilon(\beta, \alpha) \neq (-1)^{\langle \alpha, \beta \rangle}$. Then V_Λ^ε is genuinely E_1 -chiral (nonlocal), and the ordered bar complex $\overline{B}^{\text{ch}}(V_\Lambda^\varepsilon)$ has:

- (1) **Differential.** In bar degree 2:

$$d([e^{\alpha_1} \mid e^{\alpha_2}]) = \varepsilon(\alpha_1, \alpha_2) \delta_{\langle \alpha_1, \alpha_2 \rangle, -1} [e^{\alpha_1 + \alpha_2}].$$

The cocycle $\varepsilon(\alpha_1, \alpha_2)$ appears with its value at the *specific ordered pair* (α_1, α_2) . For a non-symmetric cocycle, the coefficients $\varepsilon(\alpha, \beta) \neq (-1)^{\langle \alpha, \beta \rangle} \varepsilon(\beta, \alpha)$, so permuting the pair changes the differential. No Σ_2 -quotient is possible.

- (2) **R-matrix as independent input.** The R-matrix $R_{\alpha, \beta}$ is part of the defining data of the E_1 -chiral algebra, not derivable from a local OPE. The ratio

$$\frac{\varepsilon(\alpha, \beta)}{\varepsilon(\beta, \alpha)}$$

measures the asymmetry of the cocycle and enters the R-matrix directly. When this ratio is not $(-1)^{\langle \alpha, \beta \rangle}$, the braiding is genuinely nonlocal: it cannot be obtained as the monodromy of any connection on $\text{Conf}_2(\mathbb{C})$ determined by a local OPE. This is tier (iii) of the three-tier picture.

Proof. The differential follows from the lattice OPE (22.22) and the ordered bar construction: adjacent collisions in the ordered bar complex use the d log kernel, selecting simple poles $(\langle \alpha_i, \alpha_{i+1} \rangle = -1)$ with coefficient $\varepsilon(\alpha_i, \alpha_{i+1})$ at the specific ordered pair.

For the R-matrix claim: the Borchers symmetry $\varepsilon(\alpha, \beta) = (-1)^{\langle \alpha, \beta \rangle} \varepsilon(\beta, \alpha)$ is precisely the condition for the Σ_2 -action on the ordered bar complex to be compatible with the differential. When this fails, the descent $\overline{B}^{\text{ch}} \rightarrow \overline{B}$ requires independent braiding data, and the algebra is genuinely E_1 . $\square$

22.25.0.3 Koszul dual of lattice algebras

THEOREM 22.25.3 (*Ordered Koszul dual of lattice algebras;*). The ordered Koszul dual of V_Λ^ε depends on the lattice:

- (i) For a self-dual even lattice $\Lambda = \Lambda^*$ with symmetric cocycle, the Koszul dual $(V_\Lambda^\varepsilon)^\dagger$ is again a lattice vertex algebra $(V_\Lambda^{\varepsilon^{-1}})^c$ with inverse cocycle (Theorem B.6.2).
- (ii) For a non-self-dual lattice or non-symmetric cocycle, the ordered Koszul dual carries strictly more structure: the ordered bar complex has independent generators in each ordering, and the dual algebra reflects this asymmetry.
- (iii) In all cases, the lattice grading is preserved: the Koszul dual decomposes as $\bigoplus_{\gamma \in \Lambda} (V_\Lambda^\varepsilon)_\gamma^\dagger$ with the differential preserving total lattice degree.

Proof. Part (i) follows from Theorem B.6.2 and its proof: the bar complex coproduct has structure constants $\varepsilon(\alpha, \beta)^{-1}$, and linear duality recovers the lattice algebra with inverse cocycle. Self-duality $\Lambda = \Lambda^*$ ensures the dual lives on the same lattice.

Part (ii): for a non-symmetric cocycle, the ordered bar complex in degree 2 has generators $[e^\alpha \mid e^\beta]$ and $[e^\beta \mid e^\alpha]$ that are *independent* (no Σ_2 -identification). Their duals generate the Koszul dual algebra with product reflecting the asymmetric cocycle values.

Part (iii): the bar differential preserves the total lattice degree $\gamma = \sum_i \alpha_i \in \Lambda$ (Theorem B.5.2(i)), so the Koszul dual inherits the same decomposition. $\square$

Remark 22.25.4 (The three-tier picture for lattice algebras). Lattice vertex algebras provide the cleanest illustration of the three-tier picture:

- (i) *Pole-free commutative* ($R = \tau$): degenerate case where $\langle \alpha, \beta \rangle = 0$ for all α, β (the lattice is trivial or the restriction to a sublattice with vanishing pairing).
- (ii) E_∞ *with poles* ($R \neq \tau$, derived from locality): symmetric cocycle, OPE with poles from $\langle \alpha, \beta \rangle < 0$. The R-matrix is the standard lattice braiding, determined by the OPE monodromy.
- (iii) *Genuinely* E_1 ($R \neq \tau$, independent input): non-symmetric cocycle. The R-matrix is part of the defining data. The descent from ordered to unordered configurations requires this independent braiding datum.

The lattice family thus realizes all three tiers explicitly, with the cocycle symmetry as the single discrete parameter controlling the E_∞/E_1 transition.

22.26 EVALUATION MODULES AND THE LINE CATEGORY

The ordered bar complex and the Yangian $Y_h(\mathfrak{g})$ classify the line operators of the corresponding holomorphic-topological theory. This section develops the representation-theoretic side: evaluation modules, the Drinfeld polynomial classification, tensor products and their braiding, and the identification of the resulting module category with the line category $\mathcal{C}_{\text{line}}$.

Throughout, $\mathfrak{g}$ denotes a finite-dimensional simple Lie algebra over $\mathbb{C}$ of rank r , with Cartan matrix (a_{ij}) , simple roots $\alpha_1, \dots, \alpha_r$, fundamental weights $\omega_1, \dots, \omega_r$, and normalised Killing form $(\cdot, \cdot)$ for which $(\alpha, \alpha) = 2$ for long roots. We write $\Omega \in \mathfrak{g} \otimes \mathfrak{g}$ for the quadratic Casimir element and $P \in \text{End}(V \otimes W)$ for the permutation operator $v \otimes w \mapsto w \otimes v$.

22.26.1 THE YANGIAN $Y_h(\mathfrak{g})$ AND THE EVALUATION HOMOMORPHISM

Definition 22.26.1 (Drinfeld Yangian). The Yangian $Y_h(\mathfrak{g})$ is the associative $\mathbb{C}[[\hbar]]$ -algebra generated by $\{J_0^a, J_1^a \mid a = 1, \dots, \dim \mathfrak{g}\}$ subject to:

- (i) J_0^a generate a copy of $U(\mathfrak{g})$;
- (ii) $[J_0^a, J_1^b] = f^{ab}{}_c J_1^c$;
- (iii) Drinfeld's ternary relation: $[J_1^a, [J_0^b, J_1^c]] - [J_0^a, [J_1^b, J_1^c]] = \hbar^2 A_{def}^{abc} \{J_0^d, J_0^e, J_0^f\}$, where A_{def}^{abc} is the totally symmetric tensor of [471] and $\{x, y, z\} = \frac{1}{24} \sum_{\sigma \in S_3} x_{\sigma(1)} y_{\sigma(2)} z_{\sigma(3)}$.

The coproduct is $\Delta(J_0^a) = J_0^a \otimes 1 + 1 \otimes J_0^a$, $\Delta(J_1^a) = J_1^a \otimes 1 + 1 \otimes J_1^a + \frac{\hbar}{2} f^a{}_{bc} J_0^b \otimes J_0^c$.

Construction 22.26.2 (Evaluation homomorphism). For each $a \in \mathbb{C}$, there is a surjective algebra homomorphism

$$\text{ev}_a: Y_{\hbar}(\mathfrak{g}) \longrightarrow U(\mathfrak{g}), \quad J_0^a \mapsto J^a, \quad J_1^a \mapsto a J^a.$$

The evaluation map is an algebra homomorphism because $[J^a, a J^b] = a f^{ab}_c J^c = a f^{ab}_c J_0^c$, and the ternary relation reduces to the Jacobi identity in $U(\mathfrak{g})$.

Definition 22.26.3 (Evaluation module). Let (ρ, V) be a finite-dimensional $\mathfrak{g}$ -representation and $a \in \mathbb{C}$. The *evaluation module* V_a is the $Y_{\hbar}(\mathfrak{g})$ -module obtained by pulling back along ev_a :

$$V_a := \text{ev}_a^*(V).$$

Concretely, $V_a = V$ as a vector space, with

$$T^a(u) \cdot v = v + \frac{\hbar \rho(\Omega_{(1)}) \otimes \Omega_{(2)}}{u - a} \cdot v = v + \frac{\hbar}{u - a} \sum_{\alpha} \rho(J^{\alpha}) v \otimes J_{\alpha}, \quad (22.24)$$

where $\Omega = \sum_{\alpha} J^{\alpha} \otimes J_{\alpha}$ is the Casimir tensor and the transfer matrix $T(u) = 1 + \hbar \sum_{n \geq 0} J_n u^{-n-1}$.

22.26.2 EXPLICIT EVALUATION MODULES FOR $\mathfrak{sl}_2$

COMPUTATION 22.26.4 ($\mathfrak{sl}_2$ evaluation module;). Let $\mathfrak{g} = \mathfrak{sl}_2$ with standard basis e, f, h and $[h, e] = 2e$, $[h, f] = -2f$, $[e, f] = h$. The fundamental representation is $V = \mathbb{C}^2$ with basis v_+, v_- and

$$\rho(e) = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad \rho(f) = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \quad \rho(h) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

The Casimir tensor is $\Omega = \frac{1}{2} h \otimes h + e \otimes f + f \otimes e$, so $\rho(\Omega) \in \text{End}(\mathbb{C}^2)$ is $\rho(\Omega) = \frac{1}{2} C_2(\text{fund}) \cdot \text{id} = \frac{3}{4} \cdot \text{id}$ (half the quadratic Casimir eigenvalue).

The evaluation module $V_a = \mathbb{C}^2$ has

$$J_0^a \cdot v_{\pm} = \rho(J^a) v_{\pm}, \quad J_1^a \cdot v_{\pm} = a \rho(J^a) v_{\pm}.$$

The transfer matrix in the fundamental representation is

$$T(u) = \text{id}_2 + \frac{\hbar}{u - a} \begin{pmatrix} \frac{1}{2}h & f \\ e & -\frac{1}{2}h \end{pmatrix}, \quad (22.25)$$

where the matrix entries are $\mathfrak{sl}_2$ -generators acting via ρ in the quantum space and via the fundamental in the auxiliary space.

Proof. The evaluation homomorphism sends each Yangian generator to its $\mathfrak{sl}_2$ -action scaled by the spectral parameter, so the displayed formulas for J_0 and J_1 are immediate from $J_n^a \mapsto a^n \rho(J^a)$. With the chosen matrices,

$$\rho(\Omega) = \frac{1}{2} \rho(h)^2 + \rho(e)\rho(f) + \rho(f)\rho(e) = \frac{3}{4} \text{id}_{\mathbb{C}^2},$$

which is the stated fundamental Casimir value. Substituting this into the general transfer-matrix formula (22.24) yields (22.25). $\square$

THEOREM 22.26.5 (*R-matrix on $V_a \otimes V_b$ for $\mathfrak{sl}_2$* ;). The R -matrix governing the braiding of $V_a \otimes V_b$ is

$$R(a - b) = (a - b) \text{id} + \hbar P \in \text{End}(\mathbb{C}^2 \otimes \mathbb{C}^2), \quad (22.26)$$

where P is the permutation operator $v \otimes w \mapsto w \otimes v$. Equivalently, in the normalised form $\check{R}(u) = P R(u)$:

$$\check{R}(u) = u P + \hbar \text{id}.$$

This is the Yang R -matrix.

Proof. The intertwining equation $\Delta^{\text{op}}(x) R = R \Delta(x)$ for all $x \in Y_{\hbar}(\mathfrak{sl}_2)$, evaluated on $V_a \otimes V_b$, uniquely determines R up to scalar. For $x = J_0^a$: $[\rho^{(1)}(J^a) + \rho^{(2)}(J^a), R] = 0$, so R commutes with the diagonal $\mathfrak{sl}_2$ -action. By Schur's lemma applied to the decomposition $\mathbb{C}^2 \otimes \mathbb{C}^2 = \text{Sym}^2 \oplus \wedge^2$, $R = \alpha \Pi_{\text{sym}} + \beta \Pi_{\text{alt}}$ for scalars α, β . Writing $\Pi_{\text{sym}} = \frac{1}{2}(\text{id} + P)$ and $\Pi_{\text{alt}} = \frac{1}{2}(\text{id} - P)$:

$$R = \frac{\alpha+\beta}{2} \text{id} + \frac{\alpha-\beta}{2} P.$$

Evaluating the intertwining equation for $x = J_1^a$ with $\Delta(J_1^a) = J_1^a \otimes 1 + 1 \otimes J_1^a + \frac{\hbar}{2} f^a_{bc} J_0^b \otimes J_0^c$ yields $\alpha - \beta = \hbar$ and $\alpha + \beta = a - b$. Hence $R = (a - b) \text{id} + \hbar P$. $\square$

COROLLARY 22.26.6 (*Clebsch–Gordan decomposition and non-semisimplicity*;). The tensor product $V_a \otimes V_b$ of fundamental $\mathfrak{sl}_2$ -evaluation modules is:

- (a) **Semisimple** when $a - b \notin \{0, \pm\hbar\}$: the R -matrix (22.26) is invertible, and $V_a \otimes V_b \simeq W_{3,a+b} \oplus W_{1,a+b}$, where $W_{d,c}$ denotes the evaluation module of dimension d at the averaged spectral parameter.
- (b) **Non-semisimple** when $a - b = \pm\hbar$: $R(a - b) = \pm\hbar \text{id} + \hbar P$ is not scalar but remains invertible. The tensor product is reducible but indecomposable: $V_a \otimes V_b$ has a two-step filtration with Jordan–Hölder factors W_3 and W_1 , but the extension does not split.
- (c) **Singular** when $a = b$: $R(0) = \hbar P$ has eigenvalues $\pm\hbar$, and the tensor product $V_a \otimes V_a$ degenerates: the braiding becomes the graded permutation, and the intertwiner is no longer generic. The image of the bar complex at this point reflects the coalescence singularity of the ordered configuration space.

Proof. The eigenvalues of $R(u) = u \text{id} + \hbar P$ on the Sym^2 and $\wedge^2$ summands are $u + \hbar$ and $u - \hbar$, respectively. Part (a): when $u = a - b \neq 0, \pm\hbar$, both eigenvalues are nonzero and the corresponding projectors split the tensor product. Part (b): when $u = \pm\hbar$, one eigenvalue is $2\hbar$ or 0 and the other is 0 or $-2\hbar$; the zero eigenvalue signals a non-split extension. Part (c) is $u = 0$. $\square$

22.26.3 EVALUATION MODULES FOR $\mathfrak{sl}_3$

COMPUTATION 22.26.7 (*$\mathfrak{sl}_3$ fundamental evaluation module*;). Let $\mathfrak{g} = \mathfrak{sl}_3$ with standard Chevalley generators e_i, f_i, h_i ($i = 1, 2$). The fundamental representation $V = \mathbb{C}^3$ has basis v_1, v_2, v_3 with weight vectors of weights $\omega_1, \omega_1 - \alpha_1, \omega_1 - \alpha_1 - \alpha_2$. The evaluation module $V_a = \mathbb{C}^3$ has

$$J_0^{e_i} = E_i, \quad J_0^{f_i} = F_i, \quad J_0^{h_i} = H_i, \quad J_1^{e_i} = a E_i, \quad J_1^{f_i} = a F_i, \quad J_1^{h_i} = a H_i,$$

where E_i, F_i, H_i are the standard 3×3 matrices representing e_i, f_i, h_i .

The R -matrix on $V_a \otimes V_b$ in the fundamental takes the universal Yang form:

$$R(u) = u \operatorname{id} + \hbar P \in \operatorname{End}(\mathbb{C}^3 \otimes \mathbb{C}^3),$$

where $u = a - b$. Under $\mathfrak{sl}_3$, $\mathbb{C}^3 \otimes \mathbb{C}^3 \simeq \operatorname{Sym}^2(\mathbb{C}^3) \oplus \wedge^2(\mathbb{C}^3)$ (dimensions $6 + 3$), and the eigenvalues of $R(u)$ are $u + \hbar$ on Sym^2 and $u - \hbar$ on $\wedge^2$, exactly as for $\mathfrak{sl}_2$.

Proof. Applying the evaluation map to the defining representation of $\mathfrak{sl}_3$ gives the displayed formulas for the level-0 and level-1 generators. The decomposition $\mathbb{C}^3 \otimes \mathbb{C}^3 = \operatorname{Sym}^2(\mathbb{C}^3) \oplus \wedge^2(\mathbb{C}^3)$ is the standard $\mathfrak{sl}_3$ tensor-product splitting. Theorem 22.27.2 gives $R(u) = u \operatorname{id} + \hbar P$ on the fundamental tensor square. Since P acts by $+1$ on the symmetric summand and by -1 on the alternating summand, the two eigenvalues are $u + \hbar$ and $u - \hbar$. $\square$

COMPUTATION 22.26.8 (*$\mathfrak{sl}_3$ adjoint evaluation module;*). The adjoint representation $W = \mathfrak{sl}_3$ has $\dim W = 8$. The evaluation module W_a is the pullback of the adjoint $\mathfrak{sl}_3$ -module along ev_a . Since $\mathbb{C}^3 \otimes (\mathbb{C}^3)^* \simeq \mathfrak{sl}_3 \oplus \mathbb{C}$, one has

$$W_a \simeq (V_a \otimes V_a^*)/\mathbb{C},$$

where V_a^* is the contragredient evaluation module at the same spectral parameter. The R -matrix on $V_a \otimes W_b$ (fundamental $\otimes$ adjoint) is determined by the Yangian intertwining equation and decomposes into three eigenvalues on the three $\mathfrak{sl}_3$ -irreducible summands of $\mathbb{C}^3 \otimes \mathfrak{sl}_3$:

$$\mathbb{C}^3 \otimes \mathfrak{sl}_3 \simeq V(2\omega_1 + \omega_2) \oplus V(\omega_1) \oplus V(\omega_2),$$

with eigenvalues $u + 2\hbar$, $u - \hbar$, $u + \hbar$ respectively, where $u = a - b$.

Proof. The identification $W_a \simeq (V_a \otimes V_a^*)/\mathbb{C}$ is the usual realization of the adjoint representation as the traceless part of $\operatorname{End}(\mathbb{C}^3)$, transported through the evaluation map. The tensor-product decomposition $\mathbb{C}^3 \otimes \mathfrak{sl}_3 \cong V(2\omega_1 + \omega_2) \oplus V(\omega_1) \oplus V(\omega_2)$ is the standard Littlewood–Richardson decomposition $\mathbf{3} \otimes \mathbf{8} = \mathbf{15} \oplus \mathbf{3} \oplus \mathbf{6}^*$. Proposition 22.27.1 implies that the Yangian R -matrix acts by scalars on these three irreducible summands. Using the fusion realization of W_a from the fundamental and dual fundamental evaluation modules, those scalars are fixed by the fundamental Yang R -matrix of Computation 22.26.7; the three channels pick up the shifts $+2\hbar$, $-\hbar$, and $+\hbar$, which gives the stated eigenvalues. $\square$

22.26.4 DRINFELD POLYNOMIALS AND THE CLASSIFICATION OF FINITE-DIMENSIONAL MODULES

THEOREM 22.26.9 (*Drinfeld classification;*). For $\mathfrak{g}$ a finite-dimensional simple Lie algebra of rank r , the isomorphism classes of irreducible finite-dimensional $Y_\hbar(\mathfrak{g})$ -modules are in bijection with r -tuples of monic polynomials $(P_1(u), \dots, P_r(u)) \in \mathbb{C}[u]^r$, called the *Drinfeld polynomials*.

The bijection sends an irreducible module L to the r -tuple where $P_i(u)$ records the eigenvalues of the level-1 generating series associated to the i -th simple root on a highest-weight vector of L :

$$T_i(u) \cdot v_+ = \frac{P_i(u - \hbar)}{P_i(u)} v_+.$$

PROPOSITION 22.26.10 (*Evaluation modules as single-root Drinfeld polynomials;*). Let $V(\omega_i)$ be the i -th fundamental representation of $\mathfrak{g}$ and $a \in \mathbb{C}$. The evaluation module $V(\omega_i)_a$ has Drinfeld polynomials

$$P_j(u) = \begin{cases} u - a & \text{if } j = i, \\ 1 & \text{if } j \neq i. \end{cases}$$

More generally, the evaluation of an irreducible $\mathfrak{g}$ -module $V(\lambda)$ with highest weight $\lambda = \sum_i m_i \omega_i$ at points $a_1, \dots, a_N \in \mathbb{C}$ produces the tensor product evaluation module $V(\lambda_1)_{a_1} \otimes \dots \otimes V(\lambda_N)_{a_N}$, whose Drinfeld polynomials are

$$P_j(u) = \prod_{k=1}^N (u - a_k)^{m_j^{(k)}},$$

where $m_j^{(k)}$ is the multiplicity of ω_j in λ_k .

Proof. By definition, ev_a sends $J_1^a \mapsto a J^a$, so the generating series $T_i(u)$ acts on the highest-weight vector v_+ of $V(\omega_i)_a$ as a rational function of u . In the normalisation where $P_i(u) = u - a$, one obtains $T_i(u) \cdot v_+ = (u - a - \hbar)/(u - a) \cdot v_+$ and $T_j(u) \cdot v_+ = v_+$ for $j \neq i$, matching the classification. The general formula follows from the tensor product rule for Drinfeld polynomials: the P_j of a tensor product is the product of the P_j 's of the factors. $\square$

Example 22.26.11 (Drinfeld polynomials for evaluation chains). For $\mathfrak{g} = \mathfrak{sl}_2$, rank $r = 1$, and an evaluation chain at points $a_1, \dots, a_n \in \mathbb{C}$ in the fundamental representation:

$$P(u) = \prod_{k=1}^n (u - a_k).$$

The module $V_{a_1} \otimes \dots \otimes V_{a_n}$ is irreducible if and only if $a_i - a_j \notin \mathbb{Z}\hbar$ for all $i \neq j$ (the non-resonance condition). When $a_i - a_j \in \mathbb{Z}\hbar$ for some pair, the tensor product is reducible and the irreducible subquotients are classified by combinatorial data (segments in the sense of Zelevinsky).

22.26.5 THE LINE CATEGORY

The line operators of a holomorphic-topological theory on $\mathbb{C}_z \times \mathbb{R}_t$ are operators supported on lines $\{z = z_0\} \times \mathbb{R}_t$. These form a category $\mathcal{C}_{\text{line}}$, and the ordered bar complex identifies it with the module category of the E_1 -chiral Koszul dual.

THEOREM 22.26.12 (Line category as Yangian modules;). Let A be a strongly admissible E_1 -chiral algebra with ordered bar coalgebra $C = \overline{B}^{\text{ch,ord}}(A)$ and E_1 -chiral Koszul dual $A_{\text{line}}^!$. Then:

- (i) The line category is

$$\mathcal{C}_{\text{line}} \simeq A_{\text{line}}^! \text{-mod}^{\text{fd}},$$

the category of finite-dimensional modules over the E_1 -chiral Koszul dual.

- (ii) On the chirally Koszul locus (where the bar-cobar equivalence holds and $A_{\text{line}}^!$ is formal), for A in the affine lineage (i.e., $A = \hat{\mathfrak{g}}_k$ for simple $\mathfrak{g}$ at non-critical level),

$$A_{\text{line}}^! \simeq Y_{\hbar}(\mathfrak{g})$$

and accordingly

$$\mathcal{C}_{\text{line}} \simeq Y_{\hbar}(\mathfrak{g}) \text{-mod}^{\text{fd}}.$$

- (iii) The evaluation modules V_a of Definition 22.26.3 are the line operators obtained by inserting a Wilson line in representation V at position $z = a$. The spectral parameter a is the holomorphic position on $\mathbb{C}_z$.

Proof. Part (i) is the content of the one-sided module/comodule duality (Hypothesis 22.2.3(I)) combined with the ordered bar–cobar equivalence: left C -comodules are equivalently right $A_{\text{line}}^!$ -modules. Part (ii) follows from the identification of $A_{\text{line}}^!$ with the dg-shifted Yangian (proved in Volume II, Theorem K.7.1). Part (iii) is the physical interpretation: a Wilson line in representation ρ at position $z = a$ defines a line operator whose endomorphism algebra is $\text{ev}_a^* \rho$, and the intertwining between different Wilson lines is governed by the R -matrix. $\square$

22.26.6 TENSOR PRODUCTS AND THE BRAIDED MONOIDAL STRUCTURE

THEOREM 22.26.13 (*Braiding from the R -matrix;*). The tensor product of evaluation modules $V_a \otimes W_b$, with V, W finite-dimensional $\mathfrak{g}$ -representations, is a $Y_h(\mathfrak{g})$ -module via the coproduct Δ . The braiding isomorphism

$$\sigma_{V_a, W_b} : V_a \otimes W_b \xrightarrow{\sim} W_b \otimes V_a$$

is given by $\sigma_{V_a, W_b} = P \circ R_{V, W}(a - b)$, where $R_{V, W}(u) \in \text{End}(V \otimes W)((u^{-1}))$ is the universal R -matrix of $Y_h(\mathfrak{g})$ evaluated in $V \otimes W$.

When $a = b$, the R -matrix $R_{V, W}(0)$ degenerates: its kernel is nontrivial whenever $V \otimes W$ is not multiplicity-free. This singularity reflects the coalescence of two line operators at the same point, corresponding to the boundary stratum $z_1 = z_2$ in $\overline{\text{FM}}_2^{\text{ord}}(\mathbb{C})$.

Proof. The coproduct Δ of $Y_h(\mathfrak{g})$ defines the tensor product module structure. The universal R -matrix satisfies the intertwining equation $\Delta^{\text{op}}(x) R = R \Delta(x)$, which means $R_{V, W}(a - b)$ intertwines the two orderings of the tensor product. The braiding axioms (Yang–Baxter equation) follow from the quantum group structure. The coalescence statement follows from the fact that $R_{V, W}(u)$ has a pole at $u = 0$ of order determined by the Casimir eigenvalue in the tensor product, and the bar differential at the boundary stratum $\partial \overline{\text{FM}}_2$ imposes exactly the residue of this pole. $\square$

22.26.7 THE GROTHENDIECK RING

THEOREM 22.26.14 (*Grothendieck ring of Yangian modules;*). The Grothendieck ring of finite-dimensional $Y_h(\mathfrak{g})$ -modules is

$$K_0(Y_h(\mathfrak{g})\text{-mod}^{\text{fd}}) \simeq K_0(\text{Rep}(\mathfrak{g}))[u],$$

the polynomial extension of the representation ring of $\mathfrak{g}$. The isomorphism sends the class of $V(\lambda)_a$ to $[V(\lambda)] \cdot u^{\deg P_\lambda}$, and the product is the convolution of Drinfeld polynomials.

Remark 22.26.15 (*Generators of the Grothendieck ring*). The Grothendieck ring is generated as a $\mathbb{Z}[u]$ -algebra by the classes $[V(\omega_i)_a]$ ($i = 1, \dots, r, a \in \mathbb{C}$). The Drinfeld polynomial classification (Theorem 22.26.9) establishes the bijection between irreducible classes and r -tuples of monic polynomials. The ring structure reflects the fact that the tensor product of evaluation modules, while not generically irreducible as a $Y_h(\mathfrak{g})$ -module, becomes irreducible in the Grothendieck group.

Remark 22.26.16 (*Relation to the open trace formalism*). The ordered open trace formalism of Theorem 22.9.5 acquires concrete content on the Yangian locus. The diagonal bicomodule C_Δ parametrises the identity line operator; evaluation modules V_a are line operators at position a ; the interval composition $\square_C^{\mathbb{R}}$ is the sequential fusion of line operators along $\mathbb{R}_t$; and the ordered pair-of-pants μ_P is the OPE of line operators at the same holomorphic position. The Grothendieck ring K_0 of the line category is the natural receptacle for the decategorified open trace.

22.27 EXPLICIT R -MATRICES FOR THE STANDARD FAMILIES

The R -matrix is the monodromy of the Kohno connection $\nabla = d - \sum_{i < j} r_{ij}(z_{ij}) dz_{ij}$. For the Yangian $Y(\mathfrak{g})$ of a simple Lie algebra, the rational R -matrix on $V = \mathbb{C}^N$ takes a closed form: the Yang R -matrix for type A , and the Zamolodchikov–Zamolodchikov R -matrix for types B, C, D , and the exceptionals. In every case, the classical limit recovers $r(u) = \Omega/u$ with $\Omega = \sum_a I^a \otimes I_a$ the Casimir tensor. All R -matrices below are derived from the local OPE via Construction 22.4.2; they are *not* independent input.

PROPOSITION 22.27.1 (*Eigenvalue decomposition*;). Let $V \otimes V = \bigoplus_{\lambda} V_{\lambda}$ be the $\mathfrak{g}$ -irreducible decomposition. Then $R(u)|_{V_{\lambda}} = f_{\lambda}(u) \cdot \text{id}_{V_{\lambda}}$ with $f_{\lambda}(u)$ rational, $f_{\lambda}(u) \sim u$ as $u \rightarrow \infty$. For type A , f_{λ} is linear; for types $B/C/D$ and the exceptionals, additional primitive invariants introduce rational corrections.

Proof. The universal R -matrix intertwines the diagonal $\mathfrak{g}$ -action on $V \otimes V$, so each irreducible summand V_{λ} is $R(u)$ -stable. Schur's lemma therefore implies that the restriction of $R(u)$ to V_{λ} is scalar, say $f_{\lambda}(u) \cdot \text{id}_{V_{\lambda}}$. The rationality of f_{λ} comes from the RTT presentation of the Yangian, where $R(u)$ is a rational function of the spectral parameter, and the normalization of the universal R -matrix gives $R(u) = u \text{id} + O(1)$ as $u \rightarrow \infty$, hence $f_{\lambda}(u) \sim u$. For type A , only the permutation operator appears, so the eigenvalue functions are linear; the other types acquire extra invariant tensors, which produce the stated rational corrections. $\square$

THEOREM 22.27.2 (*Yang R -matrix for $\mathfrak{sl}_N$* ;). For all $\mathfrak{sl}_N$, the rational R -matrix on $V = \mathbb{C}^N$ is

$$R(u) = u \cdot \text{id}_{V \otimes V} + P,$$

where $P(v \otimes w) = w \otimes v$ is the permutation. The eigenvalues are $u+1$ on $\text{Sym}^2(\mathbb{C}^N)$ and $u-1$ on $\wedge^2(\mathbb{C}^N)$. In the standard basis of $\mathbb{C}^2 \otimes \mathbb{C}^2$:

$$R(u) = \begin{pmatrix} u+1 & 0 & 0 & 0 \\ 0 & u & 1 & 0 \\ 0 & 1 & u & 0 \\ 0 & 0 & 0 & u+1 \end{pmatrix}.$$

Proof. P has eigenvalue $+1$ on symmetric and -1 on alternating tensors. The YBE holds in $\text{End}(V^{\otimes 3})$ for any V , using only $P_{ij}^2 = \text{id}$ and $P_{12}P_{13}P_{23} = P_{23}P_{13}P_{12}$. The classical limit $r(u) = P/u = \Omega/u$ satisfies the CYBE (22.2). $\square$

Remark 22.27.3 (*Type- A universality*). For $\mathfrak{sl}_N$, the centraliser $\text{End}_{\mathfrak{sl}_N}(V \otimes V)$ is two-dimensional (spanned by id and P), so the R -matrix is linear in u . Types $B/C/D$ and the exceptionals have larger centralisers, necessitating rational corrections.

The orthogonal and symplectic R -matrices for B_2 and C_2 , and the four-projector R -matrix for G_2 , are recorded in Theorem 22.19.4 (equations (22.16)–(22.17)) with full eigenvalue decompositions and proofs.

Remark 22.27.4 (*The universal classical r -matrix*). For every simple $\mathfrak{g}$ and every finite-dimensional V , $r(u) = \Omega/u$ with $\Omega = \sum_a I^a \otimes I_a \in \mathfrak{g} \otimes \mathfrak{g} \hookrightarrow \text{End}(V)^{\otimes 2}$. The CYBE follows from the Jacobi identity: $[\Omega_{12}, \Omega_{13}] + [\Omega_{12}, \Omega_{23}] + [\Omega_{13}, \Omega_{23}] = 0$ is the Jacobi identity in $\mathfrak{g}^{\otimes 3}$. Quantum corrections: type A has none; types $B/C/D$ have one rational correction from the trace/symplectic contraction; the exceptionals have multiple.

22.28 ROSETTA STONE: THE E_1 ORDERED BAR COMPLEX ACROSS THE LANDSCAPE

The ordered bar complex $\overline{B}^{\text{ch}}(A)$ carries two layers of data: the collision residue $r^{\text{coll}}(z)$, which records the chiral differential of the E_1 -chiral coalgebra, and the R -matrix $R(z)$, which governs the passage from ordered to unordered configurations. The following table collects this data for all standard families.

Every entry is an E_∞ -chiral algebra (a vertex algebra in the sense of Beilinson–Drinfeld: the chiral product is defined on *unordered* configuration spaces with Σ_n -equivariant factorization structure). The ordered bar complex $\overline{B}^{\text{ch}}(A)$ retains the ordering as auxiliary bookkeeping; the descent to the symmetric bar $B^\Sigma(A)$ is the R -matrix-twisted quotient of Proposition 22.4. None of the families below is E_1 -chiral in the sense of the E_1 core of Volume II: genuinely E_1 -chiral algebras (nonlocal, ordered configurations as primitive data) are the Etingof–Kazhdan quantum vertex algebras, which lie outside the Beilinson–Drinfeld framework.

THEOREM 22.28.1 (*E_1 ordered bar landscape*;). Let A be a strongly admissible augmented associative chiral algebra from the standard landscape. The ordered bar complex $\overline{B}^{\text{ch}}(A)$ has the following invariants, where $r^{\text{coll}}(z)$ denotes the collision residue (the OPE kernel after the d log bar propagator absorbs one pole order), $R(z)$ is the spectral R -matrix on $\text{Conf}_2^{\text{ord}}(\mathbb{C})$, $r_{\max}$ is the shadow depth, $A_{\text{line}}^!$ is the ordered Koszul dual governing the line category, and “formal” means the transferred A_∞ operations m_k vanish on cohomology for all k above the shadow depth:

Family	Class	OPE poles	Collision residue $r^{\text{coll}}(z)$	R -matrix $R(z)$	$r_{\max}$	$A_{\text{line}}^!$	Formal?
$\mathcal{H}_k$	G	2	k/z	$e^{k\hbar/z}$	2	$Y(\mathfrak{u}(1))^\dagger$	yes
V_Λ (even)	G	2	$\text{diag}(\lambda_i)/z$	$\text{diag}(e^{\lambda_i \hbar/z})$	2	$Y(\mathfrak{u}(1)^{\oplus \text{rk } \Lambda})^\dagger$	yes
$\widehat{\mathfrak{g}}_k(\mathfrak{sl}_2)$	L	2	$\hbar \Omega/z$	$uI + \hbar P$	3	$Y_\hbar(\mathfrak{sl}_2)$	yes
$\widehat{\mathfrak{g}}_k(\mathfrak{sl}_3)$	L	2	$\hbar \Omega/z$	Yang (9×9)	3	$Y_\hbar(\mathfrak{sl}_3)$	yes
$\widehat{\mathfrak{g}}_k$ (general)	L	2	$\hbar \Omega/z$	Yang ($\dim \mathfrak{g}^2$)	3	$Y_\hbar(\mathfrak{g})$	yes
$\beta\gamma$	C	1	Θ (nilpotent)	$I + 2\pi i \Theta$	4	$bc^!$	yes
bc	C	1	Θ_{bc} (nilpotent)	$I + 2\pi i \Theta_{bc}$	4	$\beta\gamma^!$	yes
Vir_c	M	4	$\frac{c/2}{z^3} + \frac{2T}{z}$	[class M]	∞	$Y^{\text{dg}}(\text{Vir}_c)$	no
$\mathcal{W}_3$	M	6	degree 5 in $1/z$	[class M]	∞	$Y^{\text{dg}}(\mathcal{W}_3)$	no
$\mathcal{W}_N$	M	$2N$	degree $2N-1$ in $1/z$	[class M]	∞	$Y^{\text{dg}}(\mathcal{W}_N)$	no

[†]The Koszul dual algebra $\mathcal{H}_k^! = \text{Sym}^{\text{ch}}(V^*)$ is categorically distinct from $\mathcal{H}_{-k}$ but both have $\kappa = -k$ and the line category $C_{\text{line}} \simeq \mathcal{H}_{-k}\text{-mod}$ is equivalent. Similarly, $V_\Lambda^!$ and V_{Λ^*} share the same modular characteristic but differ as chiral algebras.

Proof. The table assembles data from three sources.

OPE pole orders. The maximal OPE pole order on generators is standard: $J(z)J(w) \sim k/(z-w)^2$ for Heisenberg; $J^a(z)J^b(w) \sim k\delta^{ab}/(z-w)^2 + f^{ab}{}_c J^c/(z-w)$ for affine Kac-Moody; $\beta(z)\gamma(w) \sim 1/(z-w)$ and $b(z)c(w) \sim 1/(z-w)$ for the free-field systems; $T(z)T(w) \sim (c/2)/(z-w)^4 + 2T/(z-w)^2 + \partial T/(z-w)$ for Virasoro; and $W_s(z)W_s(w)$ has poles up to order $2s$ for the spin- s generator of $\mathcal{W}_N$, giving maximal pole $2N$ at the top spin.

Collision residues. The d log bar kernel absorbs one pole order (the d log absorption principle; see Section 6.1.15): the collision residue $r^{\text{coll}}(z)$ from an OPE pole of order d has pole of order $d-1$. For Heisenberg: double-pole $k/(z-w)^2$ gives $r^{\text{coll}} = k/z$. For affine $\widehat{\mathfrak{g}}_k$: the Casimir $\Omega = \sum_a t^a \otimes t_a$ produces $r^{\text{coll}} = \hbar \Omega/z$. For $\beta\gamma/bc$: the simple-pole OPE $1/(z-w)$ gives a constant collision residue $r^{\text{coll}} = \Theta$, where $\Theta \in \text{End}(V)$ is the nilpotent off-diagonal matrix encoding the pairing ($\Theta^2 = 0$). For Virasoro: quartic pole gives $(c/2)/z^3 + 2T/z$ (the $\partial T/(z-w)$ term of the OPE is absorbed completely, producing no pole in the collision residue).

R-matrices. The R -matrix is the monodromy of the connection $\nabla = d - r^{\text{coll}}(z) dz$ on $\text{Conf}_2^{\text{ord}}(\mathbb{C})$. For abelian algebras $(\mathcal{H}_k, V_\Lambda)$: the connection is scalar and $R(z) = \exp(k\hbar/z)$ (Volume II, Corollary ??). For affine $\widehat{\mathfrak{g}}_k$ at $\mathfrak{g} = \mathfrak{sl}_2$: the 4×4 Yang R -matrix $R(u) = uI + P$ (up to normalisation), where P is the permutation and $u = \hbar/z$ is the spectral parameter. For $\beta\gamma/bc$: the nilpotent collision residue Θ gives $R = \exp(2\pi i \Theta) = I + 2\pi i \Theta$ (the exponential terminates at the linear term since $\Theta^2 = 0$). For class **M**: the triple-pole collision residue produces an R -matrix that is not expressible in closed form as a finite product of elementary functions.

Shadow depth and formality. The shadow depth $r_{\max}$ is the highest degree at which the transferred A_∞ operation m_k is non-vanishing on cohomology. Class **G**: $m_{k \geq 3} = 0$ (abelian OPE, clean Lagrangian intersection), so $r_{\max} = 2$ and the A_∞ -chiral structure is formal. Class **L**: $m_3 \neq 0$ from the Lie bracket but $m_{k \geq 4} = 0$ on cohomology (Jacobi closes the obstruction), so $r_{\max} = 3$ and the structure is formal. Class **C**: $m_4 \neq 0$ from the contact term but the tower terminates at $r_{\max} = 4$ by rank-one abelian rigidity, so the structure is formal. Class **M**: $m_k \neq 0$ for all $k \geq 3$ on cohomology (the quartic pole manufactures a propagating obstruction), so $r_{\max} = \infty$ and the A_∞ -chiral structure is *non-formal*.

Ordered Koszul duals. For affine $\widehat{\mathfrak{g}}_k$: the ordered Koszul dual is the Yangian $Y_\hbar(\mathfrak{g})$ (Volume II, Theorem K.7.1). For Virasoro and $\mathcal{W}_N$: the ordered Koszul dual is the dg-shifted Yangian Y^{dg} , a dg algebra with infinitely many cohomological generators reflecting non-formality (the E_1 core of Volume II). For $\beta\gamma/bc$: the Koszul duality exchanges statistics ($bc^! = \beta\gamma, \beta\gamma^! = bc$), so the line-side algebra is the dual free-field system.

All entries are chirally Koszul (bar cohomology concentrated), as established by PBW universality (Volume I) and the one-loop exactness criterion (Volume II, Theorem K.7.1). $\square$

*Remark 22.28.2 (The **G/L/C/M** classification).* The four classes are determined by the OPE pole structure on generators:

- (i) Class **G** (Gaussian): double-pole OPE with scalar residues. The bar complex is cogenerated in degree 2, the R -matrix is scalar-valued (abelian braiding), and the Lagrangian self-intersection $\mathfrak{S}_b = L \times_X L$ is clean. Archetype: $\mathcal{H}_k$.
- (ii) Class **L** (Lie): double-pole OPE with non-scalar (Lie-bracket) residues. The Lie bracket creates a transverse intersection defect at codimension 1, but the Jacobi identity kills all higher defects. The R -matrix is the Yang R -matrix: matrix-valued, satisfying the Yang-Baxter equation with spectral parameter. Archetype: $\widehat{\mathfrak{g}}_k$.

- (iii) Class **C** (Contact): simple-pole OPE on generators. The composite-field OPE reaches pole order 3, producing a quartic contact invariant. Rank-one abelian rigidity forces the quintic obstruction to vanish. The R -matrix is a unipotent perturbation of the identity ($\Theta^2 = 0$ forces $R = I + 2\pi i \Theta$). Archetype: $\beta\gamma$.
- (iv) Class **M** (Modular): quartic or higher poles on generators. The R -matrix is not expressible in closed form. The shadow obstruction tower does not terminate: the composite-field exchange generates new obstructions at every degree. Non-formality is visible already at genus 0: infinitely many A_∞ operations $m_n \neq 0$ on $\overline{\mathcal{M}}_{0,n+1}$, driven by the self-referential OPE $T_{(1)}T = 2T$. At genus $g \geq 1$, this infinite cascade interacts with the curvature $d_{\text{fib}}^2 = \kappa(\mathcal{A}) \cdot \omega_g$ to produce the genuinely modular content of the tower. Archetype: Vir_c .

Remark 22.28.3 (Formality, non-formality, and the E_1/E_∞ distinction). A critical conceptual point: non-formality *does not* imply E_1 . All ten families in Theorem 22.28.1 are E_∞ -chiral (local vertex algebras with Σ_n -equivariant factorization structure), including the non-formal families Vir_c , $\mathcal{W}_3$, and $\mathcal{W}_N$. Having OPE poles does not break E_∞ ; having non-vanishing higher A_∞ operations does not break E_∞ . The poles are singularities of a *local* product, and the non-formality measures structural complexity *within* the E_∞ world.

The three-tier picture is:

- (a) *Pole-free commutative*: $R(z) = \tau$ (the Koszul-signed flip). This is the subclass where the chiral product extends across the diagonal without singularities.
- (b) *Vertex algebras with poles* (all families in the table above): $R(z) \neq \tau$, but $R(z)$ is *derived* from the local OPE via analytic continuation. Both (a) and (b) are E_∞ -chiral.
- (c) *Genuinely E_1 -chiral* (Etingof–Kazhdan quantum vertex algebras, Yangians as independent algebras, quantum groups): $R(z) \neq \tau$ and $R(z)$ is *independent input*, not derivable from a local symmetric structure. Only (c) is genuinely E_1 .

Tiers (a) and (b) are both E_∞ . The ordered bar complex is a computational tool for E_∞ -chiral algebras; it does not make them E_1 .

Remark 22.28.4 (Pole escalation: DS reduction transports $\mathbf{L} \rightarrow \mathbf{M}$). Principal Drinfeld–Sokolov reduction sends $V_k(\mathfrak{g}) \mapsto \mathcal{W}_N(\mathfrak{g})$. On the ordered bar complex, this transports class **L** to class **M**: the affine double-pole OPE $J^a(z)J^b(w) \sim k\delta^{ab}/(z-w)^2 + \dots$ becomes the Virasoro quartic-pole OPE $T(z)T(w) \sim (c/2)/(z-w)^4 + \dots$ via the Sugawara construction. The shadow depth escalates from $r_{\text{max}} = 3$ (finite, formal) to $r_{\text{max}} = \infty$ (infinite, non-formal). The Yangian $Y_h(\mathfrak{g})$ (a classical algebra concentrated in degree 0) becomes the dg-shifted Yangian $Y^{\text{dg}}(\text{Vir}_c)$ (a dg algebra with infinitely many cohomological generators).

This pole escalation is the ordered-bar avatar of the *single-line dichotomy* of Volume I: double poles produce a linear (tree-level) bar differential, while quartic poles produce a quadratic (one-loop) bar differential whose iterations generate the infinite tower. The mechanism is the Sugawara pole: $T = \frac{1}{2(k+h^\vee)} \sum_a :J^a J_a:$ is a normally ordered composite, and the OPE of composites escalates pole orders. Theorem 22.30.7 ensures that this pole escalation is compatible with the ordered bar–cobar equivalence.

*Remark 22.28.5 ($\mathcal{W}_{1+\infty}$ as a class **M** chiral quantum group).* The $\mathcal{W}$ -algebra $\mathcal{W}_{1+\infty}[\Psi]$ (Schiffmann–Vasserot, Maulik–Okounkov) is a class **M** algebra whose CoHA origin provides all three structures of the chiral quantum group equivalence (Theorem 22.29.1): the R -matrix from the stable-envelope construction, the A_∞ -structure from the CoHA multiplication (which is E_1 -associative: the preferred direction on short

exact sequences gives the ordering), and the chiral coproduct from the Hall comultiplication. The shadow obstruction tower is infinite (class **M**: the irregular KZ connection has Stokes data), and the ordered chiral homology carries richer data than the symmetric shadow. This is the bridge between Vol I (chiral quantum group equivalence) and Vol III (CoHA as the E_1 -sector of the CY engine).

Remark 22.28.6 (Genuinely E_1 -chiral algebras: ordered $\neq$ symmetric). Every family in the Rosetta stone table above is E_∞ -chiral: the ordered bar complex carries a nontrivial R -matrix, but this R -matrix is derived from the E_∞ -chiral OPE (tier (b) of Definition 1.4.8). The averaging map $\text{av}: \overline{B}^{\text{ord}} \rightarrow \overline{B}^\Sigma$ is a quasi-isomorphism for these families (Proposition 21.2.4(i)), and ordered chiral homology agrees with Beilinson–Drinfeld chiral homology.

For genuinely E_1 -chiral algebras (tier (c): the Yangian $Y_h(\mathfrak{g})$, Etingof–Kazhdan quantum vertex algebras), this agreement fails. The R -matrix is independent input, the factorisation $\mathcal{D}$ -module $\mathcal{F}_n^{\text{ord}}$ is not Σ_n -equivariant, and $\ker(\text{av}) \neq 0$ at degree $n \geq 3$: the Drinfeld associator $\Phi_{\text{KZ}} \in \exp(\hat{\mathfrak{t}}_3)$ contributes GRT₁-dependent data visible in the ordered theory but killed by the Σ_n -coinvariant projection (Proposition 21.2.4(ii)). The Yangian is the first example in which the ordered theory is strictly richer than the symmetric one.

22.29 THE CHIRAL QUANTUM GROUP EQUIVALENCE

The ordered bar complex $\overline{B}^{\text{ord}}(\mathcal{A}) = T^c(s^{-1}\bar{\mathcal{A}})$ is a single object from which three structures are recovered: the vertex R -matrix $S(z)$ (braiding data from the degree-2 collision residue), the chiral A_∞ -structure maps m_k^{ch} (higher associativity from boundary strata of associahedra), and the chiral coproduct Δ^{ch} (coalgebra data from deconcatenation). The three structures determine each other.

THEOREM 22.29.1 (Chiral quantum group equivalence). The following three structures on an E_1 -chiral algebra $\mathcal{A}$ on the Koszul locus determine each other, up to the choice of a Drinfeld associator $\Phi \in \exp(\hat{\mathfrak{t}}_3)$:

- (I) E_1 -chiral algebra with vertex R -matrix $S(z)$ satisfying S -locality, the quantum Yang–Baxter equation, unitarity, shift condition, and hexagon axiom (the Etingof–Kazhdan axioms);
- (II) A_∞ -algebra in the chiral endomorphism operad $\text{End}_{\mathcal{A}}^{\text{ch}}$, with structure maps $m_k^{\text{ch}}: \mathcal{A}^{\otimes k} \rightarrow \mathcal{A}((\lambda_1)) \cdots ((\lambda_{k-1}))$ satisfying the Stasheff identities;
- (III) E_1 -chiral algebra with compatible chiral coproduct $\Delta^{\text{ch}}: \mathcal{A} \rightarrow (\mathcal{A} \hat{\otimes} \mathcal{A})((z))$, coassociative up to conjugation by Φ .

The equivalences form a triangle:

$$\begin{array}{ccc}
 \text{(I)} & \xrightleftharpoons[\alpha^{-1}]{\alpha} & \text{(II)} \\
 \nwarrow \gamma \gamma^{-1} & & \nearrow \beta \beta^{-1} \\
 & \text{(III)} &
 \end{array}$$

where α restricts the OPE to the real Stasheff associahedra $K_n \hookrightarrow \overline{\text{FM}}_n^{\text{ord}}(\mathbb{C})$, β applies the cobar functor to the deconcatenation coproduct on $\overline{B}^{\text{ord}}(\mathcal{A})$, and γ extracts the R -matrix as $S(z) = \sigma \circ \Delta^{\text{ch}} \circ (\Delta^{\text{ch}, \text{op}})^{-1}$ (the chiral Drinfeld formula).

Proof. **(I) $\rightarrow$ (II).** The Stasheff associahedron K_n is isomorphic to the real FM compactification $\overline{\text{FM}}_n^{\text{ord}}(\mathbb{R})$ (Sinha). The chiral A_∞ -maps are the integrals

$$m_k^{\text{ch}}(a_1, \dots, a_k) = \int_{K_k} Y(a_1, z_1) \cdots Y(a_k, z_k) \omega_k,$$

where ω_k is the canonical volume form induced by the bar propagator. The Stasheff identity follows from Stokes' theorem on K_{n+1} : the codimension-1 boundary decomposes into facets $K_{r+1} \times K_{s+1}$ recording consecutive collisions, and $\int_{K_{n+1}} d\omega = 0$ yields $\sum (-1)^\epsilon m_i^{\text{ch}} \circ_p m_j^{\text{ch}} = 0$. The inverse α^{-1} recovers $S(z)$ as the degree-2 KZ holonomy.

(II) $\rightarrow$ (III). The A_∞ -maps determine the bar differential $d_{\overline{B}^{\text{ord}}} = \sum_{k \geq 1} \hat{m}_k^{\text{ch}}$ (coderivation extension). The deconcatenation coproduct Δ on $T^c(s^{-1}\bar{\mathcal{A}})$ is a dg coalgebra map; applying the cobar functor Ω to Δ produces the chiral coproduct Δ^{ch} on $\mathcal{A}$ via $\mathcal{A} \simeq \Omega(\overline{B}^{\text{ord}}(\mathcal{A}))$ (Theorem II.1.84 on the Koszul locus). Strict coassociativity of deconcatenation becomes coassociativity-up-to- Φ after passage through the formality quasi-isomorphism underlying Ω . The inverse β^{-1} reads off m_k^{ch} as the tensor-degree- k component of $d_{\overline{B}^{\text{ord}}}$.

(III) $\rightarrow$ (I). The chiral Drinfeld formula $S(z) = \sigma \circ \Delta^{\text{ch}} \circ (\Delta^{\text{ch}, \text{op}})^{-1}$ defines the vertex R -matrix. The QYBE follows from coassociativity-up-to- Φ (via the pentagon for Φ). $\square$

COROLLARY 22.29.2 (*The ordered bar encodes all three structures*). The ordered bar complex $\overline{B}^{\text{ord}}(\mathcal{A}) = T^c(s^{-1}\bar{\mathcal{A}})$ is the universal datum: the vertex R -matrix is the degree-2 collision residue $r(z) = \text{Res}_{0,2}^{\text{coll}}(\Theta_{\mathcal{A}}^{E_1})$, the A_∞ -maps are the bar differential components $d_{\overline{B}}|_{\text{degree } k}$, and the chiral coproduct is the cobar-dual of the deconcatenation. No additional input beyond $\overline{B}^{\text{ord}}(\mathcal{A})$ is needed.

Proof. Theorem 22.29.1 provides three readouts of the same ordered bar coalgebra. Arrow α identifies the degree-2 collision residue with the vertex R -matrix. Arrow β identifies the higher components of the bar differential with the transferred A_∞ operations. Arrow γ identifies the deconcatenation coproduct, after cobar dualization, with the chiral coproduct. Since these are all functorial projections of $\overline{B}^{\text{ord}}(\mathcal{A})$, no extra datum beyond the ordered bar complex is required. $\square$

Remark 22.29.3 (*Key formulas of the equivalence*). The three equivalences involve the following explicit formulas. The OPE compatibility axiom:

$$\Delta^{\text{ch}}(Y(a, z) b) = Y^{(2)}(\Delta^{\text{ch}}(a), z) \cdot \Delta^{\text{ch}}(b), \quad (22.27)$$

where $Y^{(2)}$ is the tensorwise vertex operation. The coproduct from the bar complex:

$$\Delta^{\text{ch}}: \mathcal{A} \simeq \Omega(\overline{B}^{\text{ord}}(\mathcal{A})) \xrightarrow{\Omega(\Delta)} \Omega(\overline{B}^{\text{ord}}(\mathcal{A}) \otimes \overline{B}^{\text{ord}}(\mathcal{A})) \rightarrow (\mathcal{A} \hat{\otimes} \mathcal{A})((z)). \quad (22.28)$$

The R -matrix from the coproduct (the chiral Drinfeld formula):

$$S(z) := \sigma \circ \Delta^{\text{ch}} \circ (\Delta^{\text{ch}, \text{op}})^{-1}. \quad (22.29)$$

QYBE, unitarity, shift, hexagon. The quantum Yang–Baxter equation on $V_{\text{EK}}^{\otimes 3}$ reduces on $V^{\otimes 3}$ to (22), as in the classical Yangian case; the extension to V_{EK} follows from the universal property of $\mathcal{R}(z)$. Unitarity $S_{12}(z) \cdot (\sigma \circ S_{12}(-z) \circ \sigma) = \text{id}$ follows from Drinfeld–Jimbo unitarity. The shift condition

$$[D \otimes \text{id} + \text{id} \otimes D, S(z)] = \partial_z S(z)$$

follows from the translation-covariance of the Drinfeld coproduct. The hexagon follows from the pentagon relation for Φ (from the Stasheff boundary of $\overline{\text{FM}}_4^{\text{ord}}(C) = K_4$) combined with the QYBE for S , by the standard argument of Drinfeld [I47] lifted to the vertex-algebraic setting.

Part B: the ordered chiral center of the EK quantum VOA. We compute the ordered chiral Hochschild cohomology $\text{HH}_{\text{ch}}^{*,\text{ord}}(V_{\text{EK}}, V_{\text{EK}})$ at low degrees on the formal disk D , paralleling the classical Yangian computation but now using the *full* vertex R -matrix $S(z)$ rather than the Yang R -matrix on $V \otimes V$ alone. *Degree 2: the KZ connection with the full vertex R -matrix.* At degree 2, the KZ connection on $C_2^{\text{ord}}(C)$ with coefficients in $\text{End}(V_{\text{EK}}^{\otimes 2})$ is

$$\nabla_{\text{KZ}}^S = d + \frac{\hbar \Omega}{z} dz + \frac{\hbar^2}{z^2} \left(\Omega^{(2)} + \frac{1}{2} \Omega^2 \right) dz + O(z^{-3}), \quad (22.30)$$

where $z = z_1 - z_2$. The connection (22.30) is obtained from $S(z)$ via the general formula $\nabla = d + (\partial_z \log S(z)) dz$ (logarithmic derivative of the vertex R -matrix).

For the classical $V_k(\mathfrak{sl}_2)$ (trivial braiding $S(z) = \text{id}$), the flat sections are $\Phi(z) = z^{\Omega/(k+2)}$ with algebraic monodromy. For the EK quantum VOA ($S(z) \neq \text{id}$), the flat sections acquire quantum corrections:

$$\Phi^S(z) = z^{\hbar \Omega} \left(I + \frac{\hbar^2 \Omega^{(2)}}{z} + O(z^{-2}) \right).$$

The kernel $\ker(\text{av})$. The ordered chiral centre computation parallels the classical Yangian case; the result is identical on cohomology. On $V \otimes V$: $\ker(\text{av}_2)|_{V \otimes V} \cong \wedge^2 V = C$, the same one-dimensional space as in that classical computation. The quantum corrections from $S(z)$ shift the subleading terms of the flat sections but do not alter the $\ker(\text{av}_2)$ dimension. The scalar shadow surviving av_2 is $\kappa = 3(k+2)/4$ (equation (??)), identical to the classical value. At degree 3, the kernel $\ker(\text{av}_3) \cong \Lambda^3(\mathfrak{g}) = C$ carries the quantum-corrected Drinfeld associator

$$\Phi_{\text{KZ}}^S - 1 = \hbar^2 \zeta(2) [\Omega_{12}, \Omega_{23}] + O(\hbar^3),$$

whose leading term agrees with the classical KZ associator.

Part C: S -locality as an A_∞ relation. The braided VOA axioms of the EK quantum VOA are equivalent to the chiral A_∞ relations for V_{EK} through the chiral quantum group equivalence (Theorem 22.29.1, (I) $\Leftrightarrow$ (II)). In the ordered bar complex $\overline{B}^{\text{ord}}(V_{\text{EK}}) = T^c(s^{-1}\overline{V}_{\text{EK}})$, the S -locality axiom (??) governs the reordering of two insertions: the braid group $\pi_1(C_2^{\text{ord}}(C)) = \mathbb{Z}$ acts on degree-2 bar chains by $\sigma_1 \cdot [a|b] = S(z) \cdot [b|a]$. The S -locality axiom is the $n = 2$ Stasheff relation, the hexagon is the $n = 3$ relation, and the QYBE is the $n = 4$ relation (from the pentagon for Φ on $K_4 = \overline{\text{FM}}_4^{\text{ord}}(\mathbb{R})$).

Summary. The EK quantum VOA $(V_{\text{EK}}, Y, S(z))$ provides the first concrete instance of all three structures of the chiral quantum group equivalence (Theorem 22.29.1) exhibited simultaneously on a single algebra with all axioms verified. The ordered chiral center carries the full quantum R -matrix $S(z)$ (not just the classical r -matrix $r(z) = \hbar \Omega/z$), and the kernel $\ker(\text{av}_2) \neq 0$ demonstrates that the ordered theory is strictly richer than the symmetric Beilinson–Drinfeld chiral homology even at the quantum level.

Example 22.29.4 (Heisenberg: trivial case). For the Heisenberg algebra $\mathcal{H}_k$ (class G), all three structures are trivial: $S(z) = \text{id}$ (the braiding is symmetric); $m_k^{\text{ch}} = 0$ for $k \geq 3$ (the algebra is strictly associative in the chiral sense); $\Delta^{\text{ch}}(J) = J \otimes 1 + 1 \otimes J$ is cocommutative and strictly coassociative (Φ acts trivially). The ordered and symmetric data coincide.

THEOREM 22.29.5 ($\mathcal{W}_{1+\infty}[\Psi]$. *asachiralquantumgroup*) *The algebra* $\mathcal{W}_{1+\infty}[\Psi]$ carries a chiral quantum group datum in the sense of Theorem 22.29.1: an R -matrix, a chiral coproduct, and an A_∞ structure, all explicit and originating from the cohomological Hall algebra of the Jordan quiver. The precise content is as follows.

- (I) (R -matrix.) The Maulik–Okounkov R -matrix $[313]$ of quantum toroidal $\mathfrak{gl}_1$, restricted to the CoHA, is *scalar*:

$$R(z) = g(z) = \frac{(z - h_1)(z - h_2)(z - h_3)}{(z + h_1)(z + h_2)(z + h_3)}, \quad h_1 + h_2 + h_3 = 0, \quad (22.31)$$

where h_1, h_2, h_3 are the equivariant parameters of C^3 subject to the Calabi–Yau constraint. The classical limit is $r(z) = \Psi/z$ (class G , level prefix Ψ).

- (II) (Chiral coproduct at all spins.) The Drinfeld coproduct on $Y(\widehat{\mathfrak{gl}}_1)$ gives an explicit spectral coproduct $\Delta_z: \mathcal{W}_{1+\infty}[\Psi] \rightarrow (\mathcal{W}_{1+\infty}[\Psi] \hat{\otimes} \mathcal{W}_{1+\infty}[\Psi])((z))$ satisfying strict coassociativity, the spectral counit, and OPE compatibility at all spins. The transfer matrix $T(u) = 1 + \sum_{n \geq 1} \psi_n u^{-n}$ is scalar ($\mathfrak{gl}_1$ has rank 1), and

$$\Delta_z(T(u)) = T(u) \otimes T(u - z). \quad (22.32)$$

The general spin- n formula is

$$\Delta_z(\psi_n) = \psi_n \otimes 1 + \sum_{k=0}^{n-1} \sum_{m=1}^{n-k} \binom{n-k-1}{m-1} z^{n-k-m} \psi_k \otimes \psi_m, \quad (22.33)$$

where $\psi_0 = 1$.

- (III) (A_∞ structure.) The chiral A_∞ -operations m_k^{ch} are extracted from the ordered bar complex $\overline{B}^{\text{ord}}(\mathcal{W}_{1+\infty}) = T^c(s^{-1}\overline{\mathcal{W}}_{1+\infty})$ via the functor α of Theorem 22.29.1, with input the R -matrix (22.31).

The three structures determine each other by Theorem 22.29.1. The OPE compatibility axiom (22.27) is satisfied at all spins simultaneously by two independent arguments: the coderivation property on the Koszul-locus bar complex, and the JKL vertex bialgebra theorem on the CoHA.

Proof. The argument proceeds in seven steps.

Step 1 (CoHA identification; Schiffmann–Vasserot [368], Schiffmann–Mellit–Minets–Vasserot [508]). The critical CoHA of the Jordan quiver is

$$\mathcal{H}_{\text{Jor}} = \bigoplus_{n \geq 0} H_{\text{BM},*}^{GL_n}(\mathcal{M}_n^{\text{nil}}, \varphi_W), \quad W = \text{Tr}(x[y, z]),$$

where $\mathcal{M}_n^{\text{nil}}$ is the nilpotent locus in the representation variety of the Jordan quiver and φ_W denotes the vanishing-cycle twist. Schiffmann–Vasserot [368] proved $\mathcal{H}_{\text{Jor}} \cong Y^+(\widehat{\mathfrak{gl}}_1)$ by matching generators and relations; the critical refinement is [508]. Kontsevich–Soibelman [519] established the general CoHA framework (see also Joyce [281]).

Step 2 (Bialgebra and Drinfeld double; Yang–Zhao [541]). The CoHA carries a bialgebra coproduct $\Delta_{\text{CoHA}}: \mathcal{H}_{\text{Jor}} \rightarrow \mathcal{H}_{\text{Jor}} \otimes \mathcal{H}_{\text{Jor}}$ from restriction to Levi subalgebras $GL_{n_1} \times GL_{n_2} \hookrightarrow GL_n$. Yang–Zhao proved that the Drinfeld double is the full affine Yangian: $D(\mathcal{H}_{\text{Jor}}) \cong Y(\widehat{\mathfrak{gl}}_1)$.

Step 3 (Yangian– $\mathcal{W}$ -algebra identification; Procházka–Rapčák [528]). The quantum Miura transform gives an isomorphism of filtered associative algebras

$$Y(\widehat{\mathfrak{gl}}_1) \cong U(\mathcal{W}_{1+\infty}[\Psi]),$$

intertwining the Yangian filtration with the conformal filtration. The ψ -generators map to $\mathcal{W}_{1+\infty}$ fields via a triangular change of basis: $\psi_1 = J, \psi_n = W_n + P_n(J, W_2, \dots, W_{n-1})$ for $n \geq 2$, where $W_2 = T$ (stress tensor), $W_3 = W$ (spin-3 current), and P_n is a nonlinear polynomial in lower-spin fields with coefficients depending on Ψ .

Step 4 (Drinfeld coproduct at all spins). The transfer matrix $T(u) = 1 + \sum_{n \geq 1} \psi_n u^{-n}$ is a scalar formal power series in u^{-1} ($\mathfrak{gl}_1$ has rank 1). The Drinfeld coproduct (22.32) is the product of two such series. The expansion (22.33) follows from $(u - z)^{-m} = u^{-m} \sum_{j \geq 0} \binom{m+j-1}{j} (z/u)^j$ applied to $T(u) \otimes T(u - z)$ and collecting the coefficient of u^{-n} , giving the spin-1, 2, and 3 expansions displayed below. Through spin 3:

$$\begin{aligned} \Delta_z(\psi_1) &= \psi_1 \otimes 1 + 1 \otimes \psi_1, \\ \Delta_z(\psi_2) &= \psi_2 \otimes 1 + 1 \otimes \psi_2 + \psi_1 \otimes \psi_1 + z(1 \otimes \psi_1), \\ \Delta_z(\psi_3) &= \psi_3 \otimes 1 + 1 \otimes \psi_3 + \psi_1 \otimes \psi_2 + \psi_2 \otimes \psi_1 \\ &\quad + z(\psi_1 \otimes \psi_1 + 2 \cdot 1 \otimes \psi_2) + z^2(1 \otimes \psi_1). \end{aligned}$$

In the $\mathcal{W}_{1+\infty}$ field basis (via the Miura substitution $\psi_1 = J, \psi_2 = T + J^2/(2\Psi)$ of step 3):

$$\begin{aligned} \Delta_z(J) &= J \otimes 1 + 1 \otimes J, \\ \Delta_z(T) &= T \otimes 1 + 1 \otimes T + \frac{\Psi-1}{\Psi} J \otimes J + z(1 \otimes J). \end{aligned} \tag{22.34}$$

The coefficient $(\Psi - 1)/\Psi$ in (22.34) arises from the Miura inversion $T = \psi_2 - J^2/(2\Psi)$: the $\psi_1 \otimes \psi_1$ cross-term in $\Delta_z(\psi_2)$ has coefficient 1, and subtracting $(1/(2\Psi)) \Delta_z(J)^2 = (J^2/(2\Psi)) \otimes 1 + (1/\Psi) J \otimes J + 1 \otimes J^2/(2\Psi)$ replaces the coefficient by $1 - 1/\Psi = (\Psi - 1)/\Psi$. At $\Psi = 1$ (free boson) the cross-term vanishes; in the classical limit $\Psi \rightarrow \infty$ it tends to 1. The Heisenberg OPE $J(z)J(w) \sim \Psi/(z-w)^2$ gives $r(z) = \Psi/z$ (class G , level prefix Ψ). The general formula (22.33) gives $\Delta_z(\psi_n)$ at every spin in closed form; the coproduct on the $\mathcal{W}_{1+\infty}$ field basis $\{J, T, W, W_4, \dots\}$ is obtained by inverting the Miura transform, and the computation is triangular and algorithmic at each spin.

Step 5 (R -matrix from Maulik–Okounkov; vertex bialgebra structure; Maulik–Okounkov [313], Jindal–Kaubrys–Latyntsev [282]). The critical CoHA of any quiver with potential carries a vertex coproduct forming a vertex bialgebra ([282], Theorems A and C). The R -matrix is

$$R(z) = \frac{\Psi(\sigma^* \text{Ext}^\vee, z)}{\Psi(\text{Ext}, z)},$$

where Ψ on the right denotes the motivic exponential and Ext is the Ext^1 -bundle on the stack of quiver representations. The Maulik–Okounkov R -matrix [313] restricted to the CoHA gives $R_{\text{CoHA}} = q^{\alpha \cdot \beta}$ ($q = e^{\pi i \Psi}$) with classical limit $r(z) = \Psi/z$.

Step 6 (OPE compatibility at all spins: two independent arguments). The vertex bialgebra axiom (22.27) requires $\Delta_z(Y(a, w)b) = Y^{(2)}(\Delta_z(a), w) \Delta_z(b)$ as an identity of vertex operators, not merely of associative algebra elements. We give two independent proofs that this holds at all spins simultaneously.

Argument A (coderivation on the Koszul locus). The algebra $\mathcal{W}_{1+\infty}[\Psi]$ at generic Ψ lies on the Koszul locus (Definition 3.1.7: the bar-cobar adjunction $\Omega(\overline{B}^{\text{ord}}(\mathcal{W}_{1+\infty}[\Psi])) \xrightarrow{\sim} \mathcal{W}_{1+\infty}[\Psi]$ is an equivalence). By the direction (II) $\rightarrow$ (III) of Theorem 22.29.I, the bar construction produces a chiral coproduct on $\mathcal{W}_{1+\infty}[\Psi]$ from the deconcatenation coproduct Δ on $\overline{B}^{\text{ord}}(\mathcal{W}_{1+\infty}[\Psi]) = T^c(s^{-1}\overline{\mathcal{W}}_{1+\infty}[\Psi])$ via the cobar dualization (22.28). The bar differential $d_{\overline{B}^{\text{ord}}}$ is a coderivation with respect to Δ :

$$d_{\overline{B}^{\text{ord}}} \circ \Delta = \Delta \circ d_{\overline{B}^{\text{ord}}}. \quad (22.35)$$

This identity holds at *all arities simultaneously* as a structural property of the cofree tensor coalgebra. Under the cobar functor Ω , the coderivation property (22.35) dualizes to the OPE compatibility axiom (22.27): the bar differential encodes the vertex operation $Y(a, w)$, and the deconcatenation encodes the coproduct Δ_z (see the proof of Theorem 22.29.I, direction (II) $\rightarrow$ (III)).

It remains to identify this bar-cobar coproduct with the Drinfeld coproduct of step 4. The bar-cobar coproduct is determined by the vertex algebra structure of $\mathcal{W}_{1+\infty}[\Psi]$; the Drinfeld coproduct is determined by the generating-series formula (22.32). Both satisfy coassociativity and the counit axiom. On the Koszul locus, the coproduct compatible with a given vertex R -matrix is unique (Theorem 22.29.I: the functors α, β, γ form an equivalence triangle). The bar-cobar coproduct is compatible with the Maulik–Okounkov R -matrix (by construction via α and γ^{-1}). The Drinfeld coproduct is compatible with the same R -matrix (the Yangian R -matrix of step 5 restricts to the MO R -matrix). By uniqueness, the two coproducts coincide. Therefore the Drinfeld coproduct satisfies OPE compatibility at all spins.

Argument B (JKL vertex bialgebra on the CoHA). Jindal–Kaubrys–Latyntsev [282] construct a vertex coproduct on the critical CoHA of any quiver with potential, satisfying the vertex bialgebra axiom (22.27) (their Theorems A and C). For the Jordan quiver, the CoHA is $\mathcal{H}_{\text{Jor}} \cong Y^+(\widehat{\mathfrak{gl}}_1)$ (step 1), and the JKL vertex coproduct recovers the Drinfeld coproduct on the Yangian (their Theorem B). Since the JKL vertex bialgebra axiom is exactly the OPE compatibility axiom (22.27), this gives a second proof at all spins simultaneously.

RTT triviality (corroboration, not proof). For $\mathfrak{gl}_1$, the Maulik–Okounkov R -matrix is scalar: $R(z) = g(z)$ of (22.31). The RTT relation

$$R(u - v) T_1(u) T_2(v) = T_2(v) T_1(u) R(u - v) \quad (22.36)$$

is trivially satisfied because a scalar commutes through all operators. This confirms that the Drinfeld coproduct is compatible with the R -matrix at the *associative algebra* level; arguments A and B upgrade this to the full vertex algebra compatibility. For $Y(\widehat{\mathfrak{gl}}_N)$ with $N \geq 2$, the R -matrix is no longer scalar, and OPE compatibility at each truncation is a separate question (Remark 22.29.II).

Step 7 (Full axiom verification). The spectral coproduct (22.32) satisfies all axioms of Definition 22:

- (a) *Strict coassociativity.* $(\Delta_{z_1} \otimes \text{id}) \circ \Delta_{z_2}(T(u)) = T(u) \otimes T(u - z_2) \otimes T(u - z_1 - z_2)$ and $(\text{id} \otimes \Delta_{z_2}) \circ \Delta_{z_1}(T(u)) = T(u) \otimes T(u - z_1) \otimes T(u - z_1 - z_2)$. For $\mathfrak{gl}_1$ the Drinfeld associator acts trivially (the algebra is abelian), so Δ_z is *strictly* coassociative.
- (b) *Counit.* $\varepsilon(\psi_n) = 0$ for $n \geq 1$, $\varepsilon(1) = 1$ gives $(\varepsilon \otimes \text{id}) \circ \Delta_z(T(u)) = T(u - z)$ and $(\text{id} \otimes \varepsilon) \circ \Delta_z(T(u)) = T(u)$.
- (c) *OPE compatibility at all spins.* By step 6: the coderivation property on the bar complex of $\mathcal{W}_{1+\infty}[\Psi]$ (argument A) gives the vertex bialgebra axiom (22.27) at all spins via the Koszul-locus equivalence (Theorem 22.29.I), and the JKL vertex bialgebra theorem on the CoHA (argument B) provides an independent proof. RTT triviality for $\mathfrak{gl}_1$ corroborates the result at the associative algebra level.

No constant coproduct exists for $c \neq 0$: the conformal anomaly $T(z)T(w) \sim (c/2)/(z-w)^4 + \dots$ obstructs any z -independent ansatz $\Delta(T) = T \otimes 1 + 1 \otimes T + X$ because the quartic pole on the left maps to $(c/2 + c/2)/(z-w)^4$ while the right retains $c/2$. The spectral parameter in (22.32) absorbs this obstruction through the shift $u \mapsto u - z$.

The three structures (I)–(III) determine each other by Theorem 22.29.1: the R -matrix is given by step 5, the coproduct by steps 4 and 6, and the A_∞ structure is extracted from $\overline{B}^{\text{ord}}(\mathcal{W}_{1+\infty})$ via the functor α with input the R -matrix from step 5. $\square$

Remark 22.29.6 (Structural features of the spectral coproduct). The coproduct of Theorem 22.29.5 has the following convention-independent features:

- (1) $\Delta_z(J) = J \otimes 1 + 1 \otimes J$ is cocommutative with no z -dependence (Heisenberg is abelian, confirming class G).
- (2) $\Delta_z(\psi_2)$ has a noncocommutative cross-term $\psi_1 \otimes \psi_1$ at order z^0 and a spectral tail $z(1 \otimes \psi_1)$ from the shift $u \mapsto u - z$. In the $\mathcal{W}_{1+\infty}$ basis, $\Delta_z(T)$ acquires a correction $(\Psi - 1)/\Psi \cdot (J \otimes J)$ from the Miura inversion $T = \psi_2 - J^2/(2\Psi)$.
- (3) $\Delta_z(\psi_3)$ has cross-terms $\psi_1 \otimes \psi_2 + \psi_2 \otimes \psi_1$, a spectral tail through z^2 , and the z^1 coefficient involves both $\psi_1 \otimes \psi_1$ and $1 \otimes \psi_2$. In the $\mathcal{W}_{1+\infty}$ basis, $\Delta_z(W)$ mixes all three spins with coefficients polynomial in Ψ .
- (4) The general formula (22.33) gives $\Delta_z(\psi_n)$ at every spin in closed form. The coproduct on the $\mathcal{W}_{1+\infty}$ field basis $\{J, T, W, W_4, \dots\}$ is obtained by inverting the Miura transform; the computation is triangular and algorithmic at each spin.

Remark 22.29.7 (Effective central charge and intertwining in the Miura basis). The coproduct (22.34) in the $\mathcal{W}_{1+\infty}$ field basis has cross-term coefficient $(\Psi - 1)/\Psi$ (not $1/\Psi$), as derived in step 4.

Remark 22.29.8 (Independent proof via the cohomological Hall algebra). The equivalence (I) $\leftrightarrow$ (II) $\leftrightarrow$ (III) admits a second, independent proof for algebras arising as critical CoHAs of quivers with potential, using the framework of Kontsevich–Soibelman [519], Schiffmann–Vasserot [368], Yang–Zhao [541], and Jindal–Kaubrys–Latyntsev [282]. The logic is orthogonal to the bar-cobar adjunction above: rather than constructing the triangle abstractly from the ordered bar complex, one exhibits all three structures simultaneously on a single geometric object and verifies that they determine each other.

Step 1: simultaneous existence of (I) and (III) on the CoHA. Let (Q, W) be a quiver with potential. The critical CoHA

$$\mathcal{H}_{Q,W} = \bigoplus_{d \in \mathbb{Z}_{\geq 0}^{Q_0}} H_{\text{BM},*}^{G_d}(\mathcal{M}_d^{\text{nil}}, \varphi_W)$$

carries two structures of independent geometric origin:

- (a) *Vertex coproduct* Δ_{CoHA} , from restriction to Levi subalgebras $G_{d_1} \times G_{d_2} \hookrightarrow G_d$; and
- (b) *R-matrix* $R(z)$, from the Maulik–Okounkov stable envelope construction [313] on the Nakajima variety associated to Q .

Jindal–Kaubrys–Latyntsev [282] prove that these two structures satisfy the vertex bialgebra axiom (their Theorems A and C):

$$\Delta_{\text{CoHA},z}(Y(a, w) b) = Y^{(2)}(\Delta_{\text{CoHA},z}(a), w) \Delta_{\text{CoHA},z}(b),$$

which is the OPE compatibility axiom (22.27). The R -matrix satisfies the QYBE and unitarity by the stable envelope formalism [313]; the quasi-coassociativity of Δ_{CoHA} follows from the associativity of the Hall product on the Drinfeld double [541]. This establishes the equivalence (I) $\leftrightarrow$ (III) by construction: the R -matrix and the coproduct coexist on $\mathcal{H}_{Q,W}$ and satisfy the quasi-triangularity relation $R(z) \Delta^{\text{ch}} = \Delta^{\text{ch,op}} R(z)$.

Step 2: extraction of (II) from the CoHA vertex bialgebra. The CoHA $\mathcal{H}_{Q,W}$, equipped with its R -matrix, is an E_1 -chiral algebra in the sense of Definition 3.11.3. The functor α of the equivalence triangle (??) extracts the chiral A_∞ operations $\{m_k^{\text{ch}}\}$ by restricting the OPE to the associahedra $K_k \hookrightarrow \overline{\text{FM}}_k^{\text{ord}}(C)$ as in (??). The Stasheff identities follow from Stokes' theorem on K_{k+1} as before; the convergence of the integrals is guaranteed by S -locality of the R -matrix. This gives (I) $\rightarrow$ (II) on the CoHA.

The reverse direction (II) $\rightarrow$ (I) is the degree-2 holonomy recovery of the R -matrix from m_2^{ch} , which depends only on the formal structure of the Stasheff associahedra and not on the CoHA origin.

Step 3: the triangle closes. By the JKL vertex bialgebra theorem, the CoHA simultaneously carries (I), (II), and (III). To verify that these three structures *determine* each other (not merely coexist), one checks the uniqueness directions. On the Koszul locus:

- (i) (I) *determines* (III): given an R -matrix satisfying the QYBE and S -locality, the quasi-triangular coproduct is unique up to gauge equivalence by the Drinfeld reconstruction [137] (spectral parameter version: Etingof–Kazhdan [147]). The JKL coproduct on the CoHA is the unique one compatible with the MO R -matrix.
- (ii) (III) *determines* (I): the Drinfeld formula (22.29) recovers $S(z)$ from Δ^{ch} , independently of the CoHA construction.
- (iii) (I) $\leftrightarrow$ (II): the extraction of A_∞ operations from the R -matrix is the Stasheff–FM construction (direction α), whose inverse recovers the R -matrix as holonomy (direction α^{-1}). Neither direction uses the CoHA.

The triangle coherence $\alpha \circ \gamma \circ \beta = \text{id}$ then follows from the uniqueness of each vertex.

Independence from the bar-cobar proof. The argument above differs from the proof of Theorem 22.29.1 in two respects. First, the equivalence (I) $\leftrightarrow$ (III) is established by the geometric CoHA construction (stable envelopes for the R -matrix, Levi restriction for the coproduct, JKL for the vertex bialgebra axiom), bypassing the ordered bar complex $\overline{B}^{\text{ord}}(\mathcal{A}) = T^c(s^{-1}\overline{\mathcal{A}})$ and the cobar dualization (22.28). Second, the uniqueness of the coproduct given the R -matrix is deduced from the Drinfeld reconstruction theorem for quasi-triangular vertex bialgebras, rather than from the bar-cobar adjunction on the Koszul locus. The functor α (extraction of A_∞ operations from the R -matrix via associahedron integrals) is shared between inverting the Miura transform; the computation is triangular and algorithmic at each spin.

Remark 22.29.9 (Effective central charge and intertwining in the Miura basis). The coproduct (22.34) in the $\mathcal{W}_{1+\infty}$ field basis has cross-term coefficient $(\Psi - 1)/\Psi$ (not $1/\Psi$), as derived in step 4. This coefficient controls two structural invariants of the image $\Delta_z(T)$ in $V \otimes V$:

- (1) *Effective central charge.* The image $\Delta_z(T_n)$ generates a Virasoro subalgebra in the tensor product mode algebra with effective central charge

$$c_{\text{eff}}(\Psi) = 2 + 2(\Psi - 1)^2.$$

At $\Psi = 1$ (free boson): $c_{\text{eff}} = 2$ (two decoupled copies, the cross-term vanishes). At $\Psi = 2$: $c_{\text{eff}} = 4$. The quadratic growth $c_{\text{eff}} \sim 2\Psi^2$ at large Ψ reflects the quadratic Miura nonlinearity $\psi_2 = T + J^2/(2\Psi)$. The formula is independent of the spectral parameter z (the z -dependent terms in $\Delta_z(T)$ do not contribute to the vacuum expectation value of the commutator $[\Delta_z(T_2), \Delta_z(T_{-2})]$).

- (2) *Intertwining with $\Delta_z(J)$.* The commutator $[\Delta_z(T_n), \Delta_z(J_m)] = -\Psi \cdot m \cdot \Delta_z(J_{n+m})$ has intertwining factor Ψ (not 1). The extra factor $\Psi - 1$ beyond the original algebra relation $[T_n, J_m] = -m J_{n+m}$ arises from the cross-term $(\Psi - 1)/\Psi \cdot (J \otimes J)_n$ commuting with $\Delta_z(J_m) = J_m^L + J_m^R$: the left and right Heisenberg commutators each contribute $-((\Psi - 1)/\Psi) \cdot \Psi \cdot m = -(\Psi - 1)m$. At $\Psi = 1$: factor 1 (algebra homomorphism).

Both features are consequences of the Miura nonlinearity: the Drinfeld coproduct is an algebra homomorphism of the Yangian $Y(\widehat{\mathfrak{gl}}_1)$ (preserving the ψ -generator relations), but when expressed in the $\mathcal{W}_{1+\infty}$ field basis via the nonlinear Miura inversion $T = \psi_2 - J^2/(2\Psi)$, the image acquires Ψ -dependent structural invariants that are absent in the ψ -basis.

Remark 22.29.10 (Descent to $\mathcal{W}_N$). Drinfeld–Sokolov reduction gives $\pi_N: \mathcal{W}_{1+\infty}[\Psi] \twoheadrightarrow \mathcal{W}_N$ for each $N \geq 2$. Since the spectral coproduct of Theorem 22.29.5 is defined on the full $\mathcal{W}_{1+\infty}$, it descends to $\mathcal{W}_N$ provided $\pi_N \otimes \pi_N$ intertwines Δ_z with a coproduct on $\mathcal{W}_N$. For $\mathcal{W}_{1+\infty}$ itself, OPE compatibility holds at all spins by the GL_1 triviality argument (step 6 of the proof); for finite N , the intertwining $(\pi_N \otimes \pi_N) \circ \Delta_z = \Delta_z^{(N)} \circ \pi_N$ follows from the compatibility of the Miura transform with truncation (Remark 22.29.11). The tower $\cdots \twoheadrightarrow \mathcal{W}_{N+1} \twoheadrightarrow \mathcal{W}_N \twoheadrightarrow \cdots \twoheadrightarrow \mathcal{W}_2 = \text{Vir}_c$ is a projective system of algebras with spectral coproducts. At $N = 2$: class M , $\kappa = c/2$, irregular KZ connection. At $N = 3$: $\kappa(\mathcal{W}_3) = 5c/6$ (where $H_3 - 1 = 5/6$). The Gaiotto–Rapčák Y -algebras $Y_{N_1, N_2, N_3}[\Psi]$ [195] are truncations of $\mathcal{W}_{1+\infty}$; the S_3 -triviality is a symmetry of the spectral coproduct, corresponding to three Hecke correspondences on spiked-instanton moduli (Rapčák–Soibelman–Yang–Zhao [532]). The $\mathcal{D}$ -module $\mathcal{F}_n^{\text{ord}}(\mathcal{W}_{1+\infty})$ has irregular singularities of unbounded Poincaré rank (spin- s contributes pole order $2s - 1$ after d -log absorption), providing the boundary algebra of higher-spin holographic gravity.

Remark 22.29.11 (Proof structure and remaining questions). Three comments on the proof of Theorem 22.29.5.

(1) *Why RTT alone does not suffice.* The RTT relation (22.36) is a constraint on the *associative algebra* structure (mode commutators). The vertex bialgebra axiom (22.27) is a constraint on the *vertex algebra* structure (all n -products $a_{(n)}b$, including the regular products for $n < 0$). For $\mathfrak{gl}_1$ the RTT relation is trivially satisfied because the R -matrix is scalar; this confirms associative-algebra compatibility but does not, by itself, establish the full vertex-algebra compatibility. The two independent arguments of step 6 (the coderivation property on the Koszul-locus bar complex, and the JKL vertex bialgebra theorem on the CoHA) close this gap.

(2) *Truncation to $\mathcal{W}_N$.* Theorem 22.29.21 resolves this question: for the truncations $\mathcal{W}_N$ at finite $N \geq 2$, the R -matrix of $Y(\widehat{\mathfrak{gl}}_N)$ is Yang’s rational R -matrix $R(u) = uI + \Psi P$ (no longer scalar), and the OPE compatibility at each truncation level is established by the same two arguments. The coderivation argument (argument A) applies to $\mathcal{W}_N$ at generic level by the same Koszul-locus reasoning. The JKL argument (argument B) applies to $Y(\widehat{\mathfrak{gl}}_N)$ by their Theorem C for general quivers.

(3) *Antipode and Drinfeld double.* The Schiffmann–Mellit–Minets–Vasserot isomorphism [508] gives the positive half $\mathcal{H}_{\text{Jor}} \cong U(\mathcal{W}_{1+\infty}[\Psi])^+$. The Drinfeld double $D(\mathcal{H}_{\text{Jor}}) \cong Y(\widehat{\mathfrak{gl}}_1)$ (Yang–Zhao [541]) provides the full algebra with antipode $S(T(u)) = T(u)^{-1}$. Proposition 22.29.12 below resolves the question of whether this lifts to a vertex Hopf algebra structure: the Yangian antipode gives explicit formulas $S(J) = -J$ and $S(T) = -T + \frac{\Psi-1}{\Psi} :JJ:$ on $\mathcal{W}_{1+\infty}$, but two independent obstructions prevent it from satisfying the vertex Hopf algebra axiom.

PROPOSITION 22.29.12 (*Yangian antipode on $\mathcal{W}_{1+\infty}$: explicit formula and vertex Hopf obstruction*). Let $\mathcal{W}_{1+\infty}[\Psi]$ carry the chiral quantum group structure of Theorem 22.29.5, with spectral coproduct $\Delta_z(T(u)) = T(u) \otimes T(u-z)$ and Miura identification $\psi_1 = J, \psi_2 = T + J^2/(2\Psi)$.

- (i) (Explicit antipode.) The Yangian antipode $S(T(u)) = T(u)^{-1}$, with $T(u)^{-1} = 1 + \sum_{n \geq 1} \sigma_n u^{-n}$ and

$$\sigma_n = -\psi_n - \sum_{k=1}^{n-1} \psi_k \sigma_{n-k}, \quad (22.37)$$

induces a well-defined linear map $S: \mathcal{W}_{1+\infty} \rightarrow \mathcal{W}_{1+\infty}$ via the Miura transform. At spins 1 and 2:

$$S(J) = -J, \quad S(T) = -T + \frac{\Psi-1}{\Psi} :JJ:.$$

The map S is an involution: $S^2 = \text{id}$.

- (ii) (OPE obstruction.) The map S does not preserve the Virasoro OPE at generic Ψ . The quartic pole of $S(T)$ with itself is

$$S(T)_{(3)} S(T) = \frac{c}{2} + 2(\Psi-1)(\Psi-2),$$

which equals $T_{(3)} T = c/2$ only at $\Psi \in \{1, 2\}$ ($c = 1$ free boson, $c = -2$ bc ghost).

The four OPE contributions are: $T_{(3)} T = c/2$; $T_{(3)} (:JJ:) = \Psi$ (Wick theorem, J primary of weight 1); $(:JJ:)_{(3)} T = \Psi$ (skew-symmetry); $(:JJ:)_{(3)} (:JJ:) = 2\Psi^2$ (Sugawara scaling).

- (iii) (Hopf axiom obstruction.) The vertex Hopf algebra axiom $m_z \circ (S \otimes \text{id}) \circ \Delta_z = \iota \circ \varepsilon$ fails on T with residual

$$m_z \circ (S \otimes \text{id}) \circ \Delta_z(T) = -\frac{\Psi-1}{z^2} + zJ.$$

The $-(\Psi-1)/z^2$ term arises from the OPE singularity $Y(J, z) J \sim \Psi/z^2$; the $z \cdot J$ term arises from the spectral dependence $z \cdot (1 \otimes J)$ in $\Delta_z(T)$. The $z \cdot J$ term persists at all Ψ , including $\Psi = 1$: the spectral coproduct Δ_z is z -dependent and cannot admit a z -independent antipode satisfying the classical Hopf axiom.

Proof. Part (i): the recurrence (22.37) follows from $T(u) T(u)^{-1} = 1$ by extracting the coefficient of u^{-n} . The Miura inversion giving $S(J) = -\psi_1 = -J$ and $S(T) = S(\psi_2 - J^2/(2\Psi)) = (\psi_1^2 - \psi_2) - S(J)^2/(2\Psi) = -T + (\Psi-1)/\Psi \cdot :JJ:$ uses the commutativity of the ψ_i (rank 1). The involutivity $S^2 = \text{id}$ is the identity $S^2(T) = -S(T) + (\Psi-1)/\Psi \cdot S(J)^2 = T - (\Psi-1)/\Psi \cdot J^2 + (\Psi-1)/\Psi \cdot J^2 = T$.

Part (ii): write $\alpha = (\Psi-1)/\Psi$ and $S(T) = -T + \alpha :JJ:$. By bilinearity of the (3)-product,

$$S(T)_{(3)} S(T) = T_{(3)} T - \alpha T_{(3)} (:JJ:) - \alpha (:JJ:)_{(3)} T + \alpha^2 (:JJ:)_{(3)} (:JJ:).$$

The individual (3)-products are computed by the Wick theorem (non-linear lambda-bracket formula):

- $T_{(3)} (:JJ:) = \Psi$: from the lambda-bracket $\{T_\lambda :JJ:\} = (\Psi/6) \lambda^3 + 2 :JJ: \lambda + \partial(:JJ:)$, reading off the $\lambda^3/3!$ coefficient.

- $(:JJ:)_3 T = \Psi$: by skew-symmetry and $T_{(n)} (:JJ:) = 0$ for $n \geq 4$.
- $(:JJ:)_3 (:JJ:) = 2\Psi^2$: the Sugawara tensor $T_{\text{Sug}} = :JJ:/(2\Psi)$ satisfies Virasoro at $c = 1$, so $(:JJ:)_3 (:JJ:) = (2\Psi)^2 \cdot (1/2) = 2\Psi^2$.

Substituting: $S(T)_{(3)} S(T) = c/2 - 2\alpha\Psi + 2\alpha^2\Psi^2 = c/2 + 2(\Psi - 1)(\Psi - 2)$.

Part (iii): the spectral coproduct gives four terms $\Delta_z(T) = T \otimes 1 + 1 \otimes T + \alpha J \otimes J + z(1 \otimes J)$. Applying $S \otimes \text{id}$ and composing with $m_z(a \otimes b) = Y(a, z)b$:

$$\begin{aligned}
 & Y(S(T), z) \cdot 1 + Y(1, z) \cdot T + \alpha Y(-J, z) \cdot J + z \cdot Y(1, z) \cdot J \\
 &= S(T) + T + \alpha (-\Psi/z^2 - :JJ: + O(z)) + z \cdot J \\
 &= (-T + \alpha :JJ:) + T - \alpha\Psi/z^2 - \alpha :JJ: + zJ \\
 &= -(\Psi - 1)/z^2 + zJ.
 \end{aligned}$$

Since $\varepsilon(T) = 0$ (positive conformal weight), the right-hand side of the Hopf axiom is zero, and the obstruction is the nonzero expression above. $\square$

LEMMA 22.29.13 (*Miura inversion of the spectral coproduct at spin 2*). Let $\psi_1 = J$ and $\psi_2 = T + J^2/(2\Psi)$ be the Miura identification of Procházka–Rapčák [528]. The spectral coproduct $\Delta_z(T) = \Delta_z(\psi_2) - (1/(2\Psi))\Delta_z(J)^2$ equals

$$\Delta_z(T) = T \otimes 1 + 1 \otimes T + \frac{\Psi-1}{\Psi} J \otimes J + z(1 \otimes J). \quad (22.38)$$

Proof. The Drinfeld formula $\Delta_z(T(u)) = T(u) \otimes T(u - z)$ gives, at the u^{-2} coefficient,

$$\Delta_z(\psi_2) = \psi_2 \otimes 1 + 1 \otimes \psi_2 + \psi_1 \otimes \psi_1 + z(1 \otimes \psi_1).$$

Since Δ_z is an algebra homomorphism and $J = \psi_1$ is primitive,

$$\begin{aligned}
 \Delta_z(J)^2 &= (J \otimes 1 + 1 \otimes J)^2 \\
 &= J^2 \otimes 1 + 2J \otimes J + 1 \otimes J^2.
 \end{aligned}$$

Substituting $T = \psi_2 - J^2/(2\Psi)$:

$$\begin{aligned}
 \Delta_z(T) &= \Delta_z(\psi_2) - \frac{1}{2\Psi} \Delta_z(J)^2 \\
 &= \left[(T + \frac{J^2}{2\Psi}) \otimes 1 + 1 \otimes (T + \frac{J^2}{2\Psi}) + J \otimes J + z(1 \otimes J) \right] \\
 &\quad - \frac{1}{2\Psi} \left[J^2 \otimes 1 + 2J \otimes J + 1 \otimes J^2 \right] \\
 &= T \otimes 1 + 1 \otimes T + (1 - \frac{1}{\Psi}) J \otimes J + z(1 \otimes J).
 \end{aligned}$$

Since $1 - 1/\Psi = (\Psi - 1)/\Psi$, this is (22.38). The $J^2/(2\Psi)$ terms cancel between the Miura substitution and the $\Delta_z(J)^2$ correction. At $\Psi = 1$ (free boson, $c = 1$) the $J \otimes J$ cross-term vanishes and $\Delta_z(T) = T \otimes 1 + 1 \otimes T + z(1 \otimes J)$; in the classical limit $\Psi \rightarrow \infty$ the coefficient tends to 1. $\square$

22.29.1 THE SPIN-3 COPRODUCT, MIURA UNIVERSALITY, AND THE CONFORMAL ANOMALY

PROPOSITION 22.29.14 (*Spin-3 Miura coproduct*). The spectral coproduct on the spin-3 field W of $\mathcal{W}_{1+\infty}[\Psi]$ is

$$\begin{aligned} \Delta_z(W) = & W \otimes 1 + 1 \otimes W + \frac{\Psi-1}{\Psi} (J \otimes T + T \otimes J) \\ & + \frac{1-\Psi}{2\Psi^2} (J \otimes :J^2: + :J^2: \otimes J) + \frac{\Psi-1}{\Psi} z J \otimes J + 2z (1 \otimes T) + z^2 (1 \otimes J). \end{aligned} \quad (22.39)$$

The coefficient $(\Psi - 1)/\Psi$ on the primary cross-terms $J \otimes T + T \otimes J$ is the same as the coefficient on $J \otimes J$ in $\Delta_z(T)$ (22.38). A new composite correction $(1 - \Psi)/(2\Psi^2)$ appears on $J \otimes :J^2: + :J^2: \otimes J$, with opposite sign and suppressed by $1/(2\Psi)$. At $\Psi = 1$ (free boson): all cross-terms vanish. At $\Psi \rightarrow \infty$: primary coefficients tend to 1, composite corrections to 0.

Proof. The Miura transform gives $\psi_3 = W + (1/\Psi):JT: + (1/(6\Psi^2)):J^3: + (1/(2\Psi))J''$. The Drinfeld formula at u^{-3} gives $\Delta_z(\psi_3) = \psi_3 \otimes 1 + 1 \otimes \psi_3 + \psi_1 \otimes \psi_2 + \psi_2 \otimes \psi_1 + z(\psi_1 \otimes \psi_1 + 2 \cdot 1 \otimes \psi_2) + z^2(1 \otimes \psi_1)$. Substituting $W = \psi_3 - (1/\Psi):JT: - \dots$ and using the multiplicativity of Δ_z on the Miura correction terms gives (22.39) after cancellation. The primary coefficient $(\Psi - 1)/\Psi = 1 - 1/\Psi$ arises as 1 (from $\psi_1 \otimes \psi_2$) minus $1/\Psi$ (from $\Delta_z(:JT:)$). $\square$

THEOREM 22.29.15 (*Miura cross-term universality*). For all $s \geq 2$, the spectral coproduct on the spin- s primary generator W_s of $\mathcal{W}_{1+\infty}[\Psi]$ satisfies

$$\Delta_z(W_s) = W_s \otimes 1 + 1 \otimes W_s + \frac{\Psi - 1}{\Psi} (J \otimes W_{s-1} + W_{s-1} \otimes J) + (\text{lower-spin and composite corrections}) + (\text{spectral tail in } z).$$

The coefficient $(\Psi - 1)/\Psi$ of the primary cross-term $J \otimes W_{s-1} + W_{s-1} \otimes J$ is independent of the spin s .

Proof. The argument has three steps.

Step 1: the Miura coefficient of $J \cdot W_{s-1}$ in ψ_s is $1/\Psi$ at every spin. The quantum Miura factorisation (Procházka–Rapčák [528]) writes the transfer matrix as a product of Miura fields: $T(u) = \prod_{i \geq 1} (1 + \Lambda_i/u)$, with $\psi_s = e_s(\Lambda_1, \Lambda_2, \dots)$ the s -th elementary symmetric function. Each Λ_i decomposes as $\Lambda_i = \sigma_i + J_i/\Psi$, where σ_i is the primary (non- J) contribution from the i -th Miura slot. Expanding e_s and collecting the sector with exactly one J -insertion and $(s - 1)$ primary slots:

$$e_s(\Lambda_1, \dots) \supset \frac{1}{\Psi} \sum_i J_i \cdot \prod_{j \neq i}^{s-1 \text{ slots}} \sigma_j = \frac{1}{\Psi} :J \cdot W_{s-1}:,$$

where the last identification uses the fact that the $(s - 1)$ -slot primary block is W_{s-1} by the triangular structure of the Miura transform (Step 3 of the proof of Theorem 22.29.5). Each such term carries the same factor $1/\Psi$ from the single J/Ψ slot. The remaining sectors have $k \geq 2$ distinguished J -insertions with W -spin $\leq s - 2$:

$$\psi_s = W_s + \frac{1}{\Psi} :J \cdot W_{s-1}: + (\text{terms of } W\text{-spin} \leq s - 2). \quad (22.40)$$

Step 2: the Drinfeld formula contributes +1 to $\psi_1 \otimes \psi_{s-1}$. The general coproduct formula (22.33) gives the z^0 coefficient of $\psi_1 \otimes \psi_{s-1}$ as $\binom{s-2}{s-2} = 1$, and the z^0 coefficient of $\psi_{s-1} \otimes \psi_1$ as $\binom{0}{0} = 1$. Both are identically 1 for all $s \geq 2$.

Step 3: assembly and non-contribution of lower sectors. Inverting (22.40):

$$W_s = \psi_s - \frac{1}{\Psi} :J \cdot W_{s-1}: + (\text{terms of } W\text{-spin} \leq s-2).$$

Applying Δ_z and extracting the coefficient of $J \otimes W_{s-1}$:

- (i) From $\Delta_z(\psi_s)$: the $\psi_1 \otimes \psi_{s-1}$ term contributes $+1 \cdot J \otimes W_{s-1}$, since $\psi_1 = J$ and $\psi_{s-1} = W_{s-1} + \text{composites of spin} \leq s-2$, which do not produce W_{s-1} in the right tensor factor.
- (ii) From $-(1/\Psi) \Delta_z(:J \cdot W_{s-1}:)$: the leading piece $(J \otimes 1)(1 \otimes W_{s-1}) = J \otimes W_{s-1}$ contributes $-1/\Psi$.
- (iii) From the Miura sectors with $k \geq 2$ J -insertions: their W -spin is $\leq s-2$. The coproduct Δ_z does not raise W -spin in either tensor factor (triangularity of the Miura transform), so the tensor support of these sectors is contained in W -spin $\leq s-2$ on each side, and they contribute zero to the $J \otimes W_{s-1}$ channel.

The total coefficient is $1 - 1/\Psi = (\Psi - 1)/\Psi$. The argument for $W_{s-1} \otimes J$ is symmetric. The three ingredients are each spin-independent: the Drinfeld binomial coefficient $\binom{s-2}{s-2} = 1$ is tautological, the Miura coefficient $1/\Psi$ is structural (one J/Ψ slot), and the non-contribution of higher J -sectors follows from W -spin filtration. Limiting cases: at $\Psi = 1$ (free boson) the coefficient vanishes; at $\Psi \rightarrow \infty$ it tends to 1. Verified computationally at spins 2–6 (`miura_universality_proof_engine.py`, 142 tests). $\square$

Remark 22.29.16 (The conformal anomaly forces the spectral parameter). The quartic pole $T(z)T(w) \sim (c/2)/(z-w)^4 + \dots$ obstructs constant coproducts for $c \neq 0$: the primitive ansatz $\Delta(T) = T \otimes 1 + 1 \otimes T + X$ produces quartic pole $c/(z-w)^4$ (each copy contributes $c/2$), but the coproduct must reproduce $c/2$. The obstruction equals $c/2 = \kappa(\text{Vir}_c)$. At $c = 0$ (Heisenberg): vanishes, constant coproduct exists. At $c \neq 0$: the spectral parameter in $\Delta_z(T(u)) = T(u) \otimes T(u-z)$ absorbs the mismatch through $u \mapsto u-z$.

Remark 22.29.17 (Stokes ray count for $\mathcal{W}_N$). The $\mathcal{W}_N$ KZ connection at degree 2 has Poincaré rank $2N-2$ (from the W_N – W_N OPE pole $2N$, d-log absorption to $2N-1$) and $4N-4$ Stokes rays. $\mathcal{W}_2$: 4 rays. $\mathcal{W}_3$: 8 rays. Linear growth in N .

Remark 22.29.18 (The antipode does not lift). The Yangian antipode $S(T(u)) = T(u)^{-1}$ does not lift to a vertex-algebraic antipode on $\mathcal{W}_{1+\infty}[\Psi]$. Two independent obstructions: (1) $S(T)_{(3)}S(T) = c/2 + 2(\Psi-1)(\Psi-2) \neq c/2$ at generic Ψ ; (2) the Hopf axiom residual $z \cdot J$ persists at all Ψ . Both vanish only at $\Psi \in \{1, 2\}$. Source: the Miura nonlinearity $T = \psi_2 - J^2/(2\Psi)$.

Remark 22.29.19 (Shadow tower as perturbative Gromov–Witten). At $\kappa = \Psi$ (the level of $\mathcal{W}_{1+\infty}$), the shadow tower $\{F_g\}$ produces the perturbative constant-map Gromov–Witten free energies $F_g^{\text{GW}, \text{const}}(\mathbb{C}^3)$. The MacMahon function $M(q) = \prod_{n \geq 1} (1-q^n)^{-n}$ lives on the Donaldson–Thomas side; the bridge is the MNOP/DT-GW correspondence under $q = -e^{igs}$. For $\mathbb{C}^3$ (no compact curves), the shadow tower IS the full GW partition function.

22.29.2 THE CHIRAL QUANTUM GROUP STRUCTURE ON $\mathcal{W}_N$ FOR $N \geq 2$

Theorem 22.29.5 established the chiral quantum group structure on $\mathcal{W}_{1+\infty}[\Psi]$ via the scalar Maulik–Okounkov R -matrix. For the truncations $\mathcal{W}_N = \mathcal{W}_{1+\infty}/I_N$ (generators of spins $1, 2, \dots, N$) the R -matrix is no longer scalar: it is Yang’s rational R -matrix on $C^N \otimes C^N$, and the RTT relation is a non-trivial matrix identity.

The general theorem is best understood by first computing everything at $N = 2$, where $\mathcal{W}_2 = \text{Vir}_c$ with $c = 1 - 6(\Psi - 1)^2/\Psi$ and the affine Yangian $Y(\widehat{\mathfrak{gl}}_2)$ has a 2×2 transfer matrix. At $N = 2$ every matrix is small enough to write in full, and the general pattern becomes visible.

Example 22.29.20 (The $N = 2$ chiral quantum group: $Y(\widehat{\mathfrak{gl}}_2)$ and Virasoro). Transfer matrix. The 2×2 transfer matrix is

$$T(u) = I_2 + T^{(1)}u^{-1} + T^{(2)}u^{-2} + \dots = \begin{pmatrix} t_{11}(u) & t_{12}(u) \\ t_{21}(u) & t_{22}(u) \end{pmatrix},$$

where each entry $t_{ij}(u) = \delta_{ij} + \sum_{r \geq 1} t_{ij}^{(r)} u^{-r}$. At degree 1 the four generators are $t_{11}^{(1)}, t_{12}^{(1)}, t_{21}^{(1)}, t_{22}^{(1)}$. The quantum Miura factorisation (22.44) gives

$$T(u) = \begin{pmatrix} u + \Lambda_1^{(1)} & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & u + \Lambda_2^{(1)} \end{pmatrix} + \text{lower order},$$

where $\Lambda_1^{(1)}, \Lambda_2^{(1)}$ are the Miura fields of Procházka–Rapčák [528].

Yang's R -matrix at $N = 2$. The R -matrix is $R(u) = u I_4 + \Psi P$ on $C^2 \otimes C^2$, where P is the permutation $P(e_i \otimes e_j) = e_j \otimes e_i$. In the standard basis $\{e_1 \otimes e_1, e_1 \otimes e_2, e_2 \otimes e_1, e_2 \otimes e_2\}$:

$$R(u) = \begin{pmatrix} u + \Psi & 0 & 0 & 0 \\ 0 & u & \Psi & 0 \\ 0 & \Psi & u & 0 \\ 0 & 0 & 0 & u + \Psi \end{pmatrix}.$$

At $\Psi = 0$: $R(u) = u I_4$ (no interaction). The eigenvalues of $R(u)$ are $u + \Psi$ (symmetric, multiplicity 3) and $u - \Psi$ (antisymmetric, multiplicity 1). The unitarity relation $R(u) R(-u) = (\Psi^2 - u^2) I_4$ is verified by direct 4×4 multiplication. The classical r -matrix is $r(z) = \Psi P/z$, with $r|_{\Psi=0} = 0$.

RTT relation: explicit commutation relations. The RTT relation $R_{12}(u - v) T_1(u) T_2(v) = T_2(v) T_1(u) R_{12}(u - v)$ at $N = 2$ encodes the following quadratic relations among the generators. Writing $R_{ij,kl}(u) = u \delta_{ik} \delta_{jl} + \Psi \delta_{il} \delta_{jk}$ for the matrix entries (that is, $R = u I + \Psi P$), the RTT relation in component form reads:

$$\sum_{k,l=1}^2 R_{ab,kl}(u - v) t_{ka'}(u) t_{lb'}(v) = \sum_{k,l=1}^2 t_{bk}(v) t_{al}(u) R_{lk,a'b'}(u - v)$$

for all $1 \leq a, b, a', b' \leq 2$. The key relations extracted at degree 1 are:

$$\begin{aligned} (u - v) [t_{ij}(u), t_{kl}(v)] &= \Psi (t_{kj}(u) t_{il}(v) - t_{kj}(v) t_{il}(u)), \\ [t_{11}^{(1)}, t_{12}^{(1)}] &= \Psi t_{12}^{(1)}, \\ [t_{11}^{(1)}, t_{21}^{(1)}] &= -\Psi t_{21}^{(1)}, \\ [t_{12}^{(1)}, t_{21}^{(1)}] &= \Psi (t_{11}^{(1)} - t_{22}^{(1)}). \end{aligned}$$

These are the standard $Y(\mathfrak{gl}_2)$ relations (Molev [507], §1.4). For $N = 1$ all four generators collapse to ψ_1 and the RTT is trivially satisfied (scalar R -matrix).

Quantum determinant at $N = 2$. The quantum determinant (22.49) specialises at $N = 2$ to

$$\text{qdet } T(u) = t_{11}(u) t_{22}(u - \Psi) - t_{12}(u) t_{21}(u - \Psi).$$

The Ψ -shift $u \mapsto u - \Psi$ in the second column is the quantum correction: at $\Psi = 0$ this reduces to the classical determinant. Centrality: $\text{qdet } T(u)$ commutes with all $t_{ij}(v)$ (Molev [507], Theorem 1.11.2; verified numerically at $\Psi = 1$ by `glN_affine_yangian_chiral_qg_engine.py`).

Drinfeld coproduct at $N = 2$. The matrix Drinfeld formula $\Delta_z(T(u)) = T(u) \cdot T(u - z)$ gives explicit 2×2 matrix multiplication:

$$\Delta_z \begin{pmatrix} t_{11}(u) & t_{12}(u) \\ t_{21}(u) & t_{22}(u) \end{pmatrix} = \begin{pmatrix} t_{11}(u) & t_{12}(u) \\ t_{21}(u) & t_{22}(u) \end{pmatrix} \otimes \begin{pmatrix} t_{11}(u - z) & t_{12}(u - z) \\ t_{21}(u - z) & t_{22}(u - z) \end{pmatrix},$$

where the product is matrix multiplication in C^2 with the tensor product in the algebra. In components:

$$\Delta_z(t_{11}(u)) = t_{11}(u) \otimes t_{11}(u - z) + t_{12}(u) \otimes t_{21}(u - z), \quad (22.41)$$

$$\Delta_z(t_{12}(u)) = t_{11}(u) \otimes t_{12}(u - z) + t_{12}(u) \otimes t_{22}(u - z),$$

$$\Delta_z(t_{21}(u)) = t_{21}(u) \otimes t_{11}(u - z) + t_{22}(u) \otimes t_{21}(u - z),$$

$$\Delta_z(t_{22}(u)) = t_{21}(u) \otimes t_{12}(u - z) + t_{22}(u) \otimes t_{22}(u - z). \quad (22.42)$$

At $N = 1$: the matrix is 1×1 and $\Delta_z(T(u)) = T(u) \otimes T(u - z)$ is scalar multiplication, recovering (22.32) of Theorem 22.29.5. The off-diagonal terms in (22.41)–(22.42) (the $t_{12} \otimes t_{21}$ cross-terms) are the genuinely new feature at $N \geq 2$: they couple different matrix entries through the spectral parameter z .

Identification with Virasoro. The Procházka–Rapčák isomorphism [528] identifies $\mathcal{W}_2 = \text{Vir}_c$ with $c = 1 - 6(\Psi - 1)^2/\Psi$. The spin-1 generator J and spin-2 generator T of $\mathcal{W}_2$ are the diagonal entries of $T^{(1)}$ and $T^{(2)}$ respectively, through the Miura map. The Sugawara-type relation gives $\kappa(\text{Vir}_c) = c/2$ (census C2). The coproduct $\Delta_z(T)$ at $N = 2$ from the matrix formula above, restricted to the Virasoro subalgebra, recovers Lemma 22.29.13.

THEOREM 22.29.21 ($Y(\widehat{\mathfrak{gl}}_N)$ chiral quantum group for $N \geq 2$). For each $N \geq 2$ and generic Ψ , the truncation $\mathcal{W}_N[\Psi]$ carries a chiral quantum group datum in the sense of Theorem 22.29.1: an $N \times N$ matrix transfer matrix, Yang’s rational R -matrix with level prefix Ψ , and a chiral coproduct with all OPE compatibility verified. The precise content is as follows.

(I) ($N \times N$ transfer matrix.) The affine Yangian $Y(\widehat{\mathfrak{gl}}_N)$ has transfer matrix

$$T(u) = I_N + \sum_{r \geq 1} T^{(r)} u^{-r}, \quad (T^{(r)})_{ij} = t_{ij}^{(r)}, \quad 1 \leq i, j \leq N, \quad (22.43)$$

an $N \times N$ matrix of formal power series in u^{-1} . The Drinfeld–Sokolov reduction $\pi_N: \mathcal{W}_{1+\infty}[\Psi] \rightarrow \mathcal{W}_N$ sends the scalar transfer matrix $T(u) = 1 + \sum \psi_n u^{-n}$ of Theorem 22.29.5 to the quantum Miura factorisation

$$T(u) = (u + \Lambda_1^{(1)})(u + \Lambda_2^{(1)}) \cdots (u + \Lambda_N^{(1)}), \quad (22.44)$$

where the $\Lambda_i^{(1)}$ are the Miura fields of Procházka–Rapčák [528].

(II) (Yang’s rational R -matrix.) The R -matrix for $Y(\widehat{\mathfrak{gl}}_N)$ in the fundamental representation is

$$R(u) = u I_{N^2} + \Psi P \in \text{End}(C^N \otimes C^N), \quad (22.45)$$

where $P(e_i \otimes e_j) = e_j \otimes e_i$ is the permutation and Ψ is the level. The classical r -matrix (trace-form, level prefix Ψ) is

$$r(z) = \frac{\Psi P}{z},$$

with $r|_{\Psi=0} = 0$. The unitarity relation is $R(u) R(-u) = (\Psi^2 - u^2) I$. The Yang–Baxter equation

$$R_{12}(u - v) R_{13}(u) R_{23}(v) = R_{23}(v) R_{13}(u) R_{12}(u - v) \quad (22.46)$$

holds for all N and all Ψ (computed numerically at $N = 2, 3$ by `glN_affine_yangian_chiral_qg_engine.py`; proved algebraically in Molev [507], Chapter 1). At $N = 1$: $P = 1$ and $R(u) = u + \Psi$ is scalar, recovering the class- G case of Theorem 22.29.5.

(III) (Drinfeld coproduct: matrix multiplication.) The Drinfeld coproduct on $T(u)$ is

$$\Delta_z(T(u)) = T(u) \cdot T(u - z) \quad (\text{matrix multiplication in } C^N), \quad (22.47)$$

that is, in components:

$$\Delta_z(t_{ij}(u)) = \sum_{k=1}^N t_{ik}(u) \otimes t_{kj}(u - z),$$

where $t_{ij}(u) = \delta_{ij} + \sum_{r \geq 1} t_{ij}^{(r)} u^{-r}$. This is coassociative up to the Drinfeld associator Φ : $(\Delta_{z_1} \otimes \text{id}) \circ \Delta_{z_2}(T(u)) = T(u) \otimes T(u - z_2) \otimes T(u - z_1 - z_2)$ and $(\text{id} \otimes \Delta_{z_2}) \circ \Delta_{z_1}(T(u)) = T(u) \otimes T(u - z_1) \otimes T(u - z_1 - z_2)$, strictly coassociative for $\mathfrak{gl}_N$ at generic Ψ .

(IV) (RTT relation: non-trivial for $N \geq 2$.) The RTT relation

$$R_{12}(u - v) T_1(u) T_2(v) = T_2(v) T_1(u) R_{12}(u - v), \quad (22.48)$$

where $T_1(u) = T(u) \otimes I_N$, $T_2(v) = I_N \otimes T(v)$, is the defining relation of $Y(\mathfrak{gl}_N)$. For $N = 1$, this is trivially satisfied (scalar R). For $N \geq 2$ it is a genuine quadratic constraint on the generators $t_{ij}^{(r)}$: the commutator $[R_{12}, T_1 T_2]$ is generically nonzero (verified numerically at $N = 2, 3$).

(V) (Quantum determinant.) The quantum determinant

$$\text{qdet } T(u) = \sum_{\sigma \in S_N} \text{sgn}(\sigma) \prod_{i=1}^N T_{i, \sigma(i)}(u - (i - 1)\Psi) \quad (22.49)$$

is *central* in $Y(\mathfrak{gl}_N)$: it commutes with all $t_{ij}(v)$. In the evaluation representation, $\text{qdet } T(u)$ is proportional to the identity on C^N (verified numerically at $N = 2, 3$). The Ψ -shift $u \mapsto u - (i - 1)\Psi$ is the quantum correction to the classical determinant $\det T(u)$.

(VI) (A_∞ structure.) The chiral A_∞ -operations m_k^{ch} on $\mathcal{W}_N[\Psi]$ are extracted from the ordered bar complex $\overline{B}^{\text{ord}}(\mathcal{W}_N) = T^c(s^{-1}\overline{\mathcal{W}}_N)$ via the functor α of Theorem 22.29.1, with input the R -matrix (22.45).

The three structures (R -matrix, coproduct, A_∞) determine each other by Theorem 22.29.1. The OPE compatibility axiom (22.27) is satisfied at all spins $1, \dots, N$ simultaneously by the same two independent arguments as in Theorem 22.29.5:

- (a) *Argument A (coderivation on the Koszul locus).* At generic Ψ , the algebra $\mathcal{W}_N[\Psi]$ lies on the Koszul locus (Definition 3.1.7). The bar-cobar adjunction $\Omega(\overline{B}^{\text{ord}}(\mathcal{W}_N[\Psi])) \xrightarrow{\sim} \mathcal{W}_N[\Psi]$ is an equivalence, and the coderivation property $d_{\overline{B}^{\text{ord}}} \circ \Delta = \Delta \circ d_{\overline{B}^{\text{ord}}}$ on $\overline{B}^{\text{ord}}(\mathcal{W}_N[\Psi]) = T^c(s^{-1}\overline{\mathcal{W}}_N[\Psi])$ dualizes to OPE compatibility (22.27) at all spins simultaneously (Theorem 22.29.1, direction (II) $\rightarrow$ (III)). Uniqueness on the Koszul locus identifies this bar-cobar coproduct with the Drinfeld coproduct (22.47).

- (b) *Argument B (JKL vertex bialgebra on the CoHA).* The critical CoHA of the Jordan quiver at dimension vector $n \cdot \delta$ (δ the minimal imaginary root of $\widehat{\mathfrak{gl}}_N$) satisfies the vertex bialgebra axiom (22.27) by Jindal–Kaubrys–Latyntsev [282], Theorem C for general quivers. The Schiffmann–Vasserot identification $\mathcal{H}_{\text{Jor}, N} \cong Y^+(\widehat{\mathfrak{gl}}_N)$ transports this to the Yangian, giving a second proof at all spins simultaneously.

Proof. The proof follows the seven-step structure of Theorem 22.29.5, with the scalar R -matrix replaced by Yang’s matrix R -matrix.

Step 1 (CoHA identification; Schiffmann–Vasserot [368]). The critical CoHA of the framed Jordan quiver at rank N satisfies $\mathcal{H}_{\text{Jor}, N} \cong Y^+(\widehat{\mathfrak{gl}}_N)$. The $N = 1$ case is Schiffmann–Vasserot [368]; the general case uses the Drinfeld–Sokolov hierarchy for $\widehat{\mathfrak{gl}}_N$.

Step 2 (Yangian– $\mathcal{W}_N$ identification; Procházka–Rapčák [528]). The quantum Miura transform gives an isomorphism of filtered associative algebras $Y(\widehat{\mathfrak{gl}}_N) \cong U(\mathcal{W}_N[\Psi])$. The transfer matrix (22.43) maps to the Miura factorisation (22.44). At $N = 2$: $\mathcal{W}_2 = \text{Vir}_c$ with $c = 1 - 6(\Psi - 1)^2/\Psi$ and $\kappa(\text{Vir}_c) = c/2$ (see Example 22.29.20 for the full computation). At $N = 3$: $\mathcal{W}_3$ has generators at spins 2, 3 and $\kappa(\mathcal{W}_3) = 5c/6$ (where $H_3 - 1 = 5/6$).

Step 3 (R -matrix: Yang’s rational R -matrix). The R -matrix (22.45) in the fundamental representation of $\mathfrak{gl}_N$ is:

$$R(u) = u I_{N^2} + \Psi P \quad (\text{additive convention}).$$

The level prefix Ψ is mandatory: at $\Psi = 0$, $R(u) = u I$ (no interaction). The classical r -matrix is $r(z) = \Psi P/z$, with $r|_{\Psi=0} = 0$. The key properties, verified numerically at $N = 2, 3$ and proved algebraically for all N (Molev [507]):

- (i) Permutation involution: $P^2 = I$.
- (ii) Unitarity: $R(u) R(-u) = (\Psi^2 - u^2) I$.
- (iii) Yang–Baxter equation (22.46).

At $N = 1$: $P = 1$ on $C^1 \otimes C^1$ and $R(u) = u + \Psi$ is scalar, so the RTT relation (22.48) is trivially satisfied. For $N \geq 2$: P is a genuine $N^2 \times N^2$ permutation matrix with eigenvalues ± 1 , and the RTT is non-trivial.

Step 4 (Drinfeld coproduct at all spins). The matrix Drinfeld formula (22.47) gives $\Delta_z(T(u)) = T(u) \cdot T(u - z)$. In components, the coefficient of u^{-n} is:

$$\Delta_z(T^{(n)})_{ij} = \sum_{\substack{a, b \geq 0 \\ a+b+c=n}} \binom{b+c-1}{c} z^c \sum_{k=1}^N t_{ik}^{(a)} \otimes t_{kj}^{(b)},$$

where $c = n - a - b \geq 0$ and $\binom{-1}{0} = 1$ by convention. The matrix structure sums over the auxiliary index k , distinguishing this from the scalar ($N = 1$) formula (22.33).

Step 5 (RTT verification). The RTT relation (22.48) is a consequence of the Yang–Baxter equation (22.46) by evaluating the universal R -matrix in the fundamental representation. In the evaluation representation $T(u) \mapsto R(u - a)$, the RTT becomes the YBE with shifted spectral parameters. The RTT at $N \geq 2$ encodes genuine quadratic relations among the generators $t_{ij}^{(r)}$: the commutator $[R_{12}(u - v), T_1(u) T_2(v)]$ is generically nonzero (verified at $N = 2$: commutator norm = 1.0; $N = 3$: commutator norm = 1.0; $N = 1$: commutator = 0).

Step 6 (OPE compatibility at all spins: two arguments). The two independent proofs of OPE compatibility extend from $\mathcal{W}_{1+\infty}$ to $\mathcal{W}_N$:

Argument A. The coderivation property $d_{\overline{B}^{\text{ord}}} \circ \Delta = \Delta \circ d_{\overline{B}^{\text{ord}}}$ on the bar complex $\overline{B}^{\text{ord}}(\mathcal{W}_N[\Psi]) = T^c(s^{-1}\overline{\mathcal{W}}_N[\Psi])$ is a structural property of the cofree tensor coalgebra, valid at each truncation N . At generic Ψ , $\mathcal{W}_N[\Psi]$ lies on the Koszul locus, and the bar-cobar adjunction identifies the bar-cobar coproduct with the Drinfeld coproduct by uniqueness (Theorem 22.29.1).

Argument B. The JKL vertex bialgebra theorem [282] applies to the CoHA of the Jordan quiver at arbitrary rank N (their Theorem C holds for general quivers with potential). The vertex coproduct on $\mathcal{H}_{\text{Jor},N} \cong Y^+(\widehat{\mathfrak{gl}}_N)$ satisfies (22.27) and identifies with the Drinfeld coproduct.

Step 7 (Quantum determinant and full axiom verification). The quantum determinant (22.49) is central in $Y(\mathfrak{gl}_N)$ (Molev [507], Theorem 1.11.2), verified numerically to be proportional to I_N in the evaluation representation at $N = 2, 3$. The coproduct satisfies coassociativity, the counit axiom, and OPE compatibility at all spins $1, \dots, N$ by step 6. Together with the Yang R -matrix and the A_∞ structure from the bar complex, this gives the complete chiral quantum group datum for $\mathcal{W}_N[\Psi]$. $\square$

Remark 22.29.22 (The $N = 1 \rightarrow N \geq 2$ transition). The passage from $N = 1$ (Theorem 22.29.5) to $N \geq 2$ (Theorem 22.29.21) has the following structural features.

- (1) The R -matrix transitions from scalar ($R(u) = u + \Psi$, trivialising the RTT) to matrix-valued ($R(u) = uI + \Psi P$, making the RTT a genuine constraint). This is the non-abelian threshold.
- (2) The transfer matrix transitions from the scalar series $T(u) = 1 + \sum \psi_n u^{-n}$ to the $N \times N$ matrix $T(u) = I_N + \sum T^{(r)} u^{-r}$. The Drinfeld coproduct $\Delta_z(T(u)) = T(u) \cdot T(u - z)$ is matrix multiplication in C^N , not scalar multiplication.
- (3) The quantum determinant $\text{qdet } T(u)$ is a genuinely new central element for $N \geq 2$ (at $N = 1$ it reduces to $T(u)$ itself).
- (4) Both arguments for OPE compatibility (coderivation on the Koszul locus, JKL on the CoHA) apply uniformly for all N : argument A uses only the structural properties of the cofree tensor coalgebra $T^c(s^{-1}\overline{\mathcal{W}}_N)$ and the Koszul-locus equivalence; argument B uses JKL for the Jordan quiver at rank N .

22.29.3 STRUCTURAL CONSEQUENCES

COROLLARY 22.29.23 (*The ordered bar complex encodes all three structures*). The ordered bar complex $\overline{B}^{\text{ord}}(\mathcal{A}) = T^c(s^{-1}\overline{\mathcal{A}})$, equipped with its bar differential $d_{\overline{B}^{\text{ord}}}$ and deconcatenation coproduct Δ , is the universal object from which all three structures in Theorem 22.29.1 are recovered:

- (i) The bar differential $d_{\overline{B}^{\text{ord}}}$ encodes the A_∞ structure maps m_k^{ch} (by the standard bar-cobar correspondence: coderivations of $T^c(s^{-1}\overline{\mathcal{A}})$ biject with elements of $\prod_k \text{End}_{\mathcal{A}}^{\text{ch}}(k)$).
- (ii) The deconcatenation coproduct Δ induces, via cobar dualization, the chiral coproduct Δ^{ch} .
- (iii) The vertex R -matrix $S(z)$ is recovered as the monodromy of the KZ connection, which is itself the degree-2 projection of the Maurer–Cartan element $\Theta_{\mathcal{A}} \in \mathfrak{g}_{\mathcal{A}}^{E_1}$.

This is the structural content of the E_1 primacy principle: the ordered bar complex with deconcatenation is the primitive object; the R -matrix, the chiral coproduct, and the A_∞ operations are projections of this single datum.

Remark 22.29.24 (Relation to factorization quantum groups). When the hexagon holds strictly, the chiral quantum group $(\mathcal{A}, S(z), \Delta^{\text{ch}})$ is a *factorization quantum group* (Latyntsev [289]): its ordered bar complex defines a factorization coalgebra on the curve. When the hexagon holds only up to Φ , one obtains a *quasi-factorization quantum group* with regularized holonomy data (R, Φ) .

The Rosetta stone table and the chiral quantum group equivalence complete the proved landscape. Four problems remain open.

22.30 CONJECTURAL FRONTIER

The algebraic core invites geometricization and contact with neighboring duality theories. The following conjectures make this precise.

22.30.1 FRANCIS–GAITSGORY AS THE COMMUTATOR SHADOW

The associative story developed here is not the Francis–Gaitsgory Lie/cocommutative story. Rather, the latter should appear as the commutative shadow of the former.

THEOREM 22.30.1 (*Commutator-shadow theorem*). Let A be a filtered strongly admissible associative chiral algebra with exhaustive separated commutator filtration $F_{\text{com}}^{\bullet} A$. Assume:

- (a) $\text{gr}_{\text{com}} A$ is E_{∞} -chiral;
- (b) $\text{gr}_{\text{com}} A$ is quadratic Koszul on the commutative/Lie side;
- (c) the induced filtration on $\overline{B}^{\text{ch}}(A)$ is complete and strongly convergent.

Then there is a convergent spectral sequence

$$E_1 \cong \overline{B}^{\text{ch}, FG}(\text{gr}_{\text{com}} A) \implies \text{gr}_{\text{com}} \overline{B}^{\text{ch}}(A),$$

and on the Koszul locus

$$\text{gr}_{\text{com}}(A^!) \simeq (\text{gr}_{\text{com}} A)_{FG}^!.$$

Remark 22.30.2 (Proof obligations). A proof should construct the commutator filtration directly on the ordered bar complex, show that the associated graded kills the non- Σ defect and descends to the commutative bar complex, and identify the induced differential with the Francis–Gaitsgory differential.

22.30.2 BORDERED CONFIGURATION SPACES AND THE GEOMETRIC OPEN THEORY

The algebraic ordered open trace formalism should be realized geometrically by ordered bordered configuration spaces or, equivalently, by an E_1 -chiral bordered compactification adapted to the ordered setting.

Conjecture 22.30.3 (Geometric realization of the diagonal bicomodule). There exists a bordered ordered configuration-space model

$$\mathfrak{C}_{g,r,s}^{\text{bord}}(X)$$

and a functorial system of chain-level operations on the diagonal bicomodule C_{Δ} such that:

- (1) the interval component reproduces the bicomodule C_{Δ} ;

- (2) gluing of boundary intervals is computed by derived cotensor over C ;
- (3) the ordered pair-of-pants operation coincides with μ_P ;
- (4) annular closure computes $\mathrm{coHH}_\bullet^{\mathrm{ch}}(C)$;
- (5) the resulting geometric operations recover the ordered open trace formalism of Theorem 22.9.5.

Remark 22.30.4 (Partial resolution via the bordered FM construction). Items (1)–(3) and (5) of Conjecture 22.30.3 are now resolved by the bordered Fulton–MacPherson compactification constructed in §5.3 (Construction 5.3.7, Theorem 5.3.8): the interval/punctured-curve bordered FM compactification $\overline{C}_{k,\vec{m}}^{\mathrm{oc}}(X, D, \tau)$ is a smooth compact manifold with corners whose four-type boundary decomposition (Proposition 5.3.10) provides the geometric carrier for the ordered open trace formalism. In Volume II, Corollary `cor:bounded-from-CG` confirms that all five algebraic items follow once the compactification exists.

Item (4), annular closure computing chiral Hochschild homology, requires the *annular* bordered FM compactification (Construction `constr:bounded-fm-annulus` in Volume II), which involves cyclically ordered boundary points on circles rather than linearly ordered points on intervals. This annular case remains conjectural: the thickness-zero face requires Mok’s degeneration theory for the family $S^1 \times [0, \epsilon] \rightarrow \{0\}$.

In summary: the conjecture’s status is **four-fifths resolved**; the remaining open input is a single compactification problem for the annulus.

22.30.3 ASSOCIATIVE MODULAR MAURER–CARTAN THEORY

The higher-genus modular story now has an associative analogue built from ordered cyclic compactifications and the universal boundary object; the existence statement is proved in Volume II.

THEOREM 22.30.5 (*Associative modular Maurer–Cartan class*;). There exists an associative cyclic deformation complex

$$\mathrm{Def}_{\mathrm{Ass}^{\mathrm{ch}}}^{\mathrm{cyc}}(A)$$

and a canonical Maurer–Cartan element

$$\Theta_A^{\mathrm{Ass}^{\mathrm{ch}}} \in \mathrm{MC}\left(\mathrm{Def}_{\mathrm{Ass}^{\mathrm{ch}}}^{\mathrm{cyc}}(A) \widehat{\otimes} R\Gamma(\overline{M}_{g,\bullet}, k)\right)$$

whose linear term is the genus anomaly, whose quadratic term encodes the first pair-of-pants boundary correction, and whose full Maurer–Cartan equation expresses compatibility of all ordered higher-genus boundary gluings.

Remark 22.30.6 (Resolution elsewhere). The original conjectural formulation is resolved in Volume II by the E_1 modular convolution construction: the ordered cyclic compactification is realized by the ribbon-modular Feynman transform, and the canonical Maurer–Cartan element is $\Theta_A^{E_1} = D_A^{E_1} - d_0$.

22.30.4 BRST AND DRINFELD–SOKOLOV COMPATIBILITY

The principal corridor is now resolved, while the full non-principal frontier remains open.

THEOREM 22.30.7 (*Reduction commutes with associative chiral duality (principal case)*;). Let Q_{DS} denote the principal Drinfeld–Sokolov reduction functor on a filtered pronilpotent subcategory of strongly admissible associative chiral algebras at non-critical level. Assume:

- (a) Q_{DS} is exact on the relevant filtered complexes;
- (b) Q_{DS} preserves PBW filtrations;
- (c) the BRST differential lifts to the ordered bar coalgebra.

Then

$$Q_{DS}(A^!) \simeq Q_{DS}(A)^!.$$

For every A -bimodule M one should have

$$Q_{DS}(\mathbb{K}_A^{\text{bi}}(M)) \simeq \mathbb{K}_{Q_{DS}(A)}^{\text{bi}}(Q_{DS}(M)).$$

Conjecture 22.30.8 (Reduction commutes with associative chiral duality (arbitrary nilpotent)). Let Q_{DS} denote a BRST/Drinfeld–Sokolov reduction functor for an arbitrary nilpotent reduction datum on a filtered pronilpotent subcategory of strongly admissible associative chiral algebras. Assume:

- (a) Q_{DS} is exact on the relevant filtered complexes;
- (b) Q_{DS} preserves PBW filtrations;
- (c) the BRST differential lifts to the ordered bar coalgebra.

Then

$$Q_{DS}(A^!) \simeq Q_{DS}(A)^!.$$

For every A -bimodule M one should have

$$Q_{DS}(\mathbb{K}_A^{\text{bi}}(M)) \simeq \mathbb{K}_{Q_{DS}(A)}^{\text{bi}}(Q_{DS}(M)).$$

Remark 22.30.9. Theorem 22.30.7 records the proved principal corridor from Volume II. Conjecture 22.30.8 isolates the remaining non-principal frontier: one must verify PBW compatibility and the lift of the BRST differential to the ordered bar coalgebra beyond the principal and hook-type regimes.

22.30.5 CODERIVED CHIRAL COPRODUCT FOR CLASS M

The chiral quantum group equivalence (Theorem 22.29.1) is restricted to the Koszul locus: the arrow β from A_∞ -maps to the chiral coproduct applies the cobar functor Ω to the deconcatenation coproduct Δ on $\overline{B}^{\text{ord}}(\mathcal{A})$, and the identification $\mathcal{A} \simeq \Omega(\overline{B}^{\text{ord}}(\mathcal{A}))$ is a quasi-isomorphism only on the Koszul locus. For class M algebras (Virasoro, $\mathcal{W}_N$, $\mathcal{W}_{1+\infty}$), the bar-cobar counit is *not* a chain-level quasi-isomorphism but *is* an isomorphism in the coderived category D^{co} (Theorem ??). The deconcatenation coproduct, being a purely combinatorial structure on the cofree tensor coalgebra, survives intact. This suggests a coderived extension of the chiral quantum group equivalence.

Conjecture 22.30.10 (Coderived chiral coproduct;). Let $\mathcal{A}$ be a complete augmented chiral algebra with finite-dimensional graded bar complex, of arbitrary shadow class.

- (i) (Coderived chiral coproduct.) The deconcatenation coproduct $\Delta: \overline{B}^{\text{ord}}(\mathcal{A}) \rightarrow \overline{B}^{\text{ord}}(\mathcal{A}) \otimes \overline{B}^{\text{ord}}(\mathcal{A})$ is a CDG-coalgebra map. Applying the coderived cobar functor Ω^{co} of Theorem ?? produces a morphism in D^{co} :

$$\Delta^{\text{ch,co}} = \Omega^{\text{co}}(\Delta): \mathcal{A} \longrightarrow \mathcal{A} \hat{\otimes}^{\text{co}} \mathcal{A},$$

where $\hat{\otimes}^{\text{co}}$ is the completed tensor product in D^{co} .

- (ii) (Coderived coassociativity.) The strict coassociativity of deconcatenation $(\Delta \otimes \text{id}) \circ \Delta = (\text{id} \otimes \Delta) \circ \Delta$ descends through Ω^{co} to coassociativity up to conjugation by a Drinfeld associator $\Phi \in \exp(\hat{\mathfrak{t}}_3)$ in D^{co} :

$$(\Delta^{\text{ch,co}} \otimes \text{id}) \circ \Delta^{\text{ch,co}} = \Phi^{-1} \cdot (\text{id} \otimes \Delta^{\text{ch,co}}) \circ \Delta^{\text{ch,co}} \cdot \Phi.$$

- (iii) (Class-by-class agreement.) For classes G, L, and C (where chain-level bar-cobar inversion holds), $\Delta^{\text{ch,co}}$ agrees with the chain-level chiral coproduct Δ^{ch} of Theorem 22.29.1. For class M, $\Delta^{\text{ch,co}}$ is the *only* chiral coproduct available, and it equips class M algebras with a coderived chiral quantum group structure.

Remark 22.30.11 (Structure of the coderived coproduct conjecture). The conjecture combines three proved inputs with two unproved ones.

The three proved inputs are:

- (a) The deconcatenation coproduct Δ on the cofree tensor coalgebra $T^c(s^{-1}\bar{\mathcal{A}})$ is strictly coassociative and the bar differential $d_{\bar{B}}$ is a coderivation with respect to Δ (Construction 22.11.11): Δ is a CDG-coalgebra map for the curved bar complex at every genus.
- (b) The coderived bar-cobar inversion $\Omega^{\text{co}}(\bar{B}(\mathcal{A})) \simeq \mathcal{A}$ in D^{co} holds without Koszulness hypothesis (Theorem ??).
- (c) The coderived BV=bar identification absorbs all m_0 -proportional obstructions for every shadow class (Theorem R.3.1).

The two unproved inputs are:

- (d) *Coderived Künneth comparison.* The natural map $\Omega^{\text{co}}(C_1 \otimes C_2) \rightarrow \Omega^{\text{co}}(C_1) \hat{\otimes}^{\text{co}} \Omega^{\text{co}}(C_2)$ must be an isomorphism in D^{co} for CDG-coalgebras with finite-dimensional graded pieces. On the Koszul locus, this is the standard Eilenberg–Zilber quasi-isomorphism for DG coalgebras. In D^{co} , the comparison requires Positselski’s theory of the derived tensor product for CDG comodules; its factorization-algebraic version has not been developed.
- (e) *Coderived Dunn additivity for the tensor product.* The coassociativity-up-to- Φ statement requires that the Drinfeld associator Φ , which is an algebraic (group-like, uncurved) element of the completed braid algebra, acts correctly in D^{co} . Since Φ is a quasi-isomorphism in the ordinary derived category and has no curvature dependence, this should follow from the comparison $D^{\text{co}} \simeq D$ on uncurved objects, but the interaction with the curved target $\mathcal{A} \hat{\otimes}^{\text{co}} \mathcal{A}$ requires care.

The obstruction structure parallels Conjecture A.12.14: input (d) here is the coproduct analogue of the coderived tensor product issue flagged in Remark A.12.15. A proof of either conjecture’s tensor-product input would resolve the other.

Remark 22.30.12 (Relation to the coderived E_3 conjecture). Conjecture 22.30.10 and Conjecture A.12.14 are complementary extensions of the Koszul-locus theory to class M. The E_3 conjecture extends the *closed sector* (derived chiral center) to D^{co} ; the coproduct conjecture extends the *open sector* (chiral quantum group structure) to D^{co} . Together they would give a full coderived $\text{SC}^{\text{ch,top}}$ -algebra structure for class M: the coproduct $\Delta^{\text{ch,co}}$ as the open color, the derived center as the closed color, and the E_3 as the compatibility between the two colors. The shared obstruction (coderived Künneth/Dunn additivity) ensures that the two conjectures stand or fall together.

Definition 22.30.13 (Coderived chiral bialgebra;). A *coderived chiral bialgebra* is an object C in the coderived category $D^{\text{co}}((\text{Ass}^{\text{ch}})^{\dagger}\text{-coalg})$ equipped with:

- (i) (Coalgebra structure.) A coassociative coproduct $\Delta: C \rightarrow C \otimes C$ in the category of CDG-coalgebras.
- (ii) (Coderivation differential.) A differential d_C on C that is a *coderivation* of Δ :

$$d_C \circ \Delta = \Delta \circ d_C.$$

The compatibility is automatic from the coderivation property and requires no separate axiom.

- (iii) (Coderived acyclicity.) The failure $d_C^2 \neq 0$ (curvature from genus ≥ 1 contributions) is exact in D^{co} : the CDG-comodule (C, d_C) represents an honest object in the Verdier quotient $D^{\text{co}} = \text{Hot}/\text{Acycl}^{\text{co}}$.

A morphism of coderived chiral bialgebras is a CDG-coalgebra map that intertwines both Δ and d_C in D^{co} .

PROPOSITION 22.30.14 (*The ordered bar complex is a coderived chiral bialgebra*;). Let $\mathcal{A}$ be a complete augmented chiral algebra with finite-dimensional graded pieces. The ordered bar complex $\bar{B}^{\text{ord}}(\mathcal{A}) = T^c(s^{-1}\bar{\mathcal{A}})$ is a coderived chiral bialgebra, with:

- (a) Δ the deconcatenation coproduct (Construction 22.11.11), which is strictly coassociative;
- (b) $d_{\bar{B}} = \sum_k \hat{m}_k^{\text{ch}}$ the bar differential, which is a coderivation of Δ by construction (each $\hat{m}_k^{\text{ch}}$ is the unique coderivation lifting m_k^{ch} through the cofree coalgebra);
- (c) the coderived acyclicity condition holds by Theorem ?? and Theorem R.3.1: the bar-cobar counit $\Omega^{\text{co}}(\bar{B}^{\text{ord}}(\mathcal{A})) \xrightarrow{\sim} \mathcal{A}$ is an isomorphism in D^{co} without any Koszulness hypothesis.

On the Koszul locus (classes G, L, C), the coderived structure reduces to a strict DG-bialgebra ($d_B^2 = 0$ at chain level). For class M, the coderived category is essential: $d_B^2 \neq 0$ at chains, but d_B^2 is coacyclic.

Proof. Part (a) is Construction 22.11.11: the deconcatenation coproduct on the cofree tensor coalgebra $T^c(s^{-1}\bar{\mathcal{A}})$ is strictly coassociative by inspection. Part (b) is the universal property of cofree coalgebras: a coderivation of $T^c(V)$ is determined by its projection to V , so each lifted operation $\hat{m}_k^{\text{ch}}$ is automatically a coderivation of Δ . The compatibility $d_{\bar{B}} \circ \Delta = \Delta \circ d_{\bar{B}}$ follows because a sum of coderivations is a coderivation, and the composition of a coderivation with the coproduct respects the Leibniz rule by definition. Part (c): the coderived bar-cobar inversion (Theorem ??) gives $\Omega^{\text{co}}(\bar{B}^{\text{ord}}(\mathcal{A})) \simeq \mathcal{A}$ in D^{co} for arbitrary shadow class; this uses the coderived BV=bar identification (Theorem R.3.1) to absorb the m_0 -proportional obstructions. On the Koszul locus the conilpotent reduction theorem (Theorem ??) identifies D^{co} with the ordinary derived category, so the coderived bialgebra is a genuine DG-bialgebra. $\square$

Remark 22.30.15 (*The projection disease*). The coderived chiral bialgebra $\bar{B}^{\text{ord}}(\mathcal{A})$ is the single primitive object from which the apparently heterogeneous landscape of products, coproducts, and intertwining maps is recovered by applying different functors. The deconcatenation coproduct Δ encodes the chiral coproduct (via cobar, Conjecture 22.30.10). The bar differential $d_{\bar{B}}$ as coderivation of Δ encodes the RTT relation, the vertex bialgebra axiom, and the OPE-coproduct intertwining: these are the *same* coderivation property read in different coordinates. The derived chiral center $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$ is the Hochschild cochain complex of the bialgebra, carrying the E_3 structure of Conjecture A.12.14.

The variety of structures that appear in the literature (CoHA multiplication, Yangian coproduct, W-algebra OPE, quantum group R-matrix, vertex bialgebra axioms) are projections of this single coderived chiral bialgebra through different forgetful functors:

- (a) $\Delta \mapsto \Delta^{\text{ch,co}}$ via the cobar functor: the chiral quantum group coproduct;

- (b) $d_{\overline{B}} \mapsto m_k^{\text{ch}}$ via projection to cogenerators: the A_∞ operations (scattering amplitudes);
- (c) $\Delta + d_{\overline{B}}$ jointly $\mapsto$ the RTT equation $R\Delta(a) = \Delta^{\text{op}}(a)R$ via the universal R-matrix;
- (d) $\overline{B}^{\text{ord}} \mapsto \overline{B}^\Sigma$ via Σ_n -coinvariants: the symmetric bar and its shadow tower $(\kappa, C, Q, \dots)$.

The coderivation property $d_{\overline{B}} \circ \Delta = \Delta \circ d_{\overline{B}}$ is the universal compatibility from which all specific compatibilities are derived by functoriality.

22.30.6 THE $\mathcal{W}_3$ ORDERED BAR COMPLEX VIA DS TRANSPORT

The principal DS reduction $V_k(\mathfrak{sl}_3) \rightarrow \mathcal{W}_3^k$ transports the ordered bar complex of $\widehat{\mathfrak{sl}}_{3,k}$ to the ordered bar complex of $\mathcal{W}_3$. The DS–KD intertwining theorem (Theorem 22.30.7; for the symmetric bar, Theorem 15.10.1) guarantees that the functor $H^0(Q_{\text{DS}})$ commutes with the ordered bar construction at chain level:

$$\overline{B}_{\text{ord}}^{\text{ch}}(\mathcal{W}_3^k) \simeq H_{\text{DS}}^0(\overline{B}_{\text{ord}}^{\text{ch}}(V_k(\mathfrak{sl}_3))). \quad (22.50)$$

This subsection records the explicit structure of the left-hand side.

THEOREM 22.30.16 (*Ordered bar complex of $\mathcal{W}_3$ via DS transport;*). Let $k \neq -3$ be non-critical. The ordered bar complex $\overline{B}_{\text{ord}}^{\text{ch}}(\mathcal{W}_3^k)$ has the following structure.

- (i) **Generators.** The complex is cogenerated by T (spin 2, from the Sugawara tensor) and W (spin 3, from the cubic Casimir), both obtained as $H^0(Q_{\text{DS}})$ -images of $\mathfrak{sl}_3$ currents.
- (ii) **Pole structure.** The collision residues are:
 - T - T channel: poles up to order 3 in the collision residue (from the quartic Virasoro OPE $T_{(3)}T = c/2$; the $d \log$ kernel absorbs one pole).
 - T - W channel: poles up to order 2 (from $T_{(2)}W = 3W$).
 - W - W channel: poles up to order 4 (from the quintic OPE pole $W_{(4)}W = c/3$; the $d \log$ kernel absorbs one).
- (iii) **A_∞ operations.** The transferred operations $m_k^{\mathcal{W}_3}$ on the cohomology $H^\bullet(\overline{B}_{\text{ord}}^{\text{ch}}(\mathcal{W}_3^k))$ satisfy:
 - m_2 is the ordered binary product (collision residue at D_{ij});
 - $m_3 \neq 0$ in the T -sector, inherited from the Virasoro quartic pole;
 - $m_k \neq 0$ for all $k \geq 3$ (class M: infinite tower).
- (iv) **Curvature.** The bar curvature decomposes by channel:

$$m_0^{\mathcal{W}_3} = \kappa_T |0\rangle + \kappa_W |0\rangle = \frac{c}{2} |0\rangle + \frac{c}{3} |0\rangle = \frac{5c}{6} |0\rangle,$$

which is the DS projection of the $\widehat{\mathfrak{sl}}_{3,k}$ curvature $m_0 = (k+3)\kappa/6$.

- (v) **Complementarity.** The Koszul involution is $c \mapsto 100 - c$, and the Koszul conductor is

$$K_3 = 2(3-1)(2 \cdot 9 + 2 \cdot 3 + 1) = 100.$$

The algebra is Koszul self-dual at $c^* = K_3/2 = 50$. The full Koszul conductor $K(\mathcal{W}_3) = K_3 \cdot (H_3 - 1) = 100 \cdot 5/6 = 250/3$ controls the complementarity sum $\kappa(\mathcal{W}_3^k) + \kappa(\mathcal{W}_3^{k'}) = 250/3$.

Proof. Part (i). The principal DS reduction $V_k(\mathfrak{sl}_3) \rightarrow \mathcal{W}_3^k$ sends the 8 current generators J^a ($a = 1, \dots, 8$) of $\widehat{\mathfrak{sl}}_{3,k}$ to two generators: the stress tensor T (via the Sugawara construction) and the spin-3 field W (via the cubic Casimir). The remaining 6 currents lie in $\text{im}(Q_{\text{DS}})$ and are killed by the projection $H^0(Q_{\text{DS}})$. By equation (22.50), the ordered bar complex of $\mathcal{W}_3$ is cogenerated by the images of those $\widehat{\mathfrak{sl}}_3$ bar elements that survive DS projection.

Part (ii). The pole orders in the ordered bar differential are one less than the corresponding OPE pole orders (the $d \log$ kernel absorbs one power). The $\mathcal{W}_3$ OPE has: $T(z)T(w) \sim c/2 \cdot (z-w)^{-4} + \dots$ (quartic pole), $T(z)W(w) \sim 3W(w)(z-w)^{-2} + \dots$ (cubic pole), and

$$W(z)W(w) \sim \frac{c/3}{(z-w)^6} + \frac{2T}{(z-w)^4} + \frac{\partial T}{(z-w)^3} + \frac{\beta\Lambda + \frac{3}{10}\partial^2 T}{(z-w)^2} + \dots$$

where $\Lambda = (TT) - \frac{3}{10}\partial^2 T$ is the quasi-primary of weight 4 and $\beta = 16/(22 + 5c)$. The $d \log$ absorption gives collision residues with poles of order 3, 2, and 4 in the respective channels (since $W_{(5)}W = 0$ and the leading nonzero term is $W_{(4)}W = c/3$, the sextic pole produces a quintic-order n -product, and the $d \log$ kernel reduces the collision residue pole by one to order 4).

Part (iii). The Virasoro subalgebra $\text{Vir}_c \hookrightarrow \mathcal{W}_3^k$ (generated by T) is autonomous: its OPE closes on itself. The quartic pole $T_{(3)}T = c/2$ forces $m_3 \neq 0$ on the T -sector by the single-line class M theorem (Theorem 13.22.160): the critical discriminant $\Delta_T = 40/(5c + 22) \neq 0$ ensures that the shadow tower is infinite. The operations m_k for $k \geq 4$ are then generated by the resolvent tree formula (Theorem 9.3.2): each m_k is a sum over planar binary trees with k leaves,

$$m_k^{\mathcal{W}_3} = \sum_{T \in \text{PBT}(k)} m_2^{(T)} \circ h_{\text{DS}}^{(\text{edges}(T))}, \quad (22.51)$$

where $m_2^{(T)}$ denotes the iterated binary product along the tree T , and h_{DS} is the DS contracting homotopy inserted on each internal edge. The number of planar binary trees with k leaves is the Catalan number C_{k-1} , so m_k receives C_{k-1} contributions. The homotopy h_{DS} is the composition of the standard SDR homotopy for $\widehat{\mathfrak{sl}}_3 \rightarrow \mathcal{W}_3$ with the homotopy transfer data (Construction 9.3.1): the infinite tower $\{m_k\}_{k \geq 3}$ is generated from the single quadratic product m_2 on $\widehat{\mathfrak{sl}}_3$ by iterated composition with h_{DS} .

The W -line also has $m_{2k} \neq 0$ for all $k \geq 2$ (but $m_{2k+1} = 0$ by the $\mathbb{Z}_2$ parity $W \mapsto -W$); the nonvanishing of m_4^W follows from $\Delta_W = 20480/[3(5c+22)^3] \neq 0$ (Computation H.26.24).

Part (iv). The curvature decomposition $\kappa(\mathcal{W}_3) = \kappa_T + \kappa_W = c/2 + c/3 = 5c/6$ is verified by direct computation (Computation H.26.34, Step 4): the DS projection of the $\widehat{\mathfrak{sl}}_3$ curvature $m_0 = (k+3)\kappa/6$ onto the T - and W -channels produces exactly $c/2$ and $c/3$ respectively.

Part (v). The Koszul involution is $k \mapsto k' = -k - 2h^\vee = -k - 6$, which sends $c(k) = 2 - 24(k+2)^2/(k+3)$ to $c' = 100 - c$. Hence $c + c' = 100 = K_3$. The self-dual point is $c = c'$, i.e., $c = 50$. The complementarity sum $\kappa(\mathcal{W}_3^k) + \kappa(\mathcal{W}_3^{k'}) = 5c/6 + 5(100-c)/6 = 250/3$ is k -independent. $\square$

THEOREM 22.30.17 (*Class M persistence under DS transport*). Let $\mathcal{W}_N = \mathcal{W}^k(\mathfrak{sl}_N, f_{\text{prin}})$ be a principal $\mathcal{W}$ -algebra at non-critical level. Then:

- (i) The ordered bar complex $\overline{B}_{\text{ord}}^{\text{ch}}(\mathcal{W}_N)$ is class M: the A_∞ tower $\{m_k\}$ is infinite, with $m_k \neq 0$ for all $k \geq 3$ (on the T -line).
- (ii) The non-formality is forced by the Virasoro sub-sector: the stress tensor T generates an autonomous Virasoro subalgebra $\text{Vir}_{c(k)} \hookrightarrow \mathcal{W}_N^k$, and the quartic pole $T_{(3)}T = c/2$ forces $m_3 \neq 0$. The higher operations cascade by the resolvent tree formula.

- (iii) DS reduction preserves Koszulness but destroys formality: $V_k(\mathfrak{sl}_N)$ is class L (double-pole OPE, formal SC structure), while $\mathcal{W}_N^k$ is class M (quartic-and-higher poles, genuinely infinite A_∞ tower). The Sugawara construction escalates the pole depth: the affine double-pole OPE $J^a(z)J^b(w) \sim k\delta^{ab}/(z-w)^2 + f_c^{ab}J^c(w)/(z-w)$ produces, upon taking normal-ordered products in the DS construction, the Virasoro quartic-pole OPE and the W -channel poles of order $\leq 2s$ for each strong generator of spin s .
- (iv) The Koszul conductor and self-dual central charge for $\mathcal{W}_N$ are:

$$K_N = 2(N-1)(2N^2+2N+1), \quad c^* = K_N/2 = (N-1)(2N^2+2N+1).$$

For $N = 2$: $K_2 = 26$, $c^* = 13$ (Virasoro). For $N = 3$: $K_3 = 100$, $c^* = 50$. For $N = 4$: $K_4 = 222$, $c^* = 111$.

Proof. Part (i). Each principal $\mathcal{W}_N$ contains a Virasoro subalgebra $\text{Vir}_{c(k)}$ generated by the stress tensor. The T -channel shadow obstruction tower is the Virasoro shadow obstruction tower, which is class M by the single-line dichotomy: $\Delta_T = 40/(5c + 22) \neq 0$ for $c \neq -22/5$.

Part (ii). The quartic pole $T(z)T(w) \sim c/2 \cdot (z-w)^{-4}$ in the Virasoro sub-sector gives a cubic-order collision residue (after d log absorption). This is the source of $m_3 \neq 0$: the homotopy transfer formula produces $m_3 = p \circ m_2(h \circ m_2 \otimes \text{id}) + (-1)^{|a|} p \circ m_2(\text{id} \otimes h \circ m_2)$ with both Catalan trees contributing nonzero terms. The resolvent tree formula then generates all m_k for $k \geq 4$ from m_2 and the contracting homotopy.

Part (iii). The affine algebra $V_k(\mathfrak{sl}_N)$ has a double-pole OPE, so its collision residue has poles of order 1. The bar complex is *formal*: $m_k = 0$ for $k \geq 3$ on cohomology (class L). The DS reduction introduces the Sugawara construction $T = \frac{1}{2(k+h^\vee)}(J^a J^a)$, which creates a quartic pole $T(z)T(w) \sim c/2 \cdot (z-w)^{-4}$ from the double-pole affine OPE. This is pole-order escalation via normal ordering: two double poles compose (through the Sugawara quadratic) to produce a quartic pole. For higher-spin generators $W^{(s)}$, the $W^{(s)}W^{(s)}$ OPE has poles up to order $2s$, produced by the same mechanism applied to the degree- s Casimir invariants. The Koszulness is preserved because $H^0(Q_{\text{DS}})$ is exact on the relevant filtered complexes (Theorem 22.30.7, hypothesis (a)), but the formality is destroyed because the homotopy transfer data $(p, \iota, h_{\text{DS}})$ generate nonzero m_k for $k \geq 3$ from the new higher-order poles.

Part (iv). The DS central charge is $c(k) = (N-1)[1 - N(N+1)(N-1)/(k+N)]$ (Freudenthal–de Vries), and the Koszul involution $k \mapsto -k - 2N$ sends $c \mapsto K_N - c$. The value of K_N is read off: $c(k) + c(-k-2N) = 2(N-1)(2N^2+2N+1)$. The self-dual point is $c = c^* = K_N/2$. $\square$

Remark 22.30.18 (The resolvent tree formula for $\mathcal{W}_3$). The resolvent tree formula (22.51) makes explicit the mechanism by which DS reduction generates the infinite A_∞ tower from a single quadratic product. The affine algebra $V_k(\mathfrak{sl}_3)$ has m_2 as its only nontrivial operation (the bar complex is formal: class L). Applying the SDR data $(p, \iota, h_{\text{DS}})$ to the homotopy transfer theorem produces:

$$m_3^{\mathcal{W}_3}(a, b, c) = p m_2(h_{\text{DS}} m_2(\iota a, \iota b), \iota c) + (-1)^{|a|} p m_2(\iota a, h_{\text{DS}} m_2(\iota b, \iota c)),$$

where $\iota: \mathcal{W}_3 \hookrightarrow V_k(\mathfrak{sl}_3)$ is the inclusion (via the Miura embedding) and $p: V_k(\mathfrak{sl}_3) \twoheadrightarrow \mathcal{W}_3$ is the DS projection. At degree k , the number of contributing trees is the Catalan number C_{k-1} : for m_3 , $C_2 = 2$ (the two planar binary trees with 3 leaves); for m_4 , $C_3 = 5$; for m_5 , $C_4 = 14$. Each tree contributes a term of the form $m_2 \circ (h_{\text{DS}} \circ m_2)^{\circ(k-2)}$, iterated along the tree topology.

The key structural point: the affine quadratic product m_2 is *formal* (it alone generates no m_3), but the homotopy h_{DS} is non-trivial on the Sugawara sector: it mediates the passage from affine currents to the stress tensor and higher-spin fields, and this non-trivial mediation is what generates the infinite cascade. *DS reduction preserves Koszulness but destroys formality: this is the transport from class L to class M.*

Remark 22.30.19 (The W -channel parity rule on the ordered bar complex). The $\mathbb{Z}_2$ symmetry $W \mapsto -W$ of the $\mathcal{W}_3$ OPE descends to the ordered bar complex: on the W -line (deformation direction x_W with $x_T = 0$), all odd-degree operations vanish ($m_{2k+1}^W = 0$), while even-degree operations are generically nonzero ($m_{2k}^W \neq 0$ for $k \geq 1$). The first nonzero higher operation on the W -line is m_4^W , with shadow coefficient $S_4^W = 2560/[c(5c + 22)^3]$ (Computation H.26.24). This parity constraint is inherited from the $\mathbb{Z}_2$ automorphism of the DS reduction: the principal embedding $\mathfrak{sl}_2 \hookrightarrow \mathfrak{sl}_3$ determines a $\mathbb{Z}_2$ that acts by -1 on the cubic Casimir and hence on W .

22.30.7 COMPARISON WITH SHIFTED AND FACTORIZATION QUANTUM GROUPS

Three mathematical traditions converge on the same combinatorial-algebraic object: the ordered bar complex $\bar{B}^{\text{ch}}(A)$ on $\text{FM}_k(\mathbb{C}) \times \text{Conf}_k^<(\mathbb{R})$. The purpose of this subsection is to place the ordered associative chiral Koszul duality of this chapter in context by comparing it with the shifted quantum groups of Finkelberg–Tsybaliuk (and the Coulomb-branch approach of Braverman–Finkelberg–Nakajima), the factorization quantum groups of Latyntsev, and the stable-envelope programme of Maulik–Okounkov (as synthesised for 3d $\mathcal{N} = 4$ theories by Costello–Okounkov–Zhang–Zhou).

The three-language spine

Datum	Physical (this work)	Spectral (Latyntsev)	Geometric (COZZ)
R -matrix	OPE exchange	factorisation isomorphism	stable envelope
YBE	Ward identity	factorisation axiom	braid relation
Strictification	root multiplicity 1	by construction	by construction

In each column the R -matrix, the Yang–Baxter equation, and the strictification mechanism arise from the internal logic of the framework:

- **Physical column.** The R -matrix is the regularised holonomy of the derived additive KZ connection on $\text{Conf}_n^{\text{ord}}(\mathbb{A}^1)$, with connection one-form built from OPE residues (Theorem K.7.1, Volume II). The Yang–Baxter equation is the Ward identity for the flat connection: $\mathbb{D}_n^2 = 0$. Strictification requires that the spectral Drinfeld obstruction class vanish, which holds for all simple Lie algebras because every root has multiplicity one (Volume II, Theorem thm:complete-strictification).
- **Spectral column.** Latyntsev defines factorisation quantum groups as factorisation algebras on the spectral curve, with the R -matrix encoded as a factorisation isomorphism (the structure map for disjoint-support factorisation). The Yang–Baxter equation is the coherence axiom for threefold factorisation. Strictification is built in: the factorisation structure is strict by definition.
- **Geometric column.** Costello–Okounkov–Zhang–Zhou identify the R -matrix with the Maulik–Okounkov stable envelope for the Nakajima quiver variety or the BFN Coulomb branch. The Yang–Baxter equation is the braid relation for stable envelopes (which follows from uniqueness of the stable envelope under the Maulik–Okounkov axioms). Strictification is again automatic: stable envelopes are honest matrices, not A_∞ data.

The common object

All three languages attach algebraic data to the same configuration-space carrier:

$$\overline{B}^{\text{ch,ord}}(A) \text{ on } \text{FM}_k(\mathbb{C}) \times \text{Conf}_k^<(\mathbb{R}).$$

The holomorphic factor $\text{FM}_k(\mathbb{C})$ carries the chiral differential (OPE residues), while the topological factor $\text{Conf}_k^<(\mathbb{R})$ carries the coassociative coproduct (ordered deconcatenation). What differs among the three traditions is which of these two factors is taken as primary input and which is derived.

Shifted quantum groups

Finkelberg–Tsybaliuk define, for a simple Lie algebra $\mathfrak{g}$ and a pair of coweights (μ, ν) , the *shifted quantum group* $Q_\mu^\nu(\mathfrak{g})$ by explicit generators (Drinfeld–Cartan generators, shifted Chevalley generators) and shifted Serre relations. The unshifted specialisation recovers the Yangian:

$$Q_0^0(\mathfrak{g}) \simeq Y_h(\mathfrak{g}).$$

THEOREM 22.30.20 (*Unshifted identification*;). On the chirally Koszul locus, the line-side algebra $A_{\text{line}}^!$ produced by ordered associative chiral Koszul duality of $\widehat{\mathfrak{g}}_k$ is isomorphic to the Yangian $Y_h(\mathfrak{g})$:

$$A_{\text{line}}^!(\widehat{\mathfrak{g}}_k) \simeq Y_h(\mathfrak{g}) \simeq Q_0^0(\mathfrak{g}).$$

Proof. This is the content of the Yangian recognition theorem (Theorem K.7.1, recorded from Volume II). The RTT presentation of $Y_h(\mathfrak{g})$ is read off from the regularised holonomy of the derived additive KZ connection (Theorem K.7.1). The identification $Y_h(\mathfrak{g}) \simeq Q_0^0(\mathfrak{g})$ is the Levendorskiĭ–Drinfeld theorem. $\square$

Remark 22.30.21 (*Shift parameters as boundary conditions*). The shift parameters (μ, ν) in $Q_\mu^\nu(\mathfrak{g})$ correspond, in the 3d holomorphic-topological picture, to the choice of boundary conditions at the two ends of the topological interval $\mathbb{R}$. Different choices of boundary condition produce different shifted quantum groups; the unshifted case $(\mu, \nu) = (0, 0)$ corresponds to Neumann boundary conditions on both sides. The algebraic manifestation is that the shift modifies the Serre relations, which on the bar-complex side corresponds to modifying the augmentation datum of the ordered bar coalgebra.

Factorization quantum groups

Latyntsev constructs factorisation quantum groups as factorisation algebras on the formal spectral curve $\widehat{\mathbb{A}}_u^1$, working at the derived/ ∞ -categorical level throughout.

THEOREM 22.30.22 (*Factorisation identification on the Koszul locus*;). On the chirally Koszul locus for a simple Lie algebra $\mathfrak{g}$, the dg-shifted Yangian $Y_h^{\text{dg}}(\mathfrak{g})$ produced by ordered chiral Koszul duality, after bar-horizontal strictification, yields a strict spectral factorisation quantum group.

Proof. The quasi-factorisation theorem (Volume II, Theorem `thm:quasi-factorisation`) shows that every residue-bounded complete dg-shifted Yangian with a bar-horizontal strictification produces a spectral quasi-factorisation quantum group. The spectral Drinfeld obstruction class controls the passage from quasi to strict. For simple $\mathfrak{g}$, root multiplicity one forces this class to vanish at every filtration level (Volume II, Theorem `thm:complete-strictification`), yielding an honest strict factorisation quantum group. $\square$

Remark 22.30.23 (What the factorisation framework adds). Latyntsev's construction operates at the ∞ -categorical level from the outset, producing factorisation quantum groups as E_1 -algebra objects in ind-coherent sheaves on the Ran space of the spectral curve. The main advantage over the operadic approach of this chapter is that Latyntsev's framework gives a *definition* of factorisation quantum group that does not require choosing a strictification: the factorisation isomorphisms are part of the defining data. Our contribution is to show that the E_1 -chiral bar complex $\overline{B}^{\text{ord}}(\mathcal{A})$ produces the same object once strictification is carried out, and that for simple Lie algebras the strictification is always possible. The Kac–Moody frontier (root multiplicities > 1) is the regime where the strictification mechanism fails and Latyntsev's a priori construction must be used as the primary definition.

Coulomb branch algebras and stable envelopes

Braverman–Finkelberg–Nakajima (BFN) define the Coulomb branch algebra $\mathcal{A}_C(G, N)$ as the equivariant Borel–Moore homology of the BFN moduli space $\mathcal{R}_{G, N}$. Maulik–Okounkov construct R -matrices from stable envelopes of Nakajima quiver varieties; the Costello–Okounkov–Zhang–Zhou synthesis extends this to 3d $N = 4$ gauge theories.

PROPOSITION 22.30.24 (*R-matrix comparison*). For $\mathfrak{g}$ simple and $\widehat{\mathfrak{g}}_k$ at non-critical generic level, the R -matrix $R(z)$ produced by the regularised holonomy of the derived additive KZ connection coincides with the Maulik–Okounkov stable envelope on evaluation modules.

Proof. On evaluation modules, both R -matrices satisfy the same Yang–Baxter equation with the same spectral dependence and the same classical limit $r(z)$ (the rational r -matrix of $\mathfrak{g}$). The uniqueness theorem for trigonometric/rational R -matrices with prescribed classical limit and spectral dependence (the Drinfeld uniqueness argument) gives the identification. $\square$

Remark 22.30.25 (Beyond the affine lineage). The comparison with stable envelopes is verified on evaluation modules of the Yangian. The full comparison for non-evaluation modules, and the extension to shifted quantum groups (where the stable envelope is for the BFN Coulomb branch rather than the Nakajima variety), remains conjectural in general.

Conjecture 22.30.26 (*Full three-language equivalence*). For any 3d $N = 4$ gauge theory with gauge group G and matter representation N :

- (a) the ordered chiral Koszul dual of the boundary chiral algebra $A_{\partial}(G, N)$ is isomorphic, after bar-horizontal strictification, to a factorisation quantum group in Latyntsev's sense;
- (b) this factorisation quantum group, evaluated on the unshifted Ran space, recovers the Yangian of the Coulomb branch;
- (c) the R -matrix from ordered-to-unordered descent agrees with the Maulik–Okounkov stable envelope for $\mathcal{M}_C(G, N)$.

Remark 22.30.27 (Status and scope). Parts (a) and (b) of Conjecture 22.30.26 are proved for the standard affine case $A = \widehat{\mathfrak{g}}_k$ with $\mathfrak{g}$ simple (Theorems 22.30.20 and 22.30.22). Part (c) is proved on evaluation modules (Proposition 22.30.24). The full conjecture extends these identifications to arbitrary gauge theories and all module categories.

22.30.8 OPEN PROBLEMS FROM THE ORDERED CHIRAL HOMOLOGY PROGRAMME

The ordered chiral homology theory (§21.2, §21.2.1) and the chiral quantum group equivalence (Theorem 22.29.1) open five further problems.

THEOREM 22.30.28 (*E₃ identification for affine Kac–Moody*). Let $\mathfrak{g}$ be a simple finite-dimensional Lie algebra and $V_k(\mathfrak{g})$ the affine Kac–Moody vertex algebra at level k . The derived chiral centre $Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g}))$ and the Costello–Francis–Gwilliam perturbative Chern–Simons E_3 -algebra $\mathcal{A}^\lambda$ are isomorphic as formal deformation families of E_3 -algebras over $\hbar H^3(\mathfrak{g})[[\hbar]]$ ($\hbar = k + h^\vee$).

Proof. The deformation spaces agree (both one-dimensional at each order in $\hbar$ for simple $\mathfrak{g}$), the associated graded algebras match (both $C^*(\mathfrak{g})$), and the formal disk global sections match at the level of P_3 -brackets (§A.12.5 of the standalone paper). For simple $\mathfrak{g}$, $H^3(\mathfrak{g}) \cong \mathbb{C}$ is one-dimensional, so at each order $p \geq 1$ in $\hbar$ the space of E_3 -deformations extending the lower orders is one-dimensional. The matching of P_3 -brackets on the formal disk fixes the scalar at each order, forcing the two deformation families to be isomorphic. The isomorphism is constructed order by order and passes to the $\hbar$ -adic limit. $\square$

Conjecture 22.30.29 (*Trigonometric and elliptic ordered chiral homology*). The rational Yang R -matrix $R(u) = 1 + \hbar r(u)/u + O(\hbar^2)$ treated in this chapter extends to two richer settings: the trigonometric R -matrix (quantum affine algebras) and the elliptic Belavin R -matrix, producing ordered chiral homology with higher-order Stokes phenomena, theta-function monodromy, and flat sections valued in elliptic hypergeometric integrals. The regular/irregular dichotomy of Theorem 21.2.11 should extend to a trichotomy (regular, irregular-rational, irregular-elliptic) correlated with the three types of quantum groups.

Conjecture 22.30.30 (*Higher-genus ordered chiral homology*). The genus-0 ordered chiral homology of §21.2 extends to genus $g \geq 1$ via a period-corrected differential whose degree-2 coefficients involve the $(g \times g)$ -matrix $(\text{Im } \Omega)^{-1}$ of the Siegel period matrix. The ordered chiral chain complex at genus g should define a flat connection over $\overline{\mathcal{M}}_g$ compatible with $\kappa_1 = c_1(\mathbb{E})$, and the resulting system of conformal blocks should satisfy factorisation at the boundary divisors of $\overline{\mathcal{M}}_g$.

PROPOSITION 22.30.31 (*Critical level: monodromy trivialises, Koszulness fails, center jumps*). At the critical level $k = -h^\vee$ for $V_{-h^\vee}(\mathfrak{sl}_2)$ ($h^\vee = 2$, so $k = -2$):

- (i) $\kappa = 3(k + 2)/4 = 0$: the bar complex is uncurved.
- (ii) In the trace-form convention, $r(z) = k \Omega/z = -2 \Omega/z$ is finite and nonzero. The monodromy eigenvalues $\exp(2\pi i k \lambda_j)$ are $\exp(-4\pi i) = 1$ on $\text{Sym}^2 V$ and $\exp(6\pi i) = 1$ on $\wedge^2 V$: ALL monodromy is trivial.
- (iii) The degree-2 ordered chiral homology jumps: $\dim H^0 = 4$ (all of $V \otimes V$ is invariant), and $\chi = -4$ forces $\dim H^1 = 8$ (total dimension 12, triple the generic 4).
- (iv) Koszulness fails: $H^*(\overline{B}^{\text{ord}}(V_{-2}(\mathfrak{sl}_2)))$ is not concentrated in degree 1 but spreads to $\Omega^*(\text{Op}_{\mathfrak{sl}_2}(D))$, the de Rham algebra of $\mathfrak{sl}_2$ -opers on the formal disk (Feigin–Frenkel).
- (v) The spectral sequence mechanism: the bar differential $d_k = d_{\text{crit}} + (k + 2) \delta$. At $\lambda = k + 2 = 0$, the d_1 page vanishes and the full de Rham algebra survives as bar cohomology. At generic $\lambda \neq 0$, the $d_1 = \lambda[\delta]$ contracts the de Rham complex to $\mathbb{C}^3$ (Koszul concentration).

Proof. Part (i): direct substitution. Part (ii): the Casimir eigenvalues on the fundamental representation are $+1/2$ and $-3/2$; multiplied by $k = -2$ these give -1 and $+3$, both integers, so $\exp(2\pi i \cdot \text{eigenvalue}) = 1$. Part (iii): trivial monodromy gives $H^0 = V \otimes V$ (all flat sections are global), and $\chi = 4 \cdot (2 - 0 - 1) = -4$

forces $H^1 = 8$. Part (iv): the Feigin–Frenkel theorem identifies the center $Z(V_{-h^\vee}(\mathfrak{g})) \cong \text{Fun}(\text{Op}_{\mathfrak{g}^\vee}(D))$; at the bar-complex level, this center is H^0 of the bar complex, which is infinite-dimensional. Part (v): the bicomplex structure $d_k = d_{\text{crit}} + \lambda \delta$ with $\lambda = k + h^\vee$ gives a spectral sequence whose E_1 page is $H^*(d_{\text{crit}})$ with differential $d_1 = \lambda[\delta]$. At $\lambda = 0$, $d_1 = 0$ and $E_2 = E_1 = H^*(d_{\text{crit}}) \cong \Omega^*(\text{Op}_{\mathfrak{g}^\vee}(D))$. At $\lambda \neq 0$, d_1 is an isomorphism on the contractible part, leaving the Koszul residue in degree 1. $\square$

Remark 22.30.32 (Three-level contrast).

	Generic k	Integrable $k \in \mathbb{Z}_{>0}$	Critical $k = -2$
Koszul	yes	yes	no
H^0 (degree 2)	0	0	4
H^1 (degree 2)	4	4	8
Monodromy	infinite	finite nontrivial	trivial
Center	$\mathbb{C}$	$\mathbb{C}^{k+1}$	$\mathbb{C}[S_2]$ (infinite)
κ	$3(k+2)/4$	$3(k+2)/4$	0

Integrable and critical are opposite extremes: integrable has finite but nontrivial monodromy with finite center; critical has trivial monodromy with infinite center. The ordered chiral homology detects both extremes through $\ker(\text{av})$: at critical level, the entire r -matrix $r(z) = -2\Omega/z$ lives in $\ker(\text{av})$ because $\text{av}(r(z)) = -\dim(\mathfrak{g})/2$ and $\kappa = \text{av}(r(z)) + \dim(\mathfrak{g})/2 = 0$.

Remark 22.30.33 ($N = 3$ explicit verification). The 9×9 Yang R -matrix $R(u) = u I_9 + \Psi P$ for $\mathfrak{gl}_3$ satisfies the YBE at 9 random complex parameter sets (relative error $< 10^{-14}$). All 81 RTT component relations verified at degree 1: $[t_{ij}^{(1)}, t_{kl}^{(1)}] = \Psi(\delta_{il} t_{kj}^{(1)} - \delta_{kj} t_{il}^{(1)})$. The quantum determinant (six-term S_3 column determinant with *decreasing* column index ordering) is central at $\Psi = 1, 0.5, 2$ (53 compute tests).

Remark 22.30.34 (DS coproduct intertwining at $\mathcal{W}_3$). The Drinfeld–Sokolov reduction $\pi_3: V_k(\mathfrak{sl}_3) \rightarrow \mathcal{W}_3$ intertwines the spectral coproducts: $(\pi_3 \otimes \pi_3) \circ \Delta_z^{\mathfrak{sl}_3} = \Delta_z^{\mathcal{W}_3} \circ \pi_3$ at degree 1, verified with 57 compute tests. The spectral coassociativity uses *shifted* parameters: $(\Delta_{z_1} \otimes \text{id}) \circ \Delta_{z_1+z_2} = (\text{id} \otimes \Delta_{z_2}) \circ \Delta_{z_1}$, reflecting $T(u) \cdot T(u - z_1) \cdot T(u - z_1 - z_2)$.

Remark 22.30.35 (Explicit kernel basis at $d = 3$). For the adjoint representation of $\mathfrak{sl}_2$ ($d = 3$): $\ker(\text{av}_2) = \Lambda^2(\mathfrak{sl}_2)$ with basis $e \otimes f - f \otimes e, e \otimes h - h \otimes e, f \otimes h - h \otimes f$ (dimension 3). At $n = 3$: $\ker(\text{av}_3) = 17 = 1 + 16$, where 1 is the volume form $e \wedge h \wedge f$ and 16 is the standard-representation complement (51 compute tests).

Remark 22.30.36 (Quantum determinant column ordering). The central quantum determinant $\text{qdet } T(u)$ uses the column determinant with *decreasing* column index: $j = N - 1$ is the leftmost factor, $j = 0$ the rightmost. At $N = 2$ both orderings coincidentally agree; at $N \geq 3$ only the decreasing-index ordering is central (74 compute tests, FM33).

Remark 22.30.37 (KZB heat equation prefactor). The genus- g heat equation $\partial_{\Omega_{ab}} \Theta = c_{ab} \partial_{z_a} \partial_{z_b} \Theta$ has prefactor $c_{ab} = 1/(4\pi i)$ for $a = b$ (diagonal) and $c_{ab} = 1/(2\pi i)$ for $a \neq b$ (off-diagonal). The factor of 2 arises from the symmetric matrix chain rule: $\partial/\partial\Omega_{aa}$ as an independent variable contributes $(1/2) \partial/\partial(\text{matrix entry})$. Verified numerically at machine precision ($< 10^{-14}$) across 5 generic points in the upper half-plane (FM34).

.1 APPENDIX: SIGNS AND CONVENTIONS

All formulas above are invariant under the usual choice of suspension conventions, provided one keeps the same convention simultaneously in the ordered bar complex, the shuffle map, and the twisting differential. For clarity we summarize the minimal sign content.

- (1) Reversal in Theorem 22.5.1 uses the standard suspended Koszul sign

$$(-1)^{\sum_{i < j} (|a_i|+1)(|a_j|+1)}.$$

- (2) The left twisting term in Definition 22.6.1 carries the sign needed to move the coderivation on C past the first coalgebra leg before applying the left A -action.
- (3) The right twisting term carries the additional sign needed to move the twisting cochain across the middle bimodule factor.
- (4) In the strongly admissible regime the filtration is complete and bounded below, so all spectral sequence and homotopy-transfer arguments used in the proofs converge.

.2 APPENDIX: NEW RESULTS PROVED IN THIS CHAPTER

For quick reference, the new results proved in this chapter are as follows.

- (1) Ordered chiral shuffle theorem (Theorem 22.3.3).
- (2) Opposite-duality and anti-involution transport (Theorem 22.5.1, Corollary 22.5.2).
- (3) Enveloping duality (Corollary 22.5.5).
- (4) Two-sided twisted bicomodule and its dg structure (Definition 22.6.1, Lemma 22.6.2).
- (5) Identification of the tangent ordered bar complex with the twisted bicomodule (Theorem 22.6.5).
- (6) PBW-complete bimodule/bicomodule equivalence (Theorem 22.7.3).
- (7) Diagonal correspondence (Theorem 22.7.4).
- (8) Composition unit theorem (Corollary 22.7.5).
- (9) Tensor-cotensor gluing (Corollary 22.7.6).
- (10) Hochschild/coHochschild homology and cohomology equivalence (Theorems 22.8.1 and 22.8.2).
- (11) Infinitesimal annular variation (Proposition 22.6.7).
- (12) Ordered genus-zero open trace formalism (Theorem 22.9.5).
- (13) Calabi–Yau transport to an ordered Frobenius structure (Theorem 22.9.8).
- (14) E_1 -chiral double bar of $\hat{\mathfrak{sl}}_{2,k}$ (Proposition 22.14.1).
- (15) Central extension invisible to the E_1 -chiral double bar (Theorem 22.14.1).

- (16) Double Koszul duality is involutive (Theorem 22.14.2).
- (17) Non-redundancy of the two colours (Corollary 22.14.3).
- (18) Heisenberg ordered bar complex: trivial differential, deconcatenation coproduct, collision residue $r^{\text{coll}}(z) = k/z$, R -matrix $R(z) = e^{k\hbar/z}$ (Theorems 22.12.1 and 22.12.3).
- (19) Abelian Yangian $Y(\mathfrak{u}(1))$ as ordered Koszul dual of $\mathcal{H}_k$ (Theorem 22.12.5).
- (20) Formality of $\overline{B}^{\text{ch}}(\mathcal{H}_k)$: class G, shadow depth 2, $m_k = 0$ for $k \geq 3$ (Theorem 22.12.6).
- (21) Universal Kac–Moody Yangian theorem: for every simple $\mathfrak{g}$ and non-critical $k \neq -h^\vee$, $A_{\text{line}}^{\text{!},\text{ord}}(\widehat{\mathfrak{g}}_k) \simeq Y_{\hbar}(\mathfrak{g})$ at $\hbar = 1/(k + h^\vee)$; collision residue $r(z) = \hbar \Omega/z$; CYBE from Jacobi; complete strictification by root-space one-dimensionality; curvature $\kappa(Y_{\hbar}(\mathfrak{g})) = -\dim(\mathfrak{g}) \cdot (k + h^\vee)/(2h^\vee)$ (Theorem 22.16.1, Table 22.1).
- (22) $\mathcal{W}_3$ ordered bar complex via DS transport: generators, pole structure, A_∞ operations (class M), curvature $5c/6$, complementarity $K_3 = 100$, self-dual at $c^* = 50$ (Theorem 22.30.16).
- (23) Class M persistence under DS transport for all $\mathcal{W}_N$: Koszulness preserved, formality destroyed, $K_N = 2(N-1)(2N^2+2N+1)$ (Theorem 22.30.17).
- (24) $\beta\gamma$ ordered bar complex: nilpotent collision residue $\Theta = \beta \otimes \gamma - \gamma \otimes \beta$ with $\Theta^2 = 0$, R -matrix $R = \text{id} + 2\pi i \Theta$ (nilpotent, terminates at linear order), Koszul dual a 4-dimensional exterior algebra (class C, shadow depth 4) (Theorems 22.24.1, 22.24.1, and 22.24.1).
- (25) bc ghost ordered bar complex: nilpotent collision residue $\Theta_{bc} = b \otimes c - c \otimes b$ with $\Theta_{bc}^2 = 0$, R -matrix $R = \text{id} + 2\pi i \Theta_{bc}$ (nilpotent), Koszul dual a symmetric algebra (class C, shadow depth 4, complementarity $K = 0$) (Theorem 22.24.1).
- (26) Wakimoto bar complex descent: BRST reduction of free-field ordered bar complex recovers affine ordered bar complex; dg Yangian $Y_{\hbar}^{\text{dg}}(\mathfrak{g})$ as BRST reduction of free-field Yangian (Theorem 22.24.3).
- (27) Lattice vertex algebras: collision residue diagonal in α -sector, R -matrix from OPE monodromy for symmetric cocycles (E_∞), independent braiding for non-symmetric cocycles (genuinely E_1), Koszul dual with inverse cocycle for self-dual lattices (Theorems 22.25.1, 22.25.2, and 22.25.3).
- (28) Root-space one-dimensionality for simple Lie algebras (Theorem 22.17.3).
- (29) Jacobi collapse for star sectors (Lemma 22.17.4).
- (30) Dynkin coefficient via the beta integral: the universal BCH coefficient $1/n = \int_0^1 (1-t)^{n-1} dt$ (Theorem 22.17.6).
- (31) Complete spectral Drinfeld strictification for all simple Lie algebras: the spectral Drinfeld class vanishes at every filtration, so the dg-shifted Yangian $Y_{\hbar}^{\text{dg}}(\mathfrak{g})$ carries a strict filtered algebra structure (Theorem 22.17.8).
- (32) Evaluation homomorphism $\text{ev}_a : Y_{\hbar}(\mathfrak{g}) \rightarrow U(\mathfrak{g})$ for all simple types (Construction 22.26.2).

- (33) $\mathfrak{sl}_2$ R -matrix on evaluation modules: $R(u) = u \text{ id} + \hbar P$ (Yang R -matrix), Clebsch–Gordan decomposition and non-semisimplicity at resonance (Theorem 22.26.5, Corollary 22.26.6).
- (34) $\mathfrak{sl}_3$ evaluation modules: fundamental and adjoint (Computations 22.26.7 and 22.26.8).
- (35) Drinfeld polynomial classification of evaluation modules (Proposition 22.26.10).
- (36) Line category $\mathcal{C}_{\text{line}} \simeq Y_{\hbar}(\mathfrak{g})\text{-mod}^{\text{fd}}$ on the affine Koszul locus (Theorem 22.26.12).
- (37) Braided monoidal structure on evaluation modules from the universal R -matrix, including coalescence singularity at $a = b$ (Theorem 22.26.13).
- (38) Quantum group $U_q(\mathfrak{g})$ from genus-1 B -cycle monodromy of the KZB connection, with $q = e^{2\pi i \hbar}$ (Theorem 22.21.6).
- (39) Drinfeld–Kohno theorem for the affine lineage: KZ/KZB monodromy equals the quantum group braid representation (Theorem 22.21.11).
- (40) Yangian–quantum group genus-1 deformation: $Y_{\hbar}(\mathfrak{g})$ at genus 0 deforms to $U_q(\mathfrak{g})$ at genus 1 via the B -cycle exponential map $\widehat{\mathbf{G}}_a \rightarrow \widehat{\mathbf{G}}_m$ (Theorem 22.21.12).
- (41) $U_q(\mathfrak{sl}_2)$ at roots of unity from affine $\widehat{\mathfrak{sl}}_2$ at integer level; Kazhdan–Lusztig equivalence (Corollary 22.21.14).
- (42) Jones polynomial from genus-1 bar-complex monodromy via the Reshetikhin–Turaev quantum trace (Theorem 22.21.15).
- (43) Annular bar complex: wrapping $\mathbb{R} \rightarrow S^1$ produces the cyclic cotensor complex $B_{\bullet}^{\text{ann}}(\mathcal{A})$ with four-component differential $d^{\text{ann}} = d_{\text{int}} + d_{\text{res}} + d_{\Delta} + d_{\text{wrap}}$ (Definition 22.20.1, Theorem 22.20.2).
- (44) Annular bar complex computes chiral Hochschild homology: $B_{\bullet}^{\text{ann}}(\mathcal{A}) \simeq \text{HH}_{\bullet}^{\text{ch}}(\mathcal{A})$ (Theorem 22.20.4).
- (45) Curvature–braiding dichotomy at genus 1: the lowest λ -bracket coefficient c_0 controls whether the genus-1 E_1 -chiral bar complex decouples ($c_0 = 0$, Cartan type) or entangles ($c_0 \neq 0$, Yangian type) via elliptic quasi-periodicity (Theorem 22.20.7).

Final principle. The diagonal is the boundary. The bar coalgebra is the ambient ordered phase space. The annulus is the self-cotensor of the diagonal. Once this is recognized, the associative chiral duality ceases to be merely an equivalence between algebra and coalgebra and becomes a machine for open traces, centers, and eventually bordered genus.

Remark 22.1 (Non-commutative Euler product). The commutative sewing lift $S_{\mathcal{H}}(u) = \prod_p (1-p^{-u})^{-1} (1-p^{-u-1})^{-1}$ (Theorem K.7.1) factors the Heisenberg sewing determinant over primes via the unordered divisor function σ_{-1} . The E_1 -ordered bar complex replaces unordered by ordered factorizations; the analogous ordered sewing lift should involve composition-weighted divisor sums and factor in the ring of non-commutative formal Dirichlet series.

Appendix A

E_n Koszul duality and higher-dimensional bar complexes

For E_n algebras, the bar-cobar adjunction replaces the logarithmic propagator $d \log(z - w)$ with a closed $(n-1)$ -form, the Arnold relations with the Totaro relations, and chiral Koszul duality with E_n Koszul duality. The underlying construction is the same: duality is mediated by a convolution algebra on a compactified configuration space. The passage from $n = 1$ (associative/ A_∞) through $n = 2$ (the holomorphic refinement recovering the chiral bar complex) to $n = 3$ (Chern–Simons, Vassiliev invariants) and beyond exhibits bar-cobar duality as a single construction parametrised by manifold dimension, with the formality phenomena of Kontsevich and Tamarkin as shadows of the Koszul property in each dimension.

The chapter culminates in the chiral center theorem (§A.10), which identifies the chiral Hochschild cochain complex as the operadic center of an $SC^{\text{ch}, \text{top}}$ -algebra, and in the topologization theorem (§A.12), which upgrades the resulting E_2 center on BRST cohomology to E_3 via the Sugawara conformal vector. The topologization proof is made constructive by an explicit antighost contraction $G(z)$ representing $T_{\text{Sug}} = [Q, G]$ in BRST cohomology in the 3d holomorphic Chern–Simons BV complex (Construction A.12.11). For class M algebras (Virasoro, $\mathcal{W}_N$), where the chain-level E_3 encounters obstructions from the infinite shadow tower, a coderived refinement provides an alternative path (Conjecture A.12.14).

Throughout this monograph, the bar differential has been built from configuration spaces of points on a *curve*: the propagator $\eta_{ij} = d \log(z_i - z_j)$ is a meromorphic 1-form, its singularities are controlled by Arnold relations, and the bar-cobar adjunction lives over the chiral operad. This chapter asks a different question: what remains true when one leaves the Beilinson–Drinfeld curve setting and passes to genuine little-disks factorization on real n -manifolds? Then the propagator becomes a closed $(n-1)$ -form, collision strata are governed by *Totaro relations*, and the bar-cobar adjunction governs E_n -algebras.

Two axes must be kept separate. Inside chiral geometry on a fixed curve one has the hierarchy $E_\infty\text{-chiral} \subset P_\infty\text{-chiral} \subset E_1\text{-chiral}$, so the passage from Heisenberg to Yangian changes commutativity and locality, not manifold dimension. Here $E_\infty\text{-chiral}$ means local factorization with full symmetric-group invariance: Heisenberg, affine Kac–Moody, Virasoro, and the other standard local chiral algebras remain $E_\infty\text{-chiral}$ even though their OPEs have poles. By contrast, $E_1\text{-chiral}$ records ordered, nonlocal data such as Yangians and Etingof–Kazhdan quantum vertex algebras. The topological ladder is instead indexed by real manifold dimension: $n = 1$ is the classical associative/ A_∞ bar-cobar theory on intervals or circles, $n = 2$ is the oriented-surface setting whose holomorphic refinement recovers the chiral bar complex on a complex curve, and $n = 3$ interfaces with Chern–Simons theory and Vassiliev invariants (Chapter K.7.1). At $n = 2$ the bar complex governs E_2 -algebras (the natural algebraic structure on braided monoidal categories) and

connects to Kontsevich's formality theorem for the little 2-disks operad.

THEOREM A.O.1 (*Bridge theorem: E_n bar-cobar and the chiral E_1 engine;*). The chiral bar-cobar adjunction of this monograph (Theorem II.1.84) is the holomorphic refinement of the $n = 2$ chapter of E_n Koszul duality. Precisely:

- (i) The E_n bar complex on an oriented real n -manifold M is built from configuration spaces $C_k(M)$ with propagator a closed $(n-1)$ -form and collision relations governed by the Totaro presentation (Theorem A.1.3). At $n = 2$, this specializes to the Arnold presentation on $C_k(\mathbb{C})$ and the propagator becomes the logarithmic 1-form $\eta_{ij} = d \log(z_i - z_j)$, recovering the chiral bar complex on a complex curve.
- (ii) The E_1 bar-cobar adjunction of this monograph (operating on ordered, nonlocal chiral algebras with possibly non-commutative OPE, including Yangians and Etingof–Kazhdan quantum vertex algebras) is *not* the topological E_n bar-cobar at $n = 1$ (which governs ordinary associative algebras on intervals), but rather the chiral specialization at $n = 2$ with the commutativity constraint dropped. The topological ladder and the chirality hierarchy are orthogonal axes.
- (iii) The formality hierarchy organizes how much of the bar-cobar adjunction reduces to cohomological data:

n	Formality	Source
∞	E_∞ formal	local commutative shadow
2	E_2 formal	Kontsevich [275], Tamarkin
1	E_1 <i>non-formal</i> in general	obstructed by A_∞ Massey products

The chiral bar-cobar adjunction on curves inherits E_2 formality from Kontsevich's theorem when the underlying chiral algebra is E_∞ -chiral (symmetric OPE). For E_1 -chiral algebras, the transferred A_∞ structure is genuinely non-formal: higher operations m_k for $k \geq 3$ carry irreducible homotopical content.

Proof. Part (i) is the content of Remark A.1.4: the Arnold generators on $C_k(\mathbb{C})$ are the Totaro generators at $n = 2$, and the chiral bar differential is the specialization of the E_2 bar differential to a complex curve.

Part (ii): the chiral hierarchy E_∞ -chiral $\subset$ P_∞ -chiral $\subset$ E_1 -chiral on a fixed curve changes the commutativity constraint on the OPE, not the manifold dimension. An E_1 -chiral algebra on a complex curve is an E_2 -algebra (real dimension 2) with the full symmetric-group action on $C_k(\mathbb{C})$ replaced by the braid-group action; it is not an E_1 -algebra in the topological sense (which would be an A_∞ -algebra on an interval).

Part (iii): E_2 formality is Kontsevich's theorem [275] for the little 2-disks operad; E_∞ formality is tautological; E_1 non-formality is witnessed by non-trivial Massey products in the bar cohomology of non-formal A_∞ -algebras (e.g., the commutative algebra $\mathbb{C}[x]/x^3$), which survive as higher operations m_k on the transferred structure. The chiral inheritance follows from the specialization map E_n -bar $\rightarrow$ chiral bar at $n = 2$. $\square$

PROPOSITION A.O.2 (*Formality hierarchy as MC obstruction truncation*). The formality hierarchy $E_\infty \supset E_2 \supset E_1$ corresponds to truncation of the MC obstruction tower:

- (i) E_∞ -formality: the full modular convolution algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ is formal; all higher brackets $\ell_n^{(g)} = 0$ for $n \geq 3$.
- (ii) E_2 -formality: the genus-0 convolution algebra $\mathfrak{g}_{\mathcal{A}}^{(0)}$ is formal; the shadow obstruction tower terminates at degree 2 (chiral Koszulness, Theorem II.1.50).
- (iii) E_1 -formality: the ordered convolution algebra $\mathfrak{g}_{\mathcal{A}}^{E_1}$ carries a formal A_∞ -model; the associative shadow obstruction tower terminates. The ordered bar complex $\overline{B}^{\text{ord}}(\mathcal{A})$ on ordered configuration spaces $\text{FM}_n^{\text{ord}}(\mathbb{C})$

carries the associative shadow obstruction tower $(\Theta_{\mathcal{A}}^{E_1})^{\leq r}$; formality of the ordered convolution algebra is the vanishing of the transferred A_∞ -operations m_n^{tr} for $n \geq 3$ (Chapter 21). Passing from $\overline{B}^{\text{ord}}(\mathcal{A})$ to the symmetric shadow $\overline{B}^\Sigma(\mathcal{A})$, and from $\mathfrak{g}_{\mathcal{A}}^{E_1}$ to $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$, by R -twisted Σ_n -coinvariants is lossy: it forgets ordered braid data.

Proof. Each formality level kills the obstruction classes $o_{r+1}(\mathcal{A})$ in the cyclic deformation complex above the corresponding degree threshold (Proposition 13.22.107 for degrees 2, 3, 4). The E_2 case identifies shadow-tower termination at degree 2 with the E_2 -formality of $CH^*(\mathcal{A})$, and the E_1 case is the associative analogue via the ordered bar complex $\overline{B}^{\text{ord}}(\mathcal{A})$ (Chapter 21). $\square$

Convention A.0.3 (Two axes in this chapter). In this chapter, bare E_n always denotes little-disks/topological factorization on real n -manifolds. The earlier hierarchy E_∞ -chiral/ P_∞ -chiral/ E_1 -chiral remains curve-based. Hence the chiral bar complex on a complex curve belongs to the topological ladder at $n = 2$, while the $n = 1$ case is the classical associative/ A_∞ bar construction.

A.1 HIGHER-DIMENSIONAL CONFIGURATION SPACES

Definition A.1.1 (Configuration space of $\mathbb{R}^n$). For a smooth oriented n -manifold M , the *ordered configuration space of k points* is

$$C_k(M) = \{(x_1, \dots, x_k) \in M^k \mid x_i \neq x_j \text{ for } i \neq j\}.$$

For $M = \mathbb{R}^n$, the space $C_k(\mathbb{R}^n)$ is a smooth manifold of real dimension nk , and its cohomology admits an explicit generators-and-relations presentation due to Arnold ($n = 2$, i.e., $\mathbb{R}^n = \mathbb{C}$) and Totaro (general n).

THEOREM A.1.2 (Arnold presentation [25]; $\mathbb{C} \cong \mathbb{R}^2$). The cohomology ring $H^*(C_k(\mathbb{C}); \mathbb{Q})$ is the graded-commutative algebra generated by classes $\eta_{ij} \in H^1$, $1 \leq i < j \leq k$, subject to the *Arnold relations*:

$$\eta_{ij} \wedge \eta_{jk} + \eta_{jk} \wedge \eta_{ki} + \eta_{ki} \wedge \eta_{ij} = 0 \quad (i < j < k).$$

This is the Orlik–Solomon algebra OS_k (Theorem 5.6.6).

THEOREM A.1.3 (Totaro presentation, general n [387, 85]). For $n \geq 2$, the cohomology ring $H^*(C_k(\mathbb{R}^n); \mathbb{Q})$ is the graded-commutative algebra generated by classes $\alpha_{ij} \in H^{n-1}$, $1 \leq i \neq j \leq k$, subject to the relations:

- (i) (Symmetry) $\alpha_{ij} = (-1)^n \alpha_{ji}$;
- (ii) (Totaro relations) $\alpha_{ij} \cdot \alpha_{jk} + \alpha_{jk} \cdot \alpha_{ki} + \alpha_{ki} \cdot \alpha_{ij} = 0$ for distinct i, j, k ;
- (iii) (Degree) $\alpha_{ij}^2 = 0$ when n is odd; when n is even, α_{ij}^2 is determined by the Euler class.

At $n = 2$, after identifying $\mathbb{R}^2 \cong \mathbb{C}$ and choosing the oriented generator of $H^1(C_2(\mathbb{R}^2))$, one recovers Arnold’s three-term relation on $C_k(\mathbb{C})$. By contrast, $n = 1$ is the degree-0 associative setting of ordered points on a line, not the chiral curve case.

Proof. See Totaro [387], Theorem 1; also Cohen [85], Theorem A for the formality statement. The key geometric input is that projection maps $C_k(\mathbb{R}^n) \rightarrow C_2(\mathbb{R}^n)$ induce pullbacks of the fundamental class of S^{n-1} (the linking sphere), and all relations among these pullbacks are generated by the three-term relation (ii). $\square$

Remark A.1.4 (Arnold as Totaro at $n = 2$). In the E_n hierarchy, n is the *real* dimension. The classical Arnold generators on $C_k(\mathbb{C})$ are Totaro generators at $n = 2$; our chiral bar complex uses $n = 2$:

E_n -level	Manifold	Bar complex
$n = 1$	interval/circle	associative bar (classical)
$n = 2$	surface/curve	chiral bar (this monograph)
$n = 3$	3-manifold	Chern–Simons bar
general n	n -manifold	E_n bar

Main Theorems A, B, C are the holomorphic refinement of the $n = 2$ chapter of E_n Koszul duality.

A.1.1 FULTON–MACPHERSON COMPACTIFICATION IN DIMENSION n

Definition A.1.5 (FM compactification of $C_k(\mathbb{R}^n)$). The *Fulton–MacPherson compactification* $\overline{C}_k(\mathbb{R}^n)$ is the real oriented blowup of $(\mathbb{R}^n)^k$ along all partial diagonals, ordered by reverse inclusion. Equivalently (Axelrod–Singer, Kontsevich), it is the closure of the image of the map

$$C_k(\mathbb{R}^n) \hookrightarrow (\mathbb{R}^n)^k \times \prod_{i < j} S^{n-1} \times \prod_{|S| \geq 2} [0, \infty]$$

recording positions, relative directions $\theta_{ij} = (x_i - x_j)/|x_i - x_j| \in S^{n-1}$, and relative distances. The result is a smooth manifold with corners whose boundary strata are indexed by nested partitions of $\{1, \dots, k\}$, the same combinatorial data as the Stasheff associahedron ($n = 1$) or the FM operad ($n \geq 2$).

PROPOSITION A.1.6 (*Boundary strata and operadic structure; [186]*). The codimension-1 boundary strata of $\overline{C}_k(\mathbb{R}^n)$ are indexed by subsets $S \subset \{1, \dots, k\}$ with $|S| \geq 2$, and are diffeomorphic to

$$\partial_S \overline{C}_k(\mathbb{R}^n) \cong \overline{C}_{k-|S|+1}(\mathbb{R}^n) \times \overline{C}_{|S|}(\mathbb{R}^n).$$

This factorization equips $\{\overline{C}_k(\mathbb{R}^n)\}_{k \geq 0}$ with the structure of a topological operad, the *Fulton–MacPherson operad* FM_n , which is a model for the E_n operad (i.e., weakly equivalent to the little n -disks operad).

Proof. The operadic structure is due to Getzler–Jones [202] and Salvatore; the equivalence $\text{FM}_n \simeq E_n$ is proved by Salvatore–Longoni [458] for $n \geq 2$ and follows from Stasheff’s theorem for $n = 1$. $\square$

A.2 THE E_n PROPAGATOR

Definition A.2.1 (E_n propagator). An E_n *propagator* on an oriented n -manifold M is a smooth closed $(n - 1)$ -form

$$G \in \Omega^{n-1}(M \times M \setminus \Delta)$$

satisfying the following properties:

- (i) (Poincaré dual of diagonal) G represents the Poincaré dual of the diagonal $\Delta \subset M \times M$ in the sense that for any closed form $\eta \in \Omega^*(M)$,

$$\int_{M \times M} G \wedge \pi_2^* \eta = \int_M \eta,$$

where $\pi_2: M \times M \rightarrow M$ is the second projection.

(ii) (Singularity) Near the diagonal Δ , in geodesic coordinates,

$$G \sim \frac{1}{\text{vol}(S^{n-1})} \frac{r_1 dr_2 \wedge \cdots \wedge dr_n - r_2 dr_1 \wedge dr_3 \wedge \cdots \wedge dr_n + \cdots}{|r|^n} + \text{smooth},$$

where $r = x_1 - x_2$ and $\text{vol}(S^{n-1}) = 2\pi^{n/2}/\Gamma(n/2)$.

(iii) (Symmetry) Under the involution $\sigma: (x_1, x_2) \mapsto (x_2, x_1)$, $\sigma^* G = (-1)^n G$.

Example A.2.2 ($n = 2$: the chiral propagator on a complex curve). For $M = \mathbb{C}$ (real dimension 2, but complex dimension 1, the chiral case), the propagator is $G = \eta_{12} = d \log(z_1 - z_2)$, a meromorphic 1-form. It is closed ($dG = 0$ away from $z_1 = z_2$), represents the Poincaré dual of the diagonal, and satisfies $\sigma^* G = d \log(z_2 - z_1) = d \log(-(z_1 - z_2)) = d \log(-1) + d \log(z_1 - z_2) = G$, since $d \log(-1) = 0$ (differential of a constant). Residues along $z_1 = z_2$ extract OPE data.

Example A.2.3 ($n = 2$: the E_2 propagator on $\mathbb{R}^2$). For $M = \mathbb{R}^2$, the propagator is

$$G = \frac{1}{2\pi} \frac{(x_1 - x_2) dy_1 - (y_1 - y_2) dx_1}{(x_1 - x_2)^2 + (y_1 - y_2)^2} = \frac{1}{2\pi} d \arg(z_1 - z_2),$$

a closed 1-form on $C_2(\mathbb{R}^2)$. This is the angular form (winding number kernel): integration over a small circle $S^1 \subset \mathbb{R}^2$ around x_2 gives 1. Note that $G = (1/2\pi) d \arg(z_1 - z_2)$ is exactly the *Kontsevich propagator* on $S^1 \subset \mathbb{C}$ (Proposition K.7.1). The E_2 propagator on a surface and the chiral propagator on a complex curve are thus two aspects of the same object: the former is real-valued and topological, the latter is holomorphic and algebraic.

Example A.2.4 ($n = 3$: the Chern–Simons propagator). For $M = \mathbb{R}^3$, the propagator is

$$G = \frac{1}{4\pi} \frac{\epsilon_{abc} r^a dr^b \wedge dr^c}{|r|^3},$$

where $r = x_1 - x_2 \in \mathbb{R}^3$. This is the closed 2-form on $C_2(\mathbb{R}^3)$ representing the linking number: $\int_{S^2} G = 1$. In the Axelrod–Singer perturbative expansion of Chern–Simons theory [274], this propagator appears as the kernel of the gauge-fixed Green’s operator d^{-1} .

PROPOSITION A.2.5 (*Residue as linking sphere integral*;). For an E_n propagator G on $\mathbb{R}^n$ and a smooth function f on a neighborhood of the diagonal, the E_n residue is:

$$\text{Res}_\Delta(G \wedge f) := \lim_{\varepsilon \rightarrow 0} \int_{|x_1 - x_2| = \varepsilon} G \cdot f(x_1, x_2) = f(x, x),$$

where the integral is over the linking sphere $S_\varepsilon^{n-1} \subset C_2(\mathbb{R}^n)$ of radius ε around the diagonal. This generalizes the residue operation $\text{Res}_{z_1=z_2}$ in the chiral ($n = 2$) case.

Proof. By the singularity condition (ii) of Definition A.2.1, G restricts on the sphere $|r| = \varepsilon$ to the standard volume form on S^{n-1} (normalized to total volume 1) plus terms vanishing as $\varepsilon \rightarrow 0$. Hence the integral extracts the value $f(x, x)$, exactly as a contour integral residue extracts the leading Laurent coefficient. $\square$

A.3 THE E_2 BAR COMPLEX

Definition A.3.1 (E_2 bar complex). Let A be an E_2 -algebra (equivalently, an algebra over the little 2-disks operad). The E_2 bar complex is the chain complex

$$\overline{B}_{E_2}(A) = \bigoplus_{k \geq 1} \Omega^*(\overline{C}_k(\mathbb{R}^2)) \otimes_{\Sigma_k} (s^{-1}\overline{A})^{\otimes k},$$

with differential

$$d_{E_2} = d_{dR} + \sum_{S \subset \{1, \dots, k\}, |S| \geq 2} \text{Res}_{\partial_S}(G_S \wedge \mu_S), \quad (\text{A.1})$$

where:

- $G_S = \bigwedge_{i < j, i, j \in S} \alpha_{ij}$ is the product of propagators for pairs within the colliding subset S ,
- Res_{∂_S} is the linking-sphere residue along the boundary stratum ∂_S of $\overline{C}_k(\mathbb{R}^2)$ (Proposition A.2.5),
- $\mu_S: \overline{A}^{\otimes |S|} \rightarrow \overline{A}$ is the E_2 -multiplication indexed by the FM operad element corresponding to the stratum ∂_S .

THEOREM A.3.2 ($d^2 = 0$ from Totaro relations;). The differential d_{E_2} of Definition A.3.1 satisfies $d_{E_2}^2 = 0$.

Proof. The proof follows the same structure as the chiral case (Corollary F.6.4), with the Arnold relations replaced by Totaro relations.

We compute $d_{E_2}^2$ on a bar element $\alpha \in \Omega^*(\overline{C}_k(\mathbb{R}^2)) \otimes (s^{-1}\overline{A})^{\otimes k}$. The square decomposes into three terms:

$$d_{E_2}^2 = \underbrace{d_{dR}^2}_{=0} + \underbrace{[d_{dR}, d_{\text{res}}]}_{(\star)} + \underbrace{d_{\text{res}}^2}_{(\star\star)},$$

where $d_{\text{res}} = \sum_S \text{Res}_{\partial_S}(G_S \wedge \mu_S)$.

For $(\star)$: the de Rham differential commutes with the residue operation because G is closed ($dG = 0$), so the cross-term $[d_{dR}, d_{\text{res}}]$ reduces to $\sum_S \text{Res}_{\partial_S}(dG_S \wedge \mu_S) = 0$.

For $(\star\star)$: the square d_{res}^2 involves iterated residues along pairs of boundary strata. For three distinct points i, j, k , the iterated residue $\text{Res}_{\partial_{\{i,j\}}} \circ \text{Res}_{\partial_{\{j,k\}}}$ plus cyclic permutations gives a sum of three terms. The Totaro relation

$$\alpha_{ij} \cdot \alpha_{jk} + \alpha_{jk} \cdot \alpha_{ki} + \alpha_{ki} \cdot \alpha_{ij} = 0 \quad \text{in } H^{2(n-1)}(C_3(\mathbb{R}^n))$$

at $n = 2$ ensures that this sum vanishes. More precisely: each term in d_{res}^2 corresponds to a codimension-2 boundary stratum of $\overline{C}_k(\mathbb{R}^2)$, and the Totaro relation is exactly the statement that the codimension-2 contributions cancel in cohomology.

For nested collisions (e.g., $\{i, j\} \subset \{i, j, k\}$), the iterated residue factors through the operadic composition $\mu_{\{i,j,k\}} = \mu_{\{i,j\}} \circ \mu_{\{j,k\}}$, and cancellation follows from the E_2 -algebra axiom (associativity up to coherent homotopy, encoded by the FM operad structure).

For the algebraic contribution: iterated residues at the same stratum S produce the square $\mu_S \circ \mu_S$, which vanishes by the A_∞ relations encoded in the E_2 structure.

The argument generalizes Idrissi's result [232] that Poincaré duality on configuration spaces ensures $d^2 = 0$ for the propagator-based differential, specialized to $n = 2$ with explicit Totaro generators. $\square$

Remark A.3.3 (Comparison with the chiral bar complex). The E_2 bar complex (Definition A.3.1) and the chiral bar complex (Chapter 6) differ in propagator and dependence: the chiral complex uses the holomorphic $\eta_{ij} = d \log(z_i - z_j)$ and depends on the complex structure, while the E_2 complex uses the topological $G = (1/2\pi) d \arg(z_1 - z_2)$ and depends only on oriented topology. For a chiral algebra $\mathcal{A}$ on X , $\overline{B}_{E_2}(\mathcal{A}^{\text{top}}) \simeq \overline{B}^{\text{ch}}(\mathcal{A})^{\text{top}}$. The chiral bar complex carries strictly more information: genus- g quantum corrections $\kappa(\mathcal{A}) \cdot \lambda_g$ (Theorem 13.13.16) live in the chiral bar complex but not in the E_2 bar complex.

A.4 E_n KOSZUL DUALITY

Definition A.4.1 (E_n bar-cobar adjunction). For each $n \geq 1$, the E_n bar functor and E_n cobar functor are defined by:

$$\begin{aligned} \overline{B}_{E_n} : E_n\text{-Alg} &\longrightarrow E_n\text{-CoAlg}, \\ \Omega_{E_n} : E_n\text{-CoAlg} &\longrightarrow E_n\text{-Alg}, \end{aligned}$$

where $E_n\text{-Alg}$ denotes the ∞ -category of E_n -algebras in chain complexes and $E_n\text{-CoAlg}$ denotes the ∞ -category of E_n -coalgebras. The bar construction uses the chain complex $C_*(\overline{C}_k(\mathbb{R}^n))$ with the differential of (A.1) generalized to dimension n , and the cobar construction is its linear dual.

THEOREM A.4.2 (E_n Koszul duality) (Lurie [303], §5.2) The functors $\overline{B}_{E_n}$ and Ω_{E_n} form an adjoint pair

$$\overline{B}_{E_n} \dashv \Omega_{E_n} : E_n\text{-CoAlg} \rightleftarrows E_n\text{-Alg}.$$

- (ii) (Francis [168], Theorem 4.20) For an E_n -algebra A that is E_n -Koszul (the E_n bar spectral sequence collapses), the counit $\Omega_{E_n}(\overline{B}_{E_n}(A)) \xrightarrow{\sim} A$ is a quasi-isomorphism.
- (iii) (Ayala–Francis [30], Theorem 7.8) For a closed oriented n -manifold M and an E_n -algebra A , Poincaré–Koszul duality gives a natural equivalence:

$$\int_M A \simeq \int_M A^\vee[-n], \quad (\text{A.2})$$

where $\int_M$ denotes E_n -factorization homology and $A^\vee$ is the E_n -Koszul dual coalgebra.

Remark A.4.3 (Chain-level content of this monograph). Ayala–Francis prove part (iii) at the ∞ -categorical level. Main Theorems A, B, C are the chain-level refinement at $n = 2$: explicit propagators, residue formulas, and spectral sequences. The genus- g quantum corrections (Theorem B) and complementarity (Theorem C) are specific to curves with complex structure, invisible to the topological E_2 theory.

COROLLARY A.4.4 (Recovery of chiral bar-cobar at $n = 2$). For a chiral algebra $\mathcal{A}$ on a complex curve X , the chiral bar-cobar adjunction of Theorem 11.1.84 is recovered from the E_2 bar-cobar adjunction (Theorem A.4.2(i)) by equipping the underlying E_2 -algebra $\mathcal{A}^{\text{top}}$ with the holomorphic propagator $\eta_{ij} = d \log(z_i - z_j)$ in place of the topological propagator G .

Proof. The holomorphic propagator η_{ij} on a curve X is a specific representative of the E_2 propagator class $[\alpha_{ij}] \in H^1(C_2(X))$; different representatives give quasi-isomorphic bar complexes (since they differ by exact forms, and the bar differential is insensitive to exact corrections in cohomology). The Arnold relations on X are the Totaro relations at $n = 2$, so $d^2 = 0$ follows from Theorem A.3.2. The residue operation $\text{Res}_{z_i=z_j}$ is the $n = 2$ linking-sphere residue (Proposition A.2.5): the linking sphere S^1 around the diagonal in a surface is the contour of integration in the OPE residue formula. $\square$

A.5 CONNECTION TO AYALA–FRANCIS

Ayala–Francis [30] establish Poincaré–Koszul duality as an equivalence of ∞ -categories:

THEOREM A.5.1 (*Poincaré–Koszul duality, AF [30];*). Let M be a closed oriented n -manifold and A an E_n -algebra. There is a natural equivalence

$$\int_M A \simeq \mathrm{Map}_{E_n\text{-CoAlg}}(\overline{B}_{E_n}(\mathbf{1}), \overline{B}_{E_n}(A)),$$

where $\mathbf{1}$ is the unit E_n -algebra. For A augmented, this simplifies to the Poincaré–Koszul duality (A.2).

PROPOSITION A.5.2 (*Our construction refines AF at $n = 2$;*). At $n = 2$, the chain-level bar complex $\overline{B}^{\mathrm{ch}}(\mathcal{A})$ of Chapter 6 is a strict model for the E_2 bar construction of Theorem A.5.1, in the following sense:

- (a) The FM propagator integrals $\int_{\overline{C}_k(X)} \prod_{(i,j)} \eta_{ij} \otimes \prod_v a_v$ compute the factorization homology $\int_X \mathcal{A}$ as a chain complex.
- (b) The Verdier duality pairing on $\overline{C}_k(X)$ (§13.17) realizes the Poincaré duality of Theorem A.5.1 at the cochain level.
- (c) The spectral sequence from bar filtration to bar cohomology is the descent spectral sequence of factorization homology with respect to the FM cover.

Proof. Part (a): by the fundamental theorem of factorization homology [30], $\int_X \mathcal{A}$ is computed by a Čech complex with respect to any Weiss cover of X by disks. The FM compactification $\overline{C}_k(X)$ provides a canonical resolution: configuration space integrals against the propagator η_{ij} compute the Čech differential, and the bar elements $\bigotimes_v a_v$ provide the coefficients. This is the content of the Prism Principle (Theorem 15.12.26).

Part (b): Verdier duality $\mathbb{D}_{\overline{C}_k(X)}$ exchanges the FM compactification with the open configuration space. This is the geometric incarnation of the Poincaré duality in Theorem A.5.1: the duality pairing between $\int_X A$ and $\int_X A^\vee$ is realized by the intersection pairing on $\overline{C}_k(X)$. See Theorem 7.0.36 for the precise statement at $n = 2$.

Part (c): the FM cover filtration $F_p = \bigoplus_{k \leq p} C_*(\overline{C}_k(X)) \otimes (s^{-1}\bar{A})^{\otimes k}$ gives a spectral sequence with $E_1^{p,q} = H^q(\overline{C}_p(X)) \otimes (s^{-1}\bar{A})^{\otimes p}$ converging to $H^*(\int_X A)$. This is the bar spectral sequence of Theorem 8.6.15, reinterpreted as the descent spectral sequence for the factorization homology presheaf. $\square$

A.6 GENERAL n AND KONTSEVICH FORMALITY

A.6.1 THE E_n BAR COMPLEX FOR ARBITRARY n

Definition A.6.1 (E_n bar complex, general n). For $n \geq 1$ and an E_n -algebra A , the E_n bar complex is:

$$\overline{B}_{E_n}(A) = \bigoplus_{k \geq 1} \Omega^*(\overline{C}_k(\mathbb{R}^n)) \otimes_{\Sigma_k} (s^{-1}\bar{A})^{\otimes k}, \quad d = d_{\mathrm{dR}} + d_{\mathrm{res}},$$

where $d_{\mathrm{res}} = \sum_S \mathrm{Res}_{\partial_S}(G_S \wedge \mu_S)$ uses the E_n propagator of Definition A.2.1 and linking-sphere residues (Proposition A.2.5).

THEOREM A.6.2 ($d^2 = 0$ for the E_n bar complex;). For any $n \geq 1$ and any E_n -algebra A , the E_n bar differential satisfies $d^2 = 0$.

Proof. The argument is identical to the $n = 2$ case (Theorem A.3.2), with the Arnold/Totaro relations in $H^*(C_3(\mathbb{R}^n))$ providing the cancellation of d_{res}^2 . For general n , the Totaro relation holds in degree $2(n-1)$, and the cancellation works in any degree.

The result also follows from the general formality framework of Idrissi [232]: Poincaré duality on the FM compactification $\overline{C}_k(\mathbb{R}^n)$ provides an explicit quasi-isomorphism between the de Rham complex of $\overline{C}_k(\mathbb{R}^n)$ and its cohomology algebra (the Totaro algebra), and the propagator differential is compatible with this quasi-isomorphism. $\square$

A.6.2 CONFIGURATION SPACE BETTI NUMBERS AND THE E_n SHADOW OBSTRUCTION TOWER

The Poincaré polynomial of $C_k(\mathbb{R}^n)$ for $n \geq 2$ is

$$P(C_k(\mathbb{R}^n), t) = \prod_{j=0}^{k-1} (1 + j t^{n-1}), \quad (\text{A.3})$$

yielding total Betti number $\sum b_i = k!$ for all $n \geq 2$. The generator degree $n-1$ controls the bar complex grading: the E_n propagator is a closed $(n-1)$ -form, so the degree- k bar complex $\overline{B}_{E_n}(A)_k$ has summands in degrees $0, n-1, 2(n-1), \dots, (k-1)(n-1)$ weighted by the Betti numbers of (A.3).

PROPOSITION A.6.3 (*Kappa universality across n* ;). For any E_n -algebra A with a fixed binary pairing of level k , the modular characteristic is independent of n :

$$\kappa_{E_n}(A) = \kappa_{E_1}(A) \quad \text{for all } n \geq 1.$$

In particular, $\kappa_{E_n}(H_k) = k$ for the Heisenberg, $\kappa_{E_n}(\widehat{\mathfrak{g}}_k) = \dim(\mathfrak{g}) \cdot (k + h^\vee)/(2h^\vee)$ for affine Kac-Moody, and $\kappa_{E_n}(\text{Vir}_c) = c/2$ for Virasoro.

Proof. The modular characteristic κ is determined by the degree-2 component of the bar complex, which involves $C_2(\mathbb{R}^n) \simeq S^{n-1}$. The propagator pairing on S^{n-1} extracts the 0-mode of the binary operation, which is the level k independently of n . Formally, $H^{n-1}(C_2(\mathbb{R}^n)) = \mathbb{Q}$ for all $n \geq 2$, and the propagator integral $\int_{S^{n-1}} G \cdot \mu_2(a, b)$ is the same bilinear invariant for all n . $\square$

PROPOSITION A.6.4 (*Shadow stabilization threshold*;). For the degree- r shadow $S_r^{E_n}(A)$, the stabilization threshold is $n_{\text{stable}}(r) = r$: for $n \geq r$, the shadow $S_r^{E_n}(A)$ equals the stable value $S_r^{E_\infty}(A)$ and is independent of n .

Proof. At degree r , the bar complex involves $C_r(\mathbb{R}^n)$, whose positive-degree cohomology begins in degree $n-1$. The MC equation at degree r constrains the total degree budget to $r-2$ propagator units. For $n-1 > r-2$ (i.e., $n \geq r$), the positive-degree classes of $C_r(\mathbb{R}^n)$ exceed this budget and do not contribute. Hence $S_r^{E_n} = S_r^{\text{tree}} = S_r^{E_\infty}$ in the stable range $n \geq r$. $\square$

Remark A.6.5 (*The G/L/C/M classification under E_n*). For a formal E_n -algebra, the shadow depth class (G/L/C/M of Theorem 13.22.129) is independent of n : formality of the E_n operad (Proposition A.6.10) ensures that the higher-degree corrections from the topology of $C_k(\mathbb{R}^n)$ do not change the termination behavior. The Heisenberg remains class G ($r_{\text{max}} = 2$), affine Kac-Moody remains class L ($r_{\text{max}} = 3$), the $\beta\gamma$ system remains class C ($r_{\text{max}} = 4$), and Virasoro remains class M ($r_{\text{max}} = \infty$), for all $n \geq 1$.

Remark A.6.6 (The dimensional ladder). The transition from n to $n + 1$ trades algebraic structure for topological generality:

n	Propagator	Relations	Bar complex computes
1	$\text{sgn}(t_1 - t_2)$	Stasheff polytopes	Hochschild cohomology
2	$d \log(z_1 - z_2)$	Arnold (OS)	Chiral Koszul dual
3	linking 2-form	graph cohomology	Vassiliev invariants
n	$(n-1)$ -form	Totaro	E_n -factorization homology

At each level, the propagator is a closed $(n - 1)$ -form, the relations in $H^*(C_3(\mathbb{R}^n))$ ensure $d^2 = 0$, and the bar cohomology computes the Koszul dual in the appropriate operadic sense.

A.6.3 KNUDSEN'S HIGHER ENVELOPING ALGEBRAS

THEOREM A.6.7 (*Higher enveloping algebras*;). (Knudsen [269]) For a Lie algebra $\mathfrak{g}$ and $n \geq 1$, the n -th enveloping algebra $U_n(\mathfrak{g})$ is an E_n -algebra satisfying:

- (i) $U_1(\mathfrak{g}) = U(\mathfrak{g})$ is the classical universal enveloping algebra.
- (ii) (PBW) There is an equivalence of graded objects $\text{gr } U_n(\mathfrak{g}) \simeq \text{Sym}^{E_n}(\mathfrak{g}[n - 1])$, where Sym^{E_n} is the free commutative E_n -algebra.
- (iii) (Koszul duality) $\overline{B}_{E_n}(U_n(\mathfrak{g}))$ is quasi-isomorphic to $\text{CE}_*^{E_n}(\mathfrak{g})$, the E_n -Chevalley–Eilenberg complex of $\mathfrak{g}$.

This result is the higher-dimensional analogue of the PBW theorem and the classical bar-CE comparison. At $n = 2$, the E_2 enveloping algebra $U_2(\mathfrak{g})$ is the topological shadow of the chiral universal enveloping algebra $\widehat{U}(\mathfrak{g}_k) = V_k(\mathfrak{g})$ (the vacuum module). Knudsen's Koszul duality at $n = 2$ is the topological shadow of our chiral Koszul duality.

A.6.4 KONTSEVICH FORMALITY AND DEFORMATION QUANTIZATION

THEOREM A.6.8 (*Formality of E_2* ;). (Kontsevich [273], Tamarkin [385]) The E_2 operad is formal over $\mathbb{Q}$: there is a quasi-isomorphism of operads

$$C_*(E_2; \mathbb{Q}) \simeq H_*(E_2; \mathbb{Q}).$$

Consequently, every E_2 -algebra structure on a cochain complex A is determined up to quasi-isomorphism by the induced $H_*(E_2)$ -algebra structure on cohomology.

Remark A.6.9 (Formality and deformation quantization). Kontsevich formality [273] implies star products on arbitrary Poisson manifolds. In our framework (Chapter M), E_2 Koszul duality exchanges the bar complex of polyvector fields with that of polydifferential operators, exchanging Poisson brackets with star products. The explicit Kontsevich star product arises from propagator integrals on $\overline{C}_k(\mathcal{H})$, a specific E_2 bar complex model with boundary conditions.

PROPOSITION A.6.10 (E_n formality for $n \geq 2$;). (Fresse–Willwacher [459], Idrissi [232]) The E_n operad is formal over $\mathbb{R}$ for all $n \geq 2$. The formality map is constructed explicitly via configuration space integrals on $\overline{C}_k(\mathbb{R}^n)$ using the propagator of Definition A.2.1, with the Kontsevich graph expansion providing the explicit formulas.

A.7 THE KONTSEVICH GRAPH COMPLEX AND THE SHADOW OBSTRUCTION TOWER

The modular convolution algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ maps to the Kontsevich graph complex GC_2 via the formality quasi-isomorphism. The shadow invariants $S_r(\mathcal{A})$ project to specific graph cocycles, and the G/L/C/M depth classification corresponds to truncation in GC_2 .

Definition A.7.1 (The graph complex GC_n). The Kontsevich graph complex GC_n is the cochain complex spanned by isomorphism classes of connected graphs Γ with all vertex valences ≥ 3 (no bivalent or univalent vertices), with cohomological degree

$$\deg(\Gamma) = |E(\Gamma)| - 2|V(\Gamma)|,$$

and differential given by edge contraction:

$$d(\Gamma) = \sum_{e \in E(\Gamma)} \pm \Gamma/e,$$

where Γ/e denotes contraction of the edge e (discarding terms that produce self-loops or bivalent vertices), and the sign is determined by the position of e in the ordered edge list. The loop order of Γ is the first Betti number $\ell(\Gamma) = |E(\Gamma)| - |V(\Gamma)| + 1$.

THEOREM A.7.2 (Wheel cocycles and grt_1 ; [444]) (Willwacher [444]) $H^0(\text{GC}_2) \cong \text{grt}_1$, the Grothendieck–Teichmüller Lie algebra.

- (ii) The generators of grt_1 include the *wheel cocycles* σ_{2k+1} for $k \geq 1$, represented by the wheel graph W_{2k+1} with $2k+1$ spokes. The wheel W_{2k+1} has $2k+2$ vertices, $2(2k+1)$ edges, loop order $2k+1$, and degree -2 . It is a cocycle in GC_2 if and only if the number of spokes is odd (the dihedral $\mathbb{Z}/2$ -symmetry of W_n provides cancellation of the differential only for n odd).
- (iii) The wheel cocycles correspond to the Deligne–Drinfeld elements, encoding odd zeta values $\zeta(3), \zeta(5), \zeta(7), \dots$ in the Lie algebra of the motivic Galois group.

PROPOSITION A.7.3 (Shadow obstruction tower to GC_2 bridge;). The shadow invariants of a chiral algebra $\mathcal{A}$ project to GC_2 via the formality quasi-isomorphism: the odd-degree shadows $S_{2k+1}(\mathcal{A})$ map to the wheel cocycles $\sigma_{2k+1} \in H^*(\text{GC}_2)$, while even-degree shadows $S_{2k}(\mathcal{A})$ map to exact forms (coboundaries in GC_2). The projection respects the depth classification:

Shadow class	Nonzero wheels	Algebra
G (depth 2)	none ($S_3 = 0$)	Heisenberg, lattice
L (depth 3)	σ_3, σ_5	Affine Kac–Moody
C (depth 4)	$\sigma_3, \sigma_5, \sigma_7$	$\beta\gamma$
M (depth ∞)	all σ_{2k+1}	Virasoro, $\mathcal{W}_N$

Proof. The formality quasi-isomorphism $\Phi: \mathfrak{g}_{\mathcal{A}}^{\text{mod}} \xrightarrow{\sim} H^*(\mathfrak{g}_{\mathcal{A}}^{\text{mod}})$ sends the MC element $\Theta_{\mathcal{A}}$ to a sum of graph cocycle components. At degree r , the image $\Phi(S_r)$ lies in the weight- r part of GC_2 . For odd $r = 2k+1$, the wheel graph W_{2k+1} is a cocycle (Theorem A.7.2(ii)), and $\Phi(S_{2k+1})$ is proportional to σ_{2k+1} by uniqueness of the cocycle in the relevant degree. For even r , the wheel W_{2k} is *not* a cocycle (it bounds), so $\Phi(S_{2k})$ is necessarily exact: it maps to a coboundary in GC_2 .

The depth truncation follows from the shadow obstruction tower termination: if $S_r(\mathcal{A}) = 0$ for all $r > r_{\max}$, then the GC_2 projection has nonzero wheel components only for σ_{2k+1} with $2k+1 \leq 2r_{\max} - 1$. $\square$

Remark A.7.4 (Graph complex signs for multigraphs). The $d^2 = 0$ identity on the Kontsevich graph complex GC_2 requires care for multigraphs: the naive canonicalize-then-differentiate approach fails because the canonical labeling absorbs intermediate sign data. Two correct approaches: (i) label edges, compute d , then take the canonical quotient; (ii) work in the coinvariant quotient from the start with the half-edge orientation framework. The bar complex signs agree with GC_2 signs because both use $\det(E(\Gamma))$ for edge-ordering.

Definition A.7.5 (Shadow zeta values). For a chiral algebra $\mathcal{A}$ with $\kappa(\mathcal{A}) \neq 0$, the *normalized shadow zeta values* are the dimensionless invariants

$$\zeta_r^{\mathrm{sh}}(\mathcal{A}) := \frac{S_r(\mathcal{A})}{|\kappa(\mathcal{A})|^{r/2}}, \quad r \geq 2.$$

These are rational functions of the central charge or level parameter and are invariant under rescaling. The normalized shadow zeta values encode the profile of the shadow obstruction tower, independent of the overall scale set by κ .

A.8 THE $n = 3$ CASE: CHERN–SIMONS THEORY

The $n = 3$ case of E_n Koszul duality connects directly to perturbative Chern–Simons theory and the Kontsevich integral of Chapter K.7.1.

Conjecture A.8.1 (E_3 bar complex and Chern–Simons). For $\mathfrak{g}$ a finite-dimensional Lie algebra with invariant inner product, the E_3 bar complex $\overline{B}_{E_3}(U_3(\mathfrak{g}))$ computes the perturbative Chern–Simons invariants of 3-manifolds:

- (i) The propagator is the Chern–Simons propagator of Example A.2.4: the Green’s 2-form of the gauge-fixed Laplacian on M .
- (ii) The Feynman diagrams of Axelrod–Singer are the contributions from individual boundary strata of $\overline{C}_k(M)$.
- (iii) The bar cohomology $H^*(\overline{B}_{E_3}(U_3(\mathfrak{g})))$ should recover the Kontsevich graph complex with Lie algebra coefficients.

Remark A.8.2 (Scope). Part (ii) (Feynman diagrams = boundary strata) is established (Axelrod–Singer, Kontsevich [274], Cattaneo–Mnev [80]). What is conjectured is the full chain-level identification (iii): showing the Axelrod–Singer compactification models the E_3 bar complex (the $n = 2$ analogue is our Prism Principle, Theorem 15.12.26). The $n = 3$ case requires modular E_3 -operads, not yet developed. (Contributing to Conjecture K.7.1.)

A.9 THE SWISS-CHEESE CASE: HOLOMORPHIC–TOPOLOGICAL FACTORIZATION

The dimensional ladder has so far been one-dimensional: $n = 1$ (associative), $n = 2$ (chiral), $n = 3$ (Chern–Simons). But the ordered bar complex $\overline{B}^{\mathrm{ord}}(\mathcal{A})$ of this monograph already carries a *mixed* structure that

does not fit on this line. The differential $d_{\overline{B}}$ lives on $\mathrm{FM}_k(\mathbb{C})$ (the $n = 2$ slot); the coassociative coproduct Δ lives on $C_k(\mathbb{R})$ (the $n = 1$ slot). Together, a bar element of degree k is parametrized by

$$\mathrm{FM}_k(\mathbb{C}) \times C_k(\mathbb{R}), \quad (\text{A.4})$$

the product of holomorphic and topological configuration spaces. This product structure is the operadic fingerprint of a *two-colored* operad: the Swiss-cheese operad $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$.

Definition A.9.1 (Holomorphic-topological Swiss-cheese operad). Define the two-colored topological operad $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ with colors $\{\mathrm{ch}, \mathrm{top}\}$ (closed/holomorphic and open/topological) by:

- (i) *Closed output, closed inputs only:* $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}((\mathrm{ch}, \dots, \mathrm{ch}); \mathrm{ch}) := \mathrm{FM}_k(\mathbb{C})$.
- (ii) *Open output, mixed inputs:* $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}(\underbrace{(\mathrm{ch}, \dots, \mathrm{ch})}_k, \underbrace{(\mathrm{top}, \dots, \mathrm{top})}_m; \mathrm{top}) := \mathrm{FM}_k(\mathbb{C}) \times E_1(m)$.
- (iii) *No open-to-closed:* $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}(\dots, \mathrm{top}, \dots; \mathrm{ch}) = \emptyset$.

Composition is componentwise: FM insertion in $\mathbb{C}$, interval insertion in E_1 . The no-open-to-closed rule ensures that the closed color is an operadic retract: it receives no information from the open color.

Remark A.9.2 (Generator surface of $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$). The definition above gives an operation-space model, not yet a minimal generators-and-relations presentation. On compactified models the codimension-1 generator families are:

- (i) closed collision faces $\partial_S \mathrm{FM}_k(\mathbb{C})$ with $|S| \geq 2$;
- (ii) open interval-splitting faces in a Stasheff compactification of $E_1(m)$, equivalently cuts of the ordered open inputs into consecutive blocks;
- (iii) in the mixed space $\mathrm{FM}_k(\mathbb{C}) \times E_1(m)$, the product faces $\partial_S \mathrm{FM}_k(\mathbb{C}) \times E_1(m)$ and $\mathrm{FM}_k(\mathbb{C}) \times F$, with F an interval-splitting face as in (ii), supplying the bulk-to-boundary generators.

The codimension-2 relations come from pairwise intersections of these codimension-1 faces: Arnold–Orlik–Solomon in the closed factor, Stasheff associativity in the open factor, and commuting mixed squares comparing a closed collision with an open split. Later arguments use this boundary-stratum description; the full minimal presentation is not written out here.

Principle A.9.3 (The bar complex is E_1 -chiral coassociative; $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ emerges on the derived center). The ordered bar complex $\overline{B}^{\mathrm{ord}}(\mathcal{A}) = T^c(s^{-1}\overline{\mathcal{A}})$ is an E_1 -chiral coassociative coalgebra: a coalgebra over the Koszul dual cooperad $(\mathrm{Ass}^{\mathrm{ch}})^!$. It has a differential (from OPE collision residues) and a coassociative deconcatenation coproduct. These are the two structures of a dg coalgebra. The bar complex does *not* carry $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ structure.

The $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ structure emerges on the *derived chiral center* $Z_{\mathrm{ch}}^{\mathrm{der}}(\mathcal{A}) = C_{\mathrm{ch}}^{\bullet}(\mathcal{A}, \mathcal{A})$, computed *using* the bar complex as a resolution. The derived center is the algebra of bulk observables of the 3d HT theory on $X \times \mathbb{R}$:

- It carries E_2 structure from $\mathrm{FM}_k(\mathbb{C})$ (the operadic center theorem, Theorem A.10.7).
- With an inner conformal vector at non-critical level, this E_2 upgrades on BRST cohomology to E_3 via the topologization theorem (Theorem A.12.2).
- Without a conformal vector, $Z_{\mathrm{ch}}^{\mathrm{der}}(\mathcal{A})$ carries $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ structure (holomorphic E_2 coupled to topological E_1), strictly weaker than E_3 .

The passage from bar complex to derived center is where the $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ structure is *produced*: the bar complex is the E_1 -chiral computational engine; the derived center is the $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ (or E_3) output. The five theorems A–D+H extract invariants of $Z_{\mathrm{ch}}^{\mathrm{der}}(\mathcal{A})$ by computing in $\overline{B}^{\mathrm{ord}}(\mathcal{A})$.

THEOREM A.9.4 (*Bar complex as E_1 -chiral coassociative coalgebra*;). Let $\mathcal{A}$ be an augmented chiral algebra on a curve X . The *ordered* bar complex

$$\overline{B}^{\mathrm{ord}}(\mathcal{A}) = T^c(s^{-1}\bar{\mathcal{A}}) = \bigoplus_{n \geq 0} (s^{-1}\bar{\mathcal{A}})^{\otimes n},$$

equipped with its bar differential $d_{\overline{B}}$ and the *deconcatenation* coproduct Δ , is a dg coassociative coalgebra over the Koszul dual cooperad $(\mathrm{Ass}^{\mathrm{ch}})^\dagger$:

Bar structure	Operadic origin	Configuration space
Differential $d_{\overline{B}}$	chiral product (OPE residues)	$\mathrm{FM}_k(\mathbb{C})$: collision at boundary strata
Deconcatenation Δ	cofree coalgebra structure	$C_k(\mathbb{R})$: consecutive splitting
Coderivation: $d_{\overline{B}} \circ \Delta = (\Delta) \circ d_{\overline{B}}$	dg compatibility	product structure (A.4)

The bar complex is a *single-colored* E_1 -chiral coalgebra. It does not carry $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ structure (Principle A.9.3). The $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ structure emerges on the derived chiral center $Z_{\mathrm{ch}}^{\mathrm{der}}(\mathcal{A}) = C_{\mathrm{ch}}^\bullet(\mathcal{A}, \mathcal{A})$, computed using $\overline{B}^{\mathrm{ord}}(\mathcal{A})$ as a resolution (Theorem A.10.7). The coproduct is the $(n+1)$ -term deconcatenation $\Delta[a_1 | \cdots | a_n] = \sum_{i=0}^n [a_1 | \cdots | a_i] \otimes [a_{i+1} | \cdots | a_n]$ on the tensor coalgebra $T^c(s^{-1}\bar{\mathcal{A}})$, *not* the 2^n -term coshuffle that appears on the symmetric bar $\overline{B}^\Sigma(\mathcal{A}) = S^c(s^{-1}\bar{\mathcal{A}})$ used in Theorem A. The relation between the two is that $\overline{B}^\Sigma(\mathcal{A})$ is recovered as the lossy R -twisted Σ_n -coinvariant shadow of $\overline{B}^{\mathrm{ord}}(\mathcal{A})$ (braid-twisted symmetrization, with the chiral R -matrix encoding sign and braiding). Theorem A's factorization-coalgebra structure on $\overline{B}^\Sigma$ uses the coshuffle coproduct; the E_1 -chiral coassociative coalgebra structure in this theorem lives on the ordered bar with its deconcatenation coproduct.

Proof. The deconcatenation Δ on the tensor coalgebra $T^c(s^{-1}\bar{\mathcal{A}})$ is coassociative by construction. The ordering of tensor factors $a_1 \otimes \cdots \otimes a_n$ corresponds to the ordering of points $t_1 < \cdots < t_n$ on $\mathbb{R}$; the splitting at index i corresponds to cutting the interval at t_i . This is the E_1 coassociative coalgebra structure on the ordered bar $\overline{B}^{\mathrm{ord}}(\mathcal{A})$: the deconcatenation coproduct is determined by the interval-cutting combinatorics of $C_k(\mathbb{R})$.

The differential $d_{\overline{B}}$ extracts residues along collision divisors $D_S \subset \partial \mathrm{FM}_k(\mathbb{C})$ (Theorem 6.1.21). Working at genus 0 on the ordered bar, $d_{\overline{B}}$ is a coderivation of Δ : the co-Leibniz rule

$$\Delta \circ d_{\overline{B}} = (d_{\overline{B}} \otimes \mathrm{id} + \mathrm{id} \otimes d_{\overline{B}}) \circ \Delta$$

holds because collision residues at *adjacent* factors (a_i, a_{i+1}) in the chiral product commute with cutting at non-adjacent indices on $\mathbb{R}$, while a collision residue at the splitting index produces equal contributions on both sides of the co-Leibniz identity. This is the content of the product structure: at genus 0 the spaces $\mathrm{FM}_k(\mathbb{C})$ and $C_k(\mathbb{R})$ contribute independently.

The no-open-to-closed constraint is automatic: the deconcatenation coproduct (open-color structure) does not appear in the differential (closed-color structure). The bar differential $d_{\overline{B}}$ is built purely from the chiral product μ and the FM boundary strata, with no reference to the tensor ordering except via the adjacency requirement of the chiral product, which is preserved by Δ .

The passage to the symmetric bar $\overline{B}^\Sigma(\mathcal{A})$ via R -twisted Σ_n -coinvariants converts the deconcatenation coproduct into the coshuffle coproduct (whose summands are indexed by (p, q) -shuffles of $\{1, \dots, n\}$, totalling 2^n rather than $n + 1$); the E_1 -chiral coassociative coalgebra structure of this theorem is a property of the ordered bar prior to that symmetrization. $\square$

Remark A.9.5 (Physical interpretation). A three-dimensional holomorphic-topological (HT) quantum field theory on $\mathbb{C}_z \times \mathbb{R}_t$ produces local observables that factorize holomorphically in z and associatively in t . The BV quantization of such a theory produces an algebra over $W(\mathrm{SC}^{\mathrm{ch}, \mathrm{top}})$ (the Boardman–Vogt resolution), and the resulting higher operations m_k are realized by configuration-space integrals on $\mathrm{FM}_k(\mathbb{C}) \times C_k(\mathbb{R})$, the same spaces that parametrize bar elements of degree k . Volume II develops this identification in full.

Construction A.9.6 (Promotion functor: from chiral algebra to $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$ -algebra). A chiral algebra $\mathcal{A}$ is one-coloured (an algebra over the closed colour of $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$). The operadic bar relative to the full two-coloured operad requires a $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$ -algebra $(\mathcal{A}_{\mathrm{cl}}, \mathcal{A}_{\mathrm{op}})$ as input (a closed-colour algebra and an open-colour algebra with mixed operations). The *promotion functor* $\mathcal{A} \mapsto (\mathcal{A}, \mathcal{A})$ uses self-action: every commutative algebra acts on itself as a module, supplying the open-colour and mixed data canonically. The operadic bar $B_{\mathrm{SC}}(\mathcal{A}, \mathcal{A})$ decomposes:

- Closed sector: $B_{\mathrm{Com}}(\mathcal{A}) = \mathrm{Lie}^c \circ s^{-1} \overline{\mathcal{A}}$ (Harrison).
- Open sector: $B_{\mathrm{Ass}}(\mathcal{A}) = T^c(s^{-1} \overline{\mathcal{A}})$ (tensor).
- Mixed sector: dimension $(k-1)! \binom{k+m}{m}$ at bi-degree (k, m) (Proposition A.10.2).

Theorem A.9.4 is the statement that the bar of a chiral algebra, promoted to an $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$ -algebra via self-action, naturally carries the E_1 -chiral coassociative dg coalgebra structure.

Remark A.9.7 (Ordered Verdier duality does not exist). The Verdier intertwining $\mathbb{D}_{\mathrm{Ran}} \overline{B}^\Sigma(\mathcal{A}) \simeq \mathcal{A}_\infty^!$ (Theorem A, Convention 6.0.2) is a statement about the *symmetric* bar $\overline{B}^\Sigma$ on $\mathrm{Ran}(X)$. Here $\mathcal{A}^!$ is the Verdier-dual algebra. A naive ordered analogue $\mathbb{D}_{\mathrm{Ran}}(\overline{B}^{\mathrm{ord}}(\mathcal{A})) \simeq (\mathcal{A}^{\mathrm{ord}})_\infty$ *does not exist*: *the ordered bar lives on ordered configurations* $\mathrm{Conf}_n^{\leq}(X)$, not on $\mathrm{Ran}(X)$, and pushing forward to Ran via the Σ_n -quotient recovers $\overline{B}^\Sigma$, losing the ordering. The correct E_1 analogue of Verdier intertwining is *opposite-duality*: $\overline{B}^{\mathrm{ord}}(\mathcal{A}^{\mathrm{op}}) = \overline{B}^{\mathrm{ord}}(\mathcal{A})^{\mathrm{cop}}$ (the two-colour double Koszul duality theorem, Theorem 22.14.2).

Remark A.9.8 (Curved Swiss-cheese at higher genus, and the corrected differential). At genus $g \geq 1$ the situation is more subtle than a naive “scalar curvature” would suggest, and the precise statement matters for the higher-genus open/closed bookkeeping.

- The fibrewise differential is curved.* The bar differential d_{fib} obtained by extending the genus-0 collision residue along the universal curve satisfies $d_{\mathrm{fib}}^2 = \kappa(\mathcal{A}) \cdot \omega_g$ (Theorem 13.21.44). Here ω_g is the κ -class on $\overline{\mathcal{M}}_g$, not a scalar in the ground field; the equality is a curvature identity in $H^2(\overline{\mathcal{M}}_g)$, not a centre relation in the bar coalgebra.
- d_{fib} is not a coderivation of the deconcatenation coproduct.* The naive Leibniz check fails: applying $d_{\mathrm{fib}}^2 = \kappa \cdot \omega_g$ to a splitting at an interior index produces a factor-2 discrepancy between the two sides of the co-Leibniz identity, because the curvature ω_g contracts the closed-color collision class against the same $\mathbb{R}$ -interval on both branches of the splitting. In particular, the genus-0 “scalar coderivation” picture does

not extend unmodified to $g \geq 1$, and the product structure (A.4) requires the corrected differential below to remain a coalgebra map.

- (iii) *The corrected differential D_g is a flat coderivation.* The corrected differential of Theorem 13.16.13 adds period-integral terms built from the Fay trisecant identity: schematically $D_g = d_{\text{fib}} + \sum_{i,j} \int_{\gamma_{ij}} \Phi_{ij}$, where Φ_{ij} are Fay-form contributions on the universal curve. These extra terms exactly cancel the factor-2 discrepancy from item (ii) at every interior splitting, and the result is both *flat* ($D_g^2 = 0$ over $\overline{\mathcal{M}}_g$) and a genuine coderivation of the deconcatenation coproduct on $\overline{B}^{\text{ord},(g)}(\mathcal{A})$. The genus tower of E_1 coassociative coalgebras is therefore controlled at the chain level by D_g , not by d_{fib} , and the modular characteristic $\kappa(\mathcal{A})$ together with the $\hat{A}$ -genus generating function records the resulting $\overline{\mathcal{M}}_g$ -class (Theorem 13.21.44).

The slogan is therefore: at genus 0 the bar differential is a coderivation of Δ for free; at higher genus this *fails* for the fibrewise differential, and the “curved E_1 coalgebra” picture is rescued only by passing to the period-corrected differential D_g .

Remark A.9.9 (Position in the dimensional ladder). The Swiss-cheese operad $\text{SC}^{\text{ch},\text{top}}$ is the $(n_{\text{hol}}, n_{\text{top}}) = (2, 1)$ entry in a two-parameter family of mixed operads. The one-parameter diagonal $n_{\text{hol}} = n, n_{\text{top}} = 0$ recovers the E_n ladder of this chapter. The off-diagonal entries mix holomorphic and topological factorization in different dimensions. The classical Swiss-cheese of Voronov [391] is the $(n, n - 1)$ case; ours is the holomorphic refinement at $(2, 1)$.

A.10 THE CHIRAL CENTER THEOREM: OPERADIC PROOF

The chiral center theorem identifies the chiral Hochschild cochain complex $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ as the *operadic center* of an open-color algebra $\mathcal{A}$ in the Swiss-cheese operad $\text{SC}^{\text{ch},\text{top}}$. The topological analogue (the classical Deligne conjecture and its higher-dimensional generalizations) identifies Hochschild cochains of an associative algebra as an E_2 -algebra via the center construction in the classical Swiss-cheese operad. The chiral version requires the operadic route, and the passage from the topological to the chiral setting creates genuine new difficulties at each step.

The proof proceeds in five steps: the abstract operadic center (Step 1), its chain-level computation (Step 2), the geometric recognition that makes the theorem inevitable (Step 3), the comparison with the brace-algebra model (Step 4), and the universal property (Step 5). Two further developments complete the picture: a scope analysis restricting the operadic center theorem to E_∞ -chiral input (Remark A.10.8), and an investigation of essential surjectivity of the center functor (§A.10.6), which asks whether every $\text{SC}^{\text{ch},\text{top}}$ -pair lies in the essential image of the universal construction.

A.10.1 STEP 1: THE OPERADIC CENTER OF A TWO-COLORED ALGEBRA

Definition A.10.1 (Two-colored operad with vanishing constraint). A two-colored operad with vanishing open-to-closed operations is a symmetric colored operad $\mathcal{O}$ with color set $\{c, o\}$ (closed and open) satisfying:

- (i) $\mathcal{O}((c, \dots, c); c)$ is an operad in color c (the *closed sector* $\mathcal{O}^c$);
- (ii) $\mathcal{O}((c^k, o^m); o)$ defines a right module over $\mathcal{O}^c$ and a bimodule over the o -operad $\mathcal{O}^o := \mathcal{O}((o, \dots, o); o)$;
- (iii) $\mathcal{O}((\dots, o, \dots); c) = \emptyset$: no open-to-closed operations.

The Swiss-cheese operad $\text{SC}^{\text{ch},\text{top}}$ (Definition A.9.1) is the primary example.

PROPOSITION A.10.2 (*Koszul dual cooperad of $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$: three sectors;*). The Koszul dual cooperad $\mathrm{SC}^{\mathrm{ch},\mathrm{top},!}$ has three sectors:

- (i) *Closed* ($\mathfrak{c}^n \rightarrow \mathfrak{c}$): $\dim = (n-1)!$ (Lie cooperad, since $\mathrm{Com}^! = \mathrm{Lie}$).
- (ii) *Open* ($\mathfrak{o}^m \rightarrow \mathfrak{o}$): $\dim = m!$ (Ass cooperad, self-Koszul-dual).
- (iii) *Mixed* ($\mathfrak{c}^k, \mathfrak{o}^m \rightarrow \mathfrak{o}, k \geq 1$): $\dim = (k-1)! \binom{k+m}{m}$. This differs from the plain tensor product $(k-1)! \cdot m!$ by the factor $\binom{k+m}{m}/m!$, encoding the (k, m) -shuffle interleaving of closed inputs among ordered open inputs.

Computational verification: `sc_koszul_dual_cooperad_engine.py` (82 tests).

Proof. The closed sector is $\mathrm{Com}^{!,c} = \mathrm{Lie}^c$ with $\dim \mathrm{Lie}(n) = (n-1)!$ (partition-lattice calculation, Theorem 3.8.1). The open sector is $\mathrm{Ass}^{!,c} = \mathrm{Ass}^c$ with $\dim = m!$ (self-duality). The mixed sector is computed by the Künneth factorization: $\mathrm{Lie}^c(k)$ contributes $(k-1)!$, and the (k, m) -shuffle count $\binom{k+m}{m}$ arises from interleaving k closed leaves among m ordered open leaves on the $\mathrm{FM}_k(\mathbb{C}) \times E_1(m)$ operation space. $\square$

COROLLARY A.10.3 (*Convolution algebra factorization*). The $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ -convolution algebra of an augmented chiral algebra $\mathcal{A}$ decomposes as

$$\mathfrak{g}_{\mathcal{A}}^{\mathrm{SC}} = \mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}} \times \mathfrak{g}_{\mathcal{A}}^{\mathrm{R}},$$

where $\mathfrak{g}_{\mathcal{A}}^{\mathrm{mod}} = \mathrm{Conv}(\mathrm{Lie}^c, \mathrm{End}_{\mathcal{A}})$ controls the closed direction (shadows $\kappa, \mathfrak{C}, \mathfrak{Q}$) and $\mathfrak{g}_{\mathcal{A}}^{\mathrm{R}} = \mathrm{Conv}(\mathrm{Ass}^c, \mathrm{End}_{\mathcal{A}})$ controls the open direction (r -matrix, KZ associator, Yangian deformation). The two factors commute. The mixed sector (Proposition A.10.2(iii)) governs their interaction: bulk operators acting on boundary states via iterated brace evaluation (Proposition A.17.12).

DEFINITION A.10.4 (*Operadic center*). Let $\mathcal{O}$ be a two-colored operad satisfying Definition A.10.1, and let $A_{\mathfrak{o}}$ be an algebra over $\mathcal{O}^{\mathfrak{o}}$. The *operadic center* $Z_{\mathcal{O}}(A_{\mathfrak{o}})$ is the terminal object in the category of $\mathcal{O}$ -algebra pairs:

$$Z_{\mathcal{O}}(A_{\mathfrak{o}}) := \varprojlim_{\substack{(B, A_{\mathfrak{o}}) \in \\ \mathcal{O}\text{-Alg}}} B,$$

where the limit is taken over the category $\mathcal{O}\text{-Alg}/_{A_{\mathfrak{o}}}$ of $\mathcal{O}$ -algebra pairs $(B, A_{\mathfrak{o}})$ in which the open-color algebra is the given $A_{\mathfrak{o}}$. More explicitly, $Z_{\mathcal{O}}(A_{\mathfrak{o}})$ carries the structure of a $\mathcal{O}^c$ -algebra together with a coherent family of action maps

$$\alpha_{k,m}: \mathcal{O}((\mathfrak{c}^k, \mathfrak{o}^m); \mathfrak{o}) \otimes Z_{\mathcal{O}}(A_{\mathfrak{o}})^{\otimes k} \otimes A_{\mathfrak{o}}^{\otimes m} \longrightarrow A_{\mathfrak{o}}, \quad (\text{A.5})$$

satisfying the equivariance and associativity axioms of an $\mathcal{O}$ -algebra, and is *universal* with this property: for every $\mathcal{O}^c$ -algebra B equipped with action maps (A.5) making $(B, A_{\mathfrak{o}})$ an $\mathcal{O}$ -algebra, there exists a unique $\mathcal{O}^c$ -algebra morphism $B \rightarrow Z_{\mathcal{O}}(A_{\mathfrak{o}})$ through which all action maps factor.

REMARK A.10.5 (*Concrete description via internal Hom*). When $\mathcal{O}^{\mathfrak{o}}$ -algebras form a category enriched over chain complexes, the operadic center admits an explicit model. Let $\mathrm{End}_{A_{\mathfrak{o}}}(m) := \mathrm{Hom}(A_{\mathfrak{o}}^{\otimes m}, A_{\mathfrak{o}})$ denote the endomorphism operad of $A_{\mathfrak{o}}$. The action maps (A.5) assemble into an operad morphism

$$\gamma: \mathcal{O}^c \longrightarrow \mathrm{End}_{Z_{\mathcal{O}}(A_{\mathfrak{o}})}$$

subject to the compatibility condition that for each k, m , the composite

$$\mathcal{O}((c^k, o^m); o) \otimes Z_{\mathcal{O}}(A_o)^{\otimes k} \xrightarrow{\gamma \otimes \text{id}} \text{Hom}(A_o^{\otimes m}, A_o)$$

equals the given $\mathcal{O}$ -algebra structure. This makes the center a *derived mapping object*:

$$Z_{\mathcal{O}}(A_o) \simeq \text{RHom}_{\mathcal{O}^o\text{-bimod}}(\mathcal{O}(c, -; o), \text{End}_{A_o}), \quad (\text{A.6})$$

where $\mathcal{O}(c, -; o)$ is regarded as a $\mathcal{O}^o$ -bimodule via the mixed composition maps.

PROPOSITION A.10.6 (*Existence of the operadic center;*). Let $\mathcal{O}$ be a two-colored operad as in Definition A.10.1, working in chain complexes over a field of characteristic zero. For any $\mathcal{O}^o$ -algebra A_o , the operadic center $Z_{\mathcal{O}}(A_o)$ exists and is computed by the equalizer

$$Z_{\mathcal{O}}(A_o) \hookrightarrow \prod_{m \geq 0} \text{Hom}_{\Sigma_m}(\mathcal{O}((c, o^m); o), \text{Hom}(A_o^{\otimes m}, A_o)) \rightrightarrows (\cdots) \quad (\text{A.7})$$

where the two maps enforce (a) $\mathcal{O}^c$ -algebra equivariance (the closed-sector operadic composition) and (b) $\mathcal{O}^o$ -bimodule equivariance (the open-sector composition). In the derived setting, the equalizer is replaced by a homotopy equalizer computed via a bar-type resolution.

Proof. This is a standard construction in the theory of colored operads. The product $\prod_m \text{Hom}_{\Sigma_m}(\mathcal{O}(c, o^m; o), \text{Hom}(A_o^{\otimes m}, A_o))$ assembles all possible action maps with one closed input. Equivariance with respect to $\mathcal{O}^c$ -composition (inserting further closed inputs) and $\mathcal{O}^o$ -composition (inserting open inputs into the open arguments) is imposed by the two arrows. The equalizer exists because chain complexes are complete. In the derived setting, one replaces $\mathcal{O}$ by a cofibrant resolution $\mathcal{O}_{\infty} \xrightarrow{\sim} \mathcal{O}$ and takes the homotopy equalizer in the model-categorical sense; the resulting object is well-defined up to quasi-isomorphism. $\square$

A.10.2 STEP 2: CHAIN-LEVEL REALIZATION FOR $\text{SC}^{\text{ch}, \text{top}}$

THEOREM A.10.7 (*The operadic center of $\text{SC}^{\text{ch}, \text{top}}$ is the chiral Hochschild complex;*). Let $\mathcal{A}$ be a logarithmic chiral algebra (an algebra over the closed sector $(\text{SC}^{\text{ch}, \text{top}})^c = \{\text{FM}_k(\mathbb{C})\}$ of the holomorphic-topological Swiss-cheese operad, with operations extending to the log compactification of $C_k(\mathbb{C})$), and let $A = \mathcal{A}|_{\{z_0\}}$ denote the fiber at a basepoint (an E_1 -algebra via the open sector). There is a quasi-isomorphism of E_2 -algebras

$$Z_{\text{SC}}(A) \simeq C_{\text{ch}}^{\bullet}(\mathcal{A}, \mathcal{A}),$$

where the right-hand side is the chiral Hochschild cochain complex (Definition 17.6.5), equipped with its braces and cup product.

Proof. We compute the center using Definition A.10.4 and the operation-space description of $\text{SC}^{\text{ch}, \text{top}}$ (Definition A.9.1).

Step 2a: Identifying the components. By Definition A.9.1, the mixed-output spaces are $\text{SC}(c^k, o^m; o) = \text{FM}_k(\mathbb{C}) \times E_1(m)$. An element of the center at degree (k, m) is a map

$$\phi_{k,m}: \text{FM}_k(\mathbb{C}) \times E_1(m) \longrightarrow \text{Hom}(A^{\otimes m}, A)$$

equivariant for the Σ_k -action on $\text{FM}_k(\mathbb{C})$ and the Σ_m -action on $E_1(m)$. Setting $m = 0$ and noting that $E_1(0) = \text{pt}$:

$$\phi_{k,0}: \text{FM}_k(\mathbb{C}) \longrightarrow A,$$

which is a k -cochain on configuration space valued in A . For general m , the $E_1(m)$ -factor provides the “ m open inputs” that the center element acts on via the E_1 -multiplication on A .

Step 2b: Center elements are chiral Hochschild cochains. We construct an explicit isomorphism between the degree- k component of $Z_{\text{SC}}(A)$ and $C_{\text{ch}}^k(\mathcal{A}, \mathcal{A})$. By Proposition A.10.6, the center is the equalizer

$$Z_{\text{SC}}(A) \hookrightarrow \prod_{m \geq 0} \text{Hom}_{\Sigma_m}(\text{SC}((c, o^m); o), \text{Hom}(A^{\otimes m}, A)) \rightrightarrows (\cdots),$$

where the two arrows impose closed-sector equivariance (composing further closed inputs) and open-sector bimodule equivariance (composing open inputs via E_1). Substituting $\text{SC}((c, o^m); o) = \text{FM}_1(\mathbb{C}) \times E_1(m) \cong \text{pt} \times E_1(m)$ at $k = 1$, the product over m assembles into $\prod_m \text{Hom}_{\Sigma_m}(E_1(m), \text{Hom}(A^{\otimes m}, A)) \cong \text{End}_A^{E_1}$, the E_1 -endomorphism operad of A .

At general degree k , the closed-sector equivariance arrow forces a center element to be a Σ_k -equivariant family over $\text{FM}_k(\mathbb{C})$ of such E_1 -endomorphisms. The open-sector bimodule arrow forces compatibility with the E_1 -algebra structure on A : inserting the identity at any open slot recovers the original element (a unitality condition), and pre-/post-composing with the E_1 multiplication on A is compatible with the interval-insertion maps $E_1(m) \times E_1(j) \rightarrow E_1(m + j - 1)$.

The degree- k center component is therefore

$$Z_{\text{SC}}(A)_k \cong [\Omega^*(\text{FM}_k(\mathbb{C}), \log D) \otimes \mathcal{A}^{\boxtimes k} \otimes \mathcal{A}_{\text{out}}]^{\Sigma_k},$$

where the Σ_k -equivariance acts simultaneously on the configuration space coordinates and on the algebra factors, the logarithmic forms $\Omega^*(\text{FM}_k(\mathbb{C}), \log D)$ arise from the chain-level model for $\text{FM}_k(\mathbb{C})$, the k copies of $\mathcal{A}$ correspond to the k closed inputs, and $\mathcal{A}_{\text{out}}$ is the output fiber at the basepoint $z_0 \in X$. This is a section of $\mathcal{A}^{\boxtimes(k+1)}$ over the compactified configuration space $\overline{C}_{k+1}(X)$ of $k+1$ points (one output and k inputs), tensored with logarithmic forms, which is the definition of $C_{\text{ch}}^k(\mathcal{A}, \mathcal{A})$ (Definition 17.6.5, §A.10.2). The open-sector bimodule condition ensures that the evaluation at the output point z_0 and the insertion of algebra elements at the input points are compatible with the chiral product, which is the Hochschild cochain compatibility condition (the cochain evaluates inputs via the chiral product and returns an output in $\mathcal{A}$).

Step 2c: Matching the differentials. The center $Z_{\text{SC}}(A)$ carries three differential contributions; we identify each with a component of the chiral Hochschild differential $d_{\text{Hoch}} = d_{\text{int}} + d_{\text{fact}} + d_{\text{config}}$ (Theorem 14.2.2).

(c.1) *Internal differential.* The $\mathcal{D}_X$ -module differential $d_{\mathcal{A}}$ of the chiral algebra acts on each fiber $\mathcal{A}(z_i)$ independently. Under the identification of Step 2b, $d_{\mathcal{A}}$ acts on the $\mathcal{A}^{\boxtimes(k+1)}$ factor, producing $d_{\text{int}}(\phi)(z_1, \dots, z_k) = \sum_{i=0}^k (-1)^{|\phi_0| + \dots + |\phi_{i-1}|} \phi_0 \otimes \dots \otimes d_{\mathcal{A}} \phi_i \otimes \dots \otimes \phi_k \otimes \omega$, which is the component d_{int} of Theorem 14.2.2.

(c.2) *Factorization differential.* The closed-sector operadic composition $\circ_i : \text{FM}_k(\mathbb{C}) \times \text{FM}_\ell(\mathbb{C}) \rightarrow \text{FM}_{k+\ell-1}(\mathbb{C})$ inserts a degree- ℓ closed element into the i -th slot of a degree- k element. At the chain level, for a center element $\phi \in Z_{\text{SC}}(A)_k$, this composition acts by restricting ϕ to the boundary stratum $\partial_{ij} \text{FM}_k(\mathbb{C})$ where $z_i \rightarrow z_j$ and extracting the residue of the chiral product μ :

$$(d_{\text{fact}} \phi)(z_1, \dots, z_{k-1}) = \sum_{1 \leq i < j \leq k} (-1)^{\epsilon(i,j)} \text{Res}_{z_i=z_j} [\phi(\dots, z_i, \dots, z_j, \dots) \cdot \mu(a_i, a_j)],$$

where $\epsilon(i, j)$ is the Koszul sign from permuting a_i past $a_{i+1}, \dots, a_{j-1}$. This is the factorization component d_{fact} from Theorem 14.2.2: the residue extraction at collision divisors $D_{ij} \subset \partial \text{FM}_k(\mathbb{C})$ using the

chiral product. The signs agree because both are determined by the codimension-1 boundary orientation of $\mathrm{FM}_k(\mathbb{C})$ and the Koszul convention for graded-symmetric tensor products.

(c.3) *Configuration-space differential.* The de Rham differential d_{dR} on $\mathrm{FM}_k(\mathbb{C})$ acts on the logarithmic form factor ω in $\phi = a_0 \otimes \cdots \otimes a_k \otimes \omega$. Under the identification of Step 2b, this is the component $d_{\mathrm{config}} = d_{\mathrm{dR}}$ of Theorem 14.2.2: it raises the form degree on $\overline{C}_{k+1}(X)$ by 1.

(c.4) *Verification that $d^2 = 0$ is preserved.* The identity $d_{\mathrm{Hoch}}^2 = 0$ is proved in Theorem 14.2.2 by checking three pure squares and three anticommutators. Under the identification of Steps 2b–2c, each cancellation in the center differential maps to the corresponding cancellation in the Hochschild differential: $d_{\mathrm{int}}^2 = 0$ from $d_{\mathcal{A}}^2 = 0$; $d_{\mathrm{config}}^2 = 0$ from $d_{\mathrm{dR}}^2 = 0$; $d_{\mathrm{fact}}^2 = 0$ from the Borchers identity (iterated residues at overlapping collision divisors); $\{d_{\mathrm{int}}, d_{\mathrm{fact}}\} = 0$ because μ is a $\mathcal{D}_X$ -module map; $\{d_{\mathrm{int}}, d_{\mathrm{config}}\} = 0$ because $d_{\mathcal{A}}$ and d_{dR} act on independent tensor factors; $\{d_{\mathrm{fact}}, d_{\mathrm{config}}\} = 0$ by the Arnold–Orlik–Solomon relations on $\mathrm{FM}_k(\mathbb{C})$. Hence the identification of Step 2b is an isomorphism of cochain complexes.

Step 2d: The E_2 -algebra structure. The closed sector $(\mathrm{SC}^{\mathrm{ch}, \mathrm{top}})^c = \{\mathrm{FM}_k(\mathbb{C})\}$ is a model for the E_2 operad (Proposition A.1.6). By the universal property of the center (Definition A.10.4), $Z_{\mathrm{SC}}(A)$ is an algebra over $(\mathrm{SC}^{\mathrm{ch}, \mathrm{top}})^c \simeq E_2$, and this E_2 -structure transfers to $C_{\mathrm{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ via the isomorphism of Steps 2b–2c. We verify directly that the two generating operations match.

(d.1) *Cup product.* The E_2 multiplication is the $(2, 0)$ -degree closed-sector composition: for $f \in C_{\mathrm{ch}}^p$ and $g \in C_{\mathrm{ch}}^q$, the operadic composition $\circ : \mathrm{FM}_2(\mathbb{C}) \times Z(A)^{\otimes 2} \rightarrow Z(A)$ yields a map $(f \cup g)(z_1, \dots, z_{p+q}) = \int_{\mathrm{FM}_2(\mathbb{C})} f(z_1, \dots, z_p) \otimes g(z_{p+1}, \dots, z_{p+q})$, where the two clusters of points are separated by the $\mathrm{FM}_2(\mathbb{C})$ operad element (one point in each cluster approaches the corresponding component of the degree-2 FM configuration). This is the cup product on chiral Hochschild cochains: the concatenation of two cochains separated by the propagator, identical in structure to the classical Gerstenhaber cup product except that the propagator is $d \log(z_1 - z_2)$ rather than the topological $d \arg(z_1 - z_2)/(2\pi)$.

(d.2) *Braces.* The brace operation $f\{g_1, \dots, g_k\}$ arises from the $(1, k)$ -degree composition: one element f in the “outer” position with k elements $g_1, \dots, g_k$ inserted into k of its slots. At the chain level, this is the composition map $\mathrm{FM}_1(\mathbb{C}) \times \mathrm{FM}_k(\mathbb{C}) \times Z(A) \times Z(A)^{\otimes k} \rightarrow Z(A)$, which by the FM operad composition rule corresponds to inserting the k cochains g_i at k distinct points within the configuration underlying f . The $\mathrm{FM}_k(\mathbb{C})$ -factor labels the relative positions of these insertion points, yielding the chiral brace operations. These satisfy the pre-Lie and higher brace identities because the operadic composition maps of $\mathrm{FM}_k(\mathbb{C})$ satisfy the corresponding associativity and equivariance, which is the content of the E_2 -operad axioms for $\{\mathrm{FM}_k(\mathbb{C})\}$ (Proposition A.1.6).

(d.3) *Compatibility.* The cup product and braces together generate the full E_2 -structure, and we have shown both are induced by the same operadic composition maps that define the center’s E_2 -algebra structure. For a more systematic proof that the center of an E_1 -algebra in a two-colored $E_1 \hookrightarrow E_2$ extension is an E_2 -algebra, see Francis [168], Theorem 5.16 (which proves the stronger result that the tangent complex of an E_n -algebra carries an E_n -algebra structure, specialized here to $n = 2$) and Lurie [303], §5.3.1 (which establishes the E_n -center of an E_1 -algebra as an E_{n+1} -algebra at the ∞ -categorical level, specialized to $n = 1$). $\square$

Remark A.10.8 (Scope: E_∞ -chiral input). Theorem A.10.7 requires the chiral algebra $\mathcal{A}$ to be E_∞ -chiral (logarithmic): the operations extend to the log compactification of $C_k(\mathbb{C})$, equivalently, the factorization $\mathcal{D}$ -module descends to the symmetric powers $X^{(n)}$ via the Σ_n -equivariance built into the $\mathrm{FM}_k(\mathbb{C})$ -action. For genuinely E_1 -chiral input (Yangians, Etingof–Kazhdan quantum vertex algebras), the factorization $\mathcal{D}$ -module does *not* descend to $X^{(n)}$, the symmetric bar $\overline{B}^\Sigma(\mathcal{A})$ does not exist, and $C_{\mathrm{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ as defined above is ill-formed. In the E_1 setting, the correct replacement is the *ordered* Hochschild complex

$\mathrm{HH}_{\mathrm{ord}}^{E_1}(\mathcal{A}, \mathcal{A})$, defined via the ordered bar complex $\overline{B}^{\mathrm{ord}}(\mathcal{A})$ with deconcatenation coproduct. The output carries E_2 structure from the classical Deligne conjecture (Kontsevich–Soibelman), *not* from the chiral Deligne–Tamarkin theorem (Theorem A.11.16). The passage from E_2 to E_3 for E_1 -chiral input requires the Drinfeld center construction (Theorem 22.30.28). See Warning 3.11.8.

Remark A.10.9 (Chiral vs. topological: the spectral-parameter difficulty). In the topological setting ($\mathrm{SC}_{\mathrm{top}}$, Voronov [391]), Step 2 is the content of the Deligne conjecture (Kontsevich–Soibelman [438], McClure–Smith, Kaufmann): the Hochschild cochain complex $C^*(A, A)$ of an associative algebra is an E_2 -algebra. The chiral setting introduces three genuine new difficulties:

- (a) *Meromorphic vs. smooth propagator.* The topological propagator $d \arg(z_1 - z_2)/(2\pi)$ is smooth on $C_2(\mathbb{R}^2)$; the chiral propagator $d \log(z_1 - z_2)$ is meromorphic. This forces the chiral Hochschild complex to live on the *compactified* configuration space $\overline{C}_{k+2}(X) = \mathrm{FM}_{k+2}(X)$ with logarithmic forms, not on the open configuration space. The Arnold relations (three-term identity on residues) replace the smooth Stokes theorem as the mechanism for $d^2 = 0$.
- (b) *Dependence on curve geometry.* The topological center $Z_{\mathrm{SC}_{\mathrm{top}}}(A)$ depends only on the homotopy type of the associative algebra A . The chiral center $Z_{\mathrm{SC}}(A)$ depends on the underlying curve X : the configuration spaces $\mathrm{FM}_k(X)$ carry the complex structure of X , and the propagator depends on the choice of coordinate (globally: on the choice of meromorphic 1-form with prescribed singularities). This geometric dependence is invisible in genus 0 (where $X = \mathbb{C}$ and $\mathrm{FM}_k(\mathbb{C})$ is canonically defined) but essential at genus $g \geq 1$, where the center carries a flat connection over $\overline{\mathcal{M}}_g$.
- (c) *Curvature at higher genus.* The bar differential $d_{\overline{B}}$ satisfies $d_{\overline{B}}^2 = 0$ at genus 0, but $d_{\mathrm{fib}}^2 = \kappa(\mathcal{A}) \cdot \omega_g$ at genus $g \geq 1$ (Theorem 13.21.44). This means the chiral Hochschild complex is *curved* at higher genus: the center is a curved E_2 -algebra, and the curvature κ is the modular characteristic. No such phenomenon occurs in the topological setting.

Difficulty (a) is handled by the Arnold–Orlik–Solomon formalism of Chapter 5. Difficulties (b) and (c) are addressed by the modular extension (Chapter 13). At genus 0, difficulties (b) and (c) are absent, and the chiral center theorem reduces to a holomorphic refinement of the Deligne conjecture.

A.10.3 STEP 3: GEOMETRIC INEVITABILITY VIA THE RECOGNITION THEOREM

The geometric content of the chiral center theorem becomes transparent once the recognition theorem (proved in Volume II) is invoked. The argument below shows that the theorem is *forced* by the geometry of the half-space $\mathbb{C} \times \mathbb{R}_{\geq 0}$.

THEOREM A.10.10 (Geometric inevitability of the chiral center;). Let $\mathcal{A}$ be a chiral algebra on a curve X , and let $\mathcal{F}_{\mathcal{A}}$ denote the corresponding prefactorization algebra on $X \times \mathbb{R}$ obtained from the $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$ -algebra structure (Theorem A.9.4). Under the recognition theorem identifying $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$ -algebras with prefactorization algebras on $D \times \mathbb{R}$ (Volume II, items F4–F5), the following identifications hold:

- (i) *Closed color = bulk observables.* The closed-sector algebra $\mathcal{O}_{\mathrm{bulk}} := \mathcal{F}_{\mathcal{A}}(\text{disks in } X)$ is the chiral algebra $\mathcal{A}$ itself.
- (ii) *Open color = boundary observables.* The open-sector algebra $\mathcal{O}_{\mathrm{bdy}} := \mathcal{F}_{\mathcal{A}}(\text{half-disks touching } X \times \{0\})$ is the E_1 -algebra $A = \mathcal{A}|_{\{z_0\}}$, the fiber of $\mathcal{A}$ at a point, equipped with its associative multiplication.
- (iii) *Center = interior bulk observables.* The observables of $\mathcal{F}_{\mathcal{A}}$ supported on disks in the interior of $X \times \mathbb{R}_{>0}$ are precisely the chiral Hochschild cochains $C_{\mathrm{ch}}^{\bullet}(\mathcal{A}, \mathcal{A})$.

Proof. The proof combines the E_1 -chiral coassociative coalgebra structure (Theorem A.9.4) with the recognition theorem.

Part (i): By definition of $SC^{\text{ch}, \text{top}}$, the closed-sector operations are indexed by $FM_k(\mathbb{C})$, which is the configuration space of points in the complex plane. A disk $D \subset X$ entirely in the bulk (away from the boundary $X \times \{0\}$) supports local observables of $\mathcal{A}$ that multiply via the chiral product (OPE on colliding points in X). The recognition theorem identifies this sector with $\mathcal{A}$.

Part (ii): Half-disks touching the boundary correspond to the open-sector operations, indexed by $E_1(m)$ (configurations of m points on the real line). The fiber $A = \mathcal{A}|_{\{z_0\}}$ is a vector space equipped with an associative product from the E_1 -structure: this is the boundary vertex algebra.

Part (iii): This is the key identification. Consider a disk D_{int} in the interior of $X \times \mathbb{R}_{>0}$, i.e., a disk that does not touch the boundary. The observables on D_{int} must satisfy two constraints simultaneously:

- (a) They act on boundary observables: pushing D_{int} to the boundary (by moving it in the $\mathbb{R}$ -direction) produces an action map $\mathcal{O}_{\text{bulk}} \otimes A^{\otimes m} \rightarrow A$, the mixed action (A.5).
- (b) They compose in the bulk via the chiral product on X : nesting disks in the holomorphic direction uses $FM_k(\mathbb{C})$ -composition.

Constraint (a) says that the interior bulk observable is an element of $\text{Hom}(A^{\otimes m}, A)$ for each m , and constraint (b) says these elements are coherently related by the $FM_k(\mathbb{C})$ -composition. But this is exactly the definition of the operadic center (Definition A.10.4).

The resulting complex $\bigoplus_k \Omega^*(FM_k(\mathbb{C})) \otimes_{\Sigma_k} \text{Hom}(A^{\otimes k}, A)$ is the chiral Hochschild cochain complex: the configuration-space forms provide the bar degree, and the Hom-space provides the coefficient. The differential is the standard chiral Hochschild differential (Theorem 14.2.2), composed of the factorization differential (from the chiral product), the de Rham differential (from the configuration space geometry), and the internal differential (from the $\mathcal{D}_X$ -module structure).

This identification is *inevitable*: once the Swiss-cheese structure is established, the only object satisfying both constraints simultaneously *is* the Hochschild cochain complex. There is no room for an alternative. $\square$

Remark A.10.11 (The open/closed map and the center). The no-open-to-closed constraint ($SC(\dots, o, \dots; c) = \emptyset$) is crucial: it means information flows from closed to open but not back. The center reverses this flow *universally*: it is the largest closed-sector algebra that acts on the given open-sector algebra. Physically, the center extracts from the boundary theory all the information that can be reconstructed about the bulk. This is the algebraic incarnation of the holographic principle: the bulk theory (chiral algebra $\mathcal{A}$) determines the boundary (E_1 -algebra A) via restriction, and the center construction recovers from A the largest closed-sector algebra acting on it.

Remark A.10.12 (The chiral Deligne–Tamarkin principle and the dimensional jump). Theorems A.10.7 and A.10.10 together constitute the *chiral Deligne–Tamarkin principle*: for every local A_∞ -chiral algebra $\mathcal{A}$, the chiral Hochschild cochain complex $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ is the universal closed-sector algebra acting on $\mathcal{A}$ through the Swiss-cheese structure. The chain of implications is:

$$\mathcal{A} \xrightarrow{\text{center}} (C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \mathcal{A}) \in \text{Alg}_{W(SC^{\text{ch}, \text{top}})} \xrightarrow{\text{recognition}} \text{local 3d HT theory on } D \times \mathbb{R}. \quad (\text{A.8})$$

The left arrow is Theorem A.10.7 (proved here). The right arrow is the recognition theorem identifying $W(SC^{\text{ch}, \text{top}})$ -algebras with holomorphic-topological prefactorization algebras on $D \times \mathbb{R}$ (Volume II, items F4–F5; not proved in this volume).

This is the mechanism by which a 2-dimensional chiral algebra on a curve X produces a 3-dimensional holomorphic-topological bulk/boundary system on $X \times \mathbb{R}$. The extra dimension is the universal normal-collar direction of a codimension-one boundary condition, forced by the center construction.

An independent physical construction corroborating this picture is given by Khan–Zeng [264], who build a mixed holomorphic-topological gauge theory on $\mathbb{R} \times \mathbb{C}$ from a freely generated Poisson vertex algebra and prove that gauge invariance holds if and only if the λ -Jacobi identity is satisfied [264, § 2.2]. They show [264, § 4.3] that an inner Virasoro element upgrades the holomorphic-topological symmetry to fully topological symmetry. We *expect* (but have not proved) that the Khan–Zeng gauge theory realizes the right-hand arrow of (A.8): that is, the universal algebraic thickening $(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \mathcal{A})$ should be identified with the perturbative local observable algebra of their holomorphic-topological gauge theory.

A.10.4 STEP 4: COMPARISON WITH THE BRACE-ALGEBRA CENTER

The brace-algebra approach to the Hochschild complex defines the E_2 -structure on $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ directly, via brace operations $f\{g_1, \dots, g_k\}$, without passing through the operadic center. We show that the two constructions agree.

Definition A.10.13 (Chiral brace operations). For cochains $f \in C_{\text{ch}}^p(\mathcal{A}, \mathcal{A})$ and $g_1 \in C_{\text{ch}}^{q_1}, \dots, g_k \in C_{\text{ch}}^{q_k}$, the *chiral brace operation* is:

$$f\{g_1, \dots, g_k\}(z_1, \dots, z_N) := \sum_{\substack{S_1 \sqcup \dots \sqcup S_k \sqcup T \\ = \{z_1, \dots, z_N\}}} \pm \text{Res}_{\substack{w_1 \rightarrow z_{S_1} \\ \vdots \\ w_k \rightarrow z_{S_k}}} f(w_1, \dots, w_k, z_T) \prod_{j=1}^k g_j(z_{S_j}), \quad (\text{A.9})$$

where the sum is over ordered partitions of the input set, the residue is at the collision loci $w_j \rightarrow z_{S_j}$ in $\text{FM}_k(\mathbb{C}) \subset \overline{\mathcal{C}}_{k+N}(X)$, and the sign $\pm$ follows the Koszul convention for the desuspended tensor product.

PROPOSITION A.10.14 (Brace operations from the operadic center;). The brace operations of Definition A.10.13 are recovered from the E_2 -algebra structure on $Z_{\text{SC}}(A)$ by restricting the closed-sector composition to the specific boundary strata of $\text{FM}_{k+1}(\mathbb{C})$ where the first point simultaneously collides with the remaining k points. Precisely, the brace $f\{g_1, \dots, g_k\}$ is the image of $(f, g_1, \dots, g_k) \in Z_{\text{SC}}(A)^{\otimes(k+1)}$ under the operadic composition map

$$\text{FM}_{k+1}(\mathbb{C}) \otimes Z_{\text{SC}}(A)^{\otimes(k+1)} \longrightarrow Z_{\text{SC}}(A),$$

restricted to the open stratum of $\text{FM}_{k+1}(\mathbb{C})$ where the first point is at the center and the remaining k are close to it.

Proof. The operadic composition in $(\text{SC}^{\text{ch}, \text{top}})^c = \{\text{FM}_k(\mathbb{C})\}$ at degree $(k+1)$ composes a $(k+1)$ -ary closed operation with individual closed operations. In configuration-space terms, this is the insertion map $\text{FM}_{k+1}(\mathbb{C}) \times \text{FM}_{q_1}(\mathbb{C}) \times \dots \times \text{FM}_{q_k}(\mathbb{C}) \rightarrow \text{FM}_N(\mathbb{C})$ that replaces each of the k satellite points by a cluster of q_j points.

At the cochain level, an element $f \in C_{\text{ch}}^p$ is represented by a form on $\text{FM}_{p+1}(\mathbb{C})$, and $g_j \in C_{\text{ch}}^{q_j}$ is a form on $\text{FM}_{q_j+1}(\mathbb{C})$. The operadic composition inserts the g_j -clusters into the f -configuration and extracts the residue along the collision loci. Unraveling the definitions, this is exactly the brace formula (A.9): the sum over partitions corresponds to the sum over ways of assigning the N input points to the k insertion sites, and the residues arise from the boundary strata of $\text{FM}_{k+1}(\mathbb{C})$ where satellite points collide with their centers. $\square$

THEOREM A.10.15 (*Comparison theorem: operadic center = brace center;*). The following three models of the “center” are quasi-isomorphic as E_2 -algebras:

- (i) The operadic center $Z_{SC}(A)$ (Definition A.10.4).
- (ii) The chiral Hochschild cochain complex $C_{ch}^\bullet(\mathcal{A}, \mathcal{A})$ with braces (Definition A.10.13).
- (iii) The derived endomorphism algebra $R\text{End}_{\mathcal{A}^e}(\mathcal{A})$, where $\mathcal{A}^e = \mathcal{A} \otimes \mathcal{A}^{\text{op}}$ is the enveloping algebra.

Proof. (i) $\simeq$ (ii): Theorem A.10.7 identifies $Z_{SC}(A)$ with $C_{ch}^\bullet(\mathcal{A}, \mathcal{A})$ as chain complexes. Proposition A.10.14 shows the E_2 -structure on the center recovers the braces. Since the E_2 -structure on the Hochschild complex is *generated* by the braces and cup product (this is the content of the higher Deligne conjecture, proved in the topological setting by Kontsevich–Soibelman [438] and extending to the chiral setting by the same FM-operad mechanism), the two E_2 -structures agree.

(ii) $\simeq$ (iii): The chiral Hochschild cochain complex computes $R\text{Hom}_{\mathcal{A}^e}(\mathcal{A}, \mathcal{A}) \simeq R\text{End}_{\mathcal{A}^e}(\mathcal{A})$ by the bar resolution (Theorem 14.3.1). The derived Hom carries the standard E_2 -structure from the Eilenberg–Zilber operad; the bar resolution provides the comparison.

The transitivity (i) $\simeq$ (ii) $\simeq$ (iii) completes the comparison. $\square$

Remark A.10.16 (*Role of homotopy-Koszulity*). The comparison in Theorem A.10.15 uses the homotopy-Koszulity of $SC^{\text{ch}, \text{top}}$ at a single point: the bar-cobar resolution of the SC-operad must be a Quillen equivalence, so that derived mapping objects computed from the bar side agree with those computed from the operadic side. Volume II proves homotopy-Koszulity of $SC^{\text{ch}, \text{top}}$ via three steps: (1) the classical Swiss-cheese operad is Koszul (Livernet, Voronov [391]); (2) Kontsevich formality gives a quasi-isomorphism $SC^{\text{ch}, \text{top}} \xrightarrow{\sim} SC_{\text{classical}}$; (3) transfer: bar-cobar preserves quasi-isomorphisms by the two-out-of-three property. *Without homotopy-Koszulity*, the operadic center still exists as a derived object but may not be computed by the explicit formula (A.7); the cochain-level model would need to be replaced by a homotopy-coherent (i.e., ∞ -categorical) one.

A.10.5 STEP 5: UNIVERSALITY AND TERMINALITY

THEOREM A.10.17 (*Terminality of the center;*). Let A be an E_1 -algebra (equivalently, an open-sector $SC^{\text{ch}, \text{top}}$ -algebra). Define the *universal SC-pair* as

$$U(A) := (Z_{SC}(A), A).$$

Then $U(A)$ is the terminal object in the category of $SC^{\text{ch}, \text{top}}$ -algebra pairs (B, A) with fixed open component A . That is, for every $SC^{\text{ch}, \text{top}}$ -algebra pair (B, A) , there exists a unique morphism of closed-sector algebras

$$\varphi: B \longrightarrow Z_{SC}(A)$$

such that the diagram of action maps

$$\begin{array}{ccc} \text{FM}_k(\mathbb{C}) \otimes B^{\otimes k} \otimes A^{\otimes m} & \xrightarrow{\alpha_{k,m}^B} & A \\ \varphi^{\otimes k} \downarrow & \nearrow \alpha_{k,m}^{\text{univ}} & \\ \text{FM}_k(\mathbb{C}) \otimes Z_{SC}(A)^{\otimes k} \otimes A^{\otimes m} & & \end{array}$$

commutes for all $k, m \geq 0$.

Proof. Existence. By the universal property of the operadic center (Definition A.10.4), any $\text{SC}^{\text{ch}, \text{top}}$ -algebra structure on (B, A) determines, for each k and m , action maps $\alpha_{k,m}^B: \text{FM}_k(\mathbb{C}) \otimes B^{\otimes k} \otimes A^{\otimes m} \rightarrow A$. The $k = 1, m = 0$ component gives a map $\alpha_{1,0}^B: B \rightarrow \text{Hom}(\mathbb{C}, A) = A$, and more generally the full collection $\{\alpha_{k,m}^B\}$ is exactly the data of an element in

$$\prod_{k,m} \text{Hom}_{\Sigma_k \times \Sigma_m}(\text{FM}_k(\mathbb{C}) \times E_1(m), \text{Hom}(B^{\otimes k} \otimes A^{\otimes m}, A)).$$

Taking the “ B -linear” part (the component linear in a single copy of B , i.e., $k = 1$) gives a map $\varphi: B \rightarrow Z_{\text{SC}}(A)$ defined by

$$\varphi(b)_m := \alpha_{1,m}^B(-, b, -) \in \text{Hom}(A^{\otimes m}, A).$$

The full equivariance conditions on the $\alpha_{k,m}^B$ ensure that φ is a map of E_2 -algebras (the closed-sector algebra structure on B is intertwined with the closed-sector structure on $Z_{\text{SC}}(A)$), and the commutativity of the diagram follows from the associativity of the SC-algebra axioms.

Uniqueness. Suppose $\varphi, \varphi': B \rightarrow Z_{\text{SC}}(A)$ are two morphisms making the diagram commute. Then for each $b \in B$ and each m , the commutativity of both diagrams gives $\alpha_{1,m}^{\text{univ}}(-, \varphi(b), -) = \alpha_{1,m}^B(-, b, -) = \alpha_{1,m}^{\text{univ}}(-, \varphi'(b), -)$. Since the universal action maps $\alpha_{1,m}^{\text{univ}}$ are injective in the center argument on the derived level (the center map (A.6) is computed by RHom , which is faithful on the derived category of bimodules), $\varphi(b) = \varphi'(b)$ for all b , hence $\varphi = \varphi'$.

Alternatively, uniqueness follows formally from the terminal property in Definition A.10.4: the center is defined as a limit, and morphisms to/from limits are unique by the universal property of limits. $\square$

COROLLARY A.10.18 (*The center functor*;). The assignment $A \mapsto U(A) = (Z_{\text{SC}}(A), A)$ defines a functor

$$U: E_1\text{-Alg} \longrightarrow \text{SC}^{\text{ch}, \text{top}}\text{-Alg}$$

that is *right adjoint* to the forgetful functor $\text{forget}_0: \text{SC}^{\text{ch}, \text{top}}\text{-Alg} \rightarrow E_1\text{-Alg}$ extracting the open component. The unit of this adjunction at (B, A) is the canonical morphism $B \rightarrow Z_{\text{SC}}(A)$ from Theorem A.10.17.

Proof. For any SC-pair (B, A) and any E_1 -algebra A' , a morphism of E_1 -algebras $A' \rightarrow A$ and a morphism $(B, A) \rightarrow U(A') = (Z_{\text{SC}}(A'), A')$ correspond bijectively to $\text{Hom}_{E_1}(A', A) \xrightarrow{1-1} \text{Hom}_{\text{SC}}((B, A), U(A'))$, which is the adjunction identity $\text{forget}_0 \dashv U$. The unit $\eta_{(B,A)}: (B, A) \rightarrow U(A) = (Z_{\text{SC}}(A), A)$ is the identity on the A -component and the canonical center map on the B -component. $\square$

Remark A.10.19 (*The chiral center theorem as a composite statement*). Assembling Steps 1–5, the chiral center theorem is the conjunction of four assertions:

- (1) *Existence:* The operadic center $Z_{\text{SC}}(A)$ exists for every E_1 -algebra A (Proposition A.10.6).
- (2) *Identification:* $Z_{\text{SC}}(A) \simeq C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ as E_2 -algebras (Theorem A.10.7).
- (3) *Geometric realization:* The center computes interior bulk observables in the half-space $X \times \mathbb{R}_{\geq 0}$ (Theorem A.10.10).
- (4) *Universality:* $(Z_{\text{SC}}(A), A)$ is terminal among SC-pairs with fixed open component (Theorem A.10.17).

In the topological setting, these four assertions are respectively: existence of the Hochschild complex, the Deligne conjecture, the bulk-boundary correspondence in 2d TFT, and Keller's recognition theorem. The chiral setting enriches each with holomorphic geometry (meromorphic propagators, configuration-space compactifications, curve-dependence) and with curvature (the modular characteristic κ at higher genus).

Remark A.10.20 (Why the chiral setting is genuinely harder). To summarize the difficulties identified in Remark A.10.9 at the level of the complete proof:

- (a) *Steps 1–2* (algebraic/chain-level) are parallel to the topological case, with Arnold relations replacing smooth Stokes. The key input is the FM compactification of $C_k(X)$, which provides the same combinatorial structure as $\text{FM}_k(\mathbb{R}^2)$ but with holomorphic forms.
- (b) *Step 3* (geometric realization) requires the recognition theorem (F_4/F_5), which itself requires homotopy-Koszulity of $\text{SC}^{\text{ch},\text{top}}$. The proof of homotopy-Koszulity uses Kontsevich formality, which is the single deepest input. In the topological case, Koszulity of the classical Swiss-cheese operad suffices.
- (c) *Step 4* (comparison) requires that the E_2 -structure from the operadic center and the E_2 -structure from braces agree. In the topological case, this is part of the Deligne conjecture proof. In the chiral case, the comparison also requires that the configuration-space forms are compatible with the brace insertion, which is guaranteed by the Arnold relations.
- (d) *Step 5* (universality) is formal and identical in both settings.

The single genuinely new ingredient is the passage from smooth to meromorphic propagators and the resulting replacement of Stokes by Arnold. Everything else (operadic center, universality, comparison) is structural and follows the same architecture. The higher-genus curvature κ introduces a further novelty (curved E_2 -algebras) not present in any topological analogue.

A.10.6 ESSENTIAL SURJECTIVITY OF THE CENTER FUNCTOR

Corollary A.10.18 establishes the center functor

$$U: E_1\text{-Alg} \longrightarrow \text{SC}^{\text{ch},\text{top}}\text{-Alg}, \quad A \longmapsto (Z_{\text{SC}}(A), A),$$

as right adjoint to the forgetful functor extracting the open component. Terminality (Theorem A.10.17) guarantees that every $\text{SC}^{\text{ch},\text{top}}$ -pair (B, A) admits a *unique* closed-sector morphism $\eta_B: B \rightarrow Z_{\text{SC}}(A)$, the unit of the adjunction. The remaining question is whether η_B is an equivalence: does every SC-pair lie in the essential image of U ?

In the topological setting, the analogous question has a negative answer. Not every E_2 -algebra arises as the Hochschild cochain complex $\text{HH}^\bullet(A, A)$ of an E_1 -algebra: the Hochschild cochain complex carries additional structure (the calculus package, compatibility with the bar construction, the BV operator at the chain level) that constrains the essential image.

The chiral setting introduces three layers of obstruction.

- (i) *Brace coherence.* The closed-sector algebra B must act on A via chiral brace operations (Definition A.10.13) satisfying the full $\text{SC}^{\text{ch},\text{top}}$ -coherence. Not every E_2 -algebra B equipped with a map $B \otimes A^{\otimes m} \rightarrow A$ satisfies these coherences: the brace relations impose nontrivial constraints that are automatically satisfied when $B = Z_{\text{SC}}(A)$ but may fail for an arbitrary pair. The unit η_B being an equivalence requires that *all* closed-sector operations on B are detected by their action on A .

- (ii) *Bar-cobar reconstruction.* On the Koszul locus, bar-cobar inversion $\Omega(\overline{B}(\mathcal{A})) \xrightarrow{\sim} \mathcal{A}$ recovers the chiral algebra from its bar coalgebra. Since the center is computed by coderivations of the bar coalgebra (Theorem A.10.7), the Koszul locus provides a reconstruction path: $B \simeq Z_{\text{SC}}(A)$ whenever the pair (B, A) arises from a Koszul chiral algebra. Off the Koszul locus, bar-cobar inversion holds only in the coderived category (Theorem R.3.1), and reconstruction requires passage to completions.
- (iii) *Curvature obstruction.* At genus $g \geq 1$, the fiberwise differential satisfies $d_{\text{fib}}^2 = \kappa \cdot \omega_g$, introducing a curved E_2 -structure on $Z_{\text{SC}}(A)$. A candidate closed-sector algebra B must carry a compatible curvature; the modular characteristic $\kappa(B)$ and $\kappa(A)$ are related by complementarity (Theorem 1.3.8). An SC-pair (B, A) with mismatched curvature data cannot lie in the image of U .

Conjecture A.10.21 (Essential surjectivity on the Koszul locus;). Let (B, A) be an $\text{SC}^{\text{ch}, \text{top}}$ -algebra pair with A on the Koszul locus. The unit of the adjunction

$$\eta_B: B \longrightarrow Z_{\text{SC}}(A)$$

is a quasi-isomorphism. Equivalently, the center functor U is essentially surjective when restricted to the full subcategory of $\text{SC}^{\text{ch}, \text{top}}$ -pairs whose open component is Koszul.

Remark A.10.22 (Evidence and obstructions). Four lines of evidence support Conjecture A.10.21.

- (a) *Koszul reconstruction.* On the Koszul locus, $\Omega(\overline{B}(\mathcal{A})) \simeq \mathcal{A}$ and $Z_{\text{SC}}(A) \simeq \text{CoDer}(\overline{B}(\mathcal{A}))$. The pair $(Z_{\text{SC}}(A), A)$ is therefore determined by the bar coalgebra $\overline{B}(\mathcal{A})$ alone. Any SC-pair (B, A) on the Koszul locus satisfies: B acts on A through the bar coalgebra via the unit η_B , and bar-cobar inversion forces η_B to capture all of B .
- (b) *Standard landscape.* For every family in the standard landscape (Heisenberg, affine Kac–Moody, Virasoro, $\mathcal{W}_N$, $\beta\gamma$ -systems, lattice algebras), the center $Z_{\text{SC}}(A)$ is computed explicitly (Theorem H), and the unit η_B is an equivalence for every known SC-pair structure on these algebras. No counterexample is known.
- (c) *Topological analogue.* In the topological setting, the center $Z(A) = \text{HH}^\bullet(A, A)$ of an E_1 -algebra A is the terminal E_2 -algebra acting on A , and Keller [260] shows that for derived-simple algebras (the topological Koszul locus), every E_2 -algebra acting centrally on A is equivalent to a subalgebra of $\text{HH}^\bullet(A, A)$.
- (d) *Finite-dimensionality of ChirHoch.* Theorem H shows $CH^*(\mathcal{A})$ is concentrated in degrees $\{0, 1, 2\}$ with total dimension at most four on the Koszul locus. This severe rigidity constrains the space of possible closed-sector algebras: any B acting on A must map into a target of dimension at most four, leaving little room for the unit to fail surjectivity.

Remark A.10.23 (Failure off the Koszul locus). Off the Koszul locus, essential surjectivity is expected to fail. The simplest potential counterexample: let A be a class M algebra (Virasoro at generic c), and let B be a *truncation* of $Z_{\text{SC}}(A)$ that retains the E_2 -structure but discards higher-degree shadow data. The truncated pair (B', A) is a valid SC-pair (the SC-axioms are satisfied by restriction), but B' is strictly smaller than $Z_{\text{SC}}(A)$, so $\eta_{B'}$ is injective but not surjective. This construction produces SC-pairs not in the image of U ; however, these pairs are “deficient” in the sense that B' does not act on A through all available operations.

A more interesting failure mode arises from *exotic* SC-pairs: an E_2 -algebra B equipped with an action on A that does not factor through any chiral algebra structure. Such pairs would represent genuinely non-geometric boundary-bulk systems. Whether exotic SC-pairs exist is an open question closely related to the formality of the Swiss-cheese operad $\text{SC}^{\text{ch}, \text{top}}$ and to the recognition problem for holomorphic-topological field theories (Volume II).

Example A.10.24 (Deficient SC-pairs from shadow tower truncation). We make Remark A.10.23 explicit. Fix c generic and let $\mathcal{A} = \text{Vir}_c$ (class M , $r_{\max} = \infty$). The center $Z_{\text{SC}}(\mathcal{A})$ is the chiral Hochschild cochain complex $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$, whose cohomology is concentrated in degrees $\{0, 2\}$ with Hilbert series $P(t) = 1 + t^2$ (Theorem 17.2.1). The universal SC-pair $U(\mathcal{A}) = (Z_{\text{SC}}(\mathcal{A}), \mathcal{A})$ carries brace operations

$$\beta_m: Z_{\text{SC}}(\mathcal{A}) \otimes \mathcal{A}^{\otimes m} \longrightarrow \mathcal{A}, \quad m \geq 0,$$

encoding the closed-sector action on the open sector. Proposition 11.1.59 establishes that for class M , the associated A_∞ -operations $m_k^{\text{SC}} \neq 0$ for all $k \geq 3$: the Stasheff cascade $\sum_{r+s+t=n} m_{r+1+t} \circ (\text{id}^{\otimes r} \otimes m_s \otimes \text{id}^{\otimes t}) = 0$ forces $m_{k+1} \neq 0$ from $m_3 \neq 0$ and pole depth 3 (the triple pole in $T_{(3)}T = c/2$).

Construction. Fix an integer $r \geq 3$. Define the *depth- r truncated SC-pair* $(Z_{\text{SC}}(\mathcal{A}), \mathcal{A})_{\leq r}$ as follows:

- The closed-sector E_2 -algebra is $Z_{\text{SC}}(\mathcal{A})$ itself (unchanged).
- The open-closed action is $\beta_m^{\leq r} := \beta_m$ for $m \leq r$ and $\beta_m^{\leq r} := 0$ for $m > r$.

The $\text{SC}^{\text{ch}, \text{top}}$ -axioms at degree $\leq r$ involve only the brace operations $\beta_0, \dots, \beta_r$; they are inherited from the full pair. Hence $(Z_{\text{SC}}(\mathcal{A}), \mathcal{A})_{\leq r}$ is a valid SC-pair in the sense that all coherences at degree $\leq r$ hold.

Deficiency. This pair does *not* lie in the essential image of the center functor U . The obstruction is the Stasheff cascade: any chiral algebra $\mathcal{A}'$ whose open sector is quasi-isomorphic to Vir_c satisfies $m_{r+1}^{\text{SC}}(\mathcal{A}') \neq 0$ (Proposition 11.1.59, class M), so the canonical pair $U(\mathcal{A}') = (Z_{\text{SC}}(\mathcal{A}'), \mathcal{A}')$ has $\beta_{r+1} \neq 0$. But $(Z_{\text{SC}}(\mathcal{A}), \mathcal{A})_{\leq r}$ has $\beta_{r+1}^{\leq r} = 0$ by construction. No SC-pair isomorphism can reconcile these: the brace operation β_{r+1} is an invariant of the SC-pair structure. Hence $(Z_{\text{SC}}(\mathcal{A}), \mathcal{A})_{\leq r}$ is deficient: a valid SC-pair that arises from no chiral algebra.

Two limiting cases.

- At $r = 2$ (retain only the E_2 -action, discard all higher braces): the pair $(Z_{\text{SC}}(\mathcal{A}), \mathcal{A})_{\leq 2}$ forgets the entire shadow tower. The closed sector acts on the open sector only through the cup product and identity. This is the maximally deficient case.
- As $r \rightarrow \infty$ the truncation exhausts the tower, and the pair converges to the full $U(\mathcal{A})$. The deficiency vanishes in the inverse limit.

Class dependence. The construction fails for class G (Heisenberg): all $m_k^{\text{SC}} = 0$ for $k \geq 3$ (Proposition 11.1.60), so $(Z_{\text{SC}}(\mathcal{A}), \mathcal{A})_{\leq r} = (Z_{\text{SC}}(\mathcal{A}), \mathcal{A})$ for every $r \geq 2$; there is nothing to truncate. For class L (affine Kac–Moody), truncation at $r \geq 3$ produces no deficiency because the tower terminates at depth 3. For class C ($\beta\gamma$), truncation at $r \geq 4$ produces no deficiency. Deficient SC-pairs from shadow truncation exist *only* for class M .

A.11 THE CHIRAL ENDOMORPHISM OPERAD AND THE CHIRAL CENTER THEOREM

The center of a chiral algebra is too small. For the Virasoro algebra Vir_c at generic central charge, the ordinary center $Z(\text{Vir}_c)$ is one-dimensional: it contains only the vacuum. Yet the algebra *has* deformations: the central charge itself can be varied, $c \mapsto c + \epsilon$. This deformation is invisible to the center because the center sees only degree-0 endomorphisms, while the deformation lives in cohomological degree 2. The naive deformation complex (infinitesimal automorphisms, first-order deformations, obstructions) captures the right numerical data in low degrees but carries no multiplicative structure, no bracket, no higher operations. The deficiency is structural: classifying *all* bulk actions on a chiral algebra requires a universal closed algebra, and neither the center nor the tangent complex is an algebra.

The resolution is the chiral derived center $Z_{\text{ch}}^{\text{der}}(\mathcal{A}) = C_{\text{ch}}^{\bullet}(\mathcal{A}, \mathcal{A})$: the chiral Hochschild cochain complex, equipped with a brace dg algebra structure (Definition A.II.3, Theorem A.II.11). The brace structure is forced: among all dg algebras receiving a map from every closed algebra that acts on $\mathcal{A}$, the chiral Hochschild cochains are the terminal object. This is the content of the chiral Deligne–Tamarkin theorem (Theorem A.II.16): the pair $(C_{\text{ch}}^{\bullet}(\mathcal{A}, \mathcal{A}), \mathcal{A})$ is the terminal local chiral Swiss-cheese pair over $\mathcal{A}$. Every bulk action factors uniquely through the derived center. No other functorial construction produces the bulk algebra.

The theory produces sharp results. For the Virasoro algebra: $CH^*(\text{Vir}_c)$ is concentrated in degrees $\{0, 2\}$, with total dimension 2 and Hilbert series $P(t) = 1 + t^2$. The single degree-2 class is the central charge deformation. This is *not* Gel'fand–Fuchs cohomology $H_{\text{cont}}^*(\text{Vect}(S^1); \mathbb{C})$, which is infinite-dimensional; it is not a polynomial ring $\mathbb{C}[\Theta]$, which would give unbounded cohomological amplitude. The chiral Hochschild cohomology is a finite-dimensional graded vector space, bounded in degrees $\{0, 1, 2\}$ for every modular Koszul algebra (Theorem I4.4.12).

Standing assumptions. Throughout this section:

- $(A, \{m_k\}_{k \geq 0})$ is a curved A_{∞} -chiral algebra in the sense of Definition 8.1.1, with $|m_k| = 2 - k$ (cohomological convention). When the curvature vanishes ($m_0 = 0$) and $m_k = 0$ for $k \geq 3$, this reduces to a strict chiral algebra with product m_2 . We assume A is *logarithmic*: the λ -brackets $\{a_{\lambda}b\} \in A[\lambda]$ are polynomial in the spectral variable, ensuring convergence of integrals over the FM compactification. All standard examples (Heisenberg, Kac–Moody, Virasoro, $\mathcal{W}$ -algebras) satisfy this condition.
- The ground field is $\mathbb{C}$. All graded vector spaces are $\mathbb{Z}$ -graded.
- *Spectral variables.* The chiral OPE of sections $a, b \in A$ at nearby points z, w on a formal disc is expanded in the formal variable $\lambda = z - w$:

$$a(z)b(w) = \sum_{n \in \mathbb{Z}} (a_{(n)}b)(w) \lambda^{-n-1}, \quad \lambda = z - w.$$

A multilinear operation of degree n depends on $n - 1$ independent spectral variables $\lambda_1, \dots, \lambda_{n-1}$, corresponding to the differences $\lambda_i = z_i - z_n$ for $i = 1, \dots, n - 1$.

- All tensor products are over $\mathbb{C}$ unless otherwise indicated. The notation $V((\lambda))$ denotes formal Laurent series $\sum_{n \gg -\infty} v_n \lambda^n$ with $v_n \in V$.

A.II.1 THE CHIRAL ENDOMORPHISM OPERAD

Definition A.II.1 (Chiral endomorphism operad). For a graded vector space A , the *chiral endomorphism operad* End_A^{ch} is the $\mathbb{N}$ -colored non- Σ operad with:

- (i) *Spaces.* For each $n \geq 0$, the space of n -ary operations is

$$\text{End}_A^{\text{ch}}(n) := \text{Hom}_{\mathbb{C}}\left(A^{\otimes n}, A((\lambda_1))((\lambda_2)) \cdots ((\lambda_{n-1}))\right),$$

where the λ_i are formal spectral variables. An element $f \in \text{End}_A^{\text{ch}}(n)$ of cohomological degree $|f|$ is a graded-linear map

$$f: A^{\otimes n} \longrightarrow A((\lambda_1)) \cdots ((\lambda_{n-1}))$$

that is $\mathbb{C}$ -multilinear. We write $f(a_1, \dots, a_n; \lambda_1, \dots, \lambda_{n-1})$ for its value on homogeneous elements. By convention, $\text{End}_A^{\text{ch}}(0) = A$ and $\text{End}_A^{\text{ch}}(1) = \text{End}(A)$.

- (ii) *Grading.* The cohomological degree of $f \in \text{End}_A^{\text{ch}}(n)$ is its degree as a graded-linear map:

$$|f(a_1, \dots, a_n; \lambda_1, \dots, \lambda_{n-1})| = |f| + |a_1| + \dots + |a_n|.$$

The *suspended degree* (or *brace degree*) is $\|f\| := |f| - 1$. This is the degree relevant for Koszul signs in brace operations.

- (iii) *Partial compositions.* For $f \in \text{End}_A^{\text{ch}}(m)$ and $g \in \text{End}_A^{\text{ch}}(n)$, the i -th partial composition $f \circ_i g \in \text{End}_A^{\text{ch}}(m+n-1)$, $1 \leq i \leq m$, is defined by *spectral substitution*:

$$\begin{aligned} & (f \circ_i g)(a_1, \dots, a_{m+n-1}; \mu_1, \dots, \mu_{m+n-2}) \\ & := (-1)^{\|g\| \cdot (|a_1| + \dots + |a_{i-1}|)} \\ & \quad \times f\left(a_1, \dots, a_{i-1}, g(a_i, \dots, a_{i+n-1}; \nu_1, \dots, \nu_{n-1}), a_{i+n}, \dots, a_{m+n-1}; \right. \\ & \quad \left. \mu_1, \dots, \mu_{i-2}, \mu_{i-1}, \mu_{i+n-1}, \dots, \mu_{m+n-2}\right) \end{aligned}$$

where the spectral variables are related by the *block-substitution rule*:

$$\left\{ \begin{array}{ll} \text{The outer variables } \lambda_j \text{ of } f \text{ are set to:} & \\ \lambda_j = \mu_j & \text{for } j = 1, \dots, i-2, \\ \lambda_{i-1} = \mu_{i-1} + \nu_1 & \text{(the } i\text{-th input of } f \text{ receives the sum),} \\ \lambda_j = \mu_{j+n-1} & \text{for } j = i, \dots, m-1; \\ \text{The inner variables } \nu_k \text{ of } g \text{ are set to:} & \\ \nu_k = \mu_{i-1+k} - \mu_{i-1} & \text{for } k = 1, \dots, n-1. \end{array} \right. \quad (\text{A.10})$$

The rule (A.10) encodes the coordinate change for nested collision of n points near the i -th point of an m -point configuration. Concretely, if the outer points have coordinates $z_1, \dots, z_m$ on a formal disc with $\lambda_j = z_j - z_m$, and the inner points have coordinates $w_1, \dots, w_n$ near z_i with $\nu_k = w_k - w_n$, then the combined $(m+n-1)$ -point configuration has spectral variables $\mu_\ell = u_\ell - u_{m+n-1}$ where u_ℓ are the merged coordinates.

The Koszul sign $(-1)^{\|g\| \cdot (|a_1| + \dots + |a_{i-1}|)}$ arises from commuting g (of suspended degree $\|g\|$) past the first $i-1$ inputs of f .

LEMMA A.II.2 (*Associativity of partial compositions*;). The partial compositions satisfy the standard operadic associativity and equivariance axioms:

- (a) *Sequential associativity.* For $i < j$:

$$(f \circ_i g) \circ_{j+n-1} h = (-1)^{\|g\| \cdot \|h\|} (f \circ_j h) \circ_i g.$$

- (b) *Nested associativity.* For $1 \leq j \leq n$:

$$(f \circ_i g) \circ_{i+j-1} h = f \circ_i (g \circ_j h).$$

Proof. Both identities reduce to the statement that the block-substitution (A.10) is associative.

For (b) (nested associativity): the left-hand side first substitutes g into the i -th slot of f , then substitutes h into the $(i + j - 1)$ -th slot (which was the j -th slot of g). The right-hand side first substitutes h into the j -th slot of g , then substitutes the result into the i -th slot of f . At the level of spectral variables, both sides perform the same three-level block substitution:

$$\lambda^{(f)} \leftarrow \lambda^{(f)}(\nu^{(g)}) \leftarrow \lambda^{(f)}(\nu^{(g)}(\rho^{(h)})),$$

and the Koszul signs are identical because the suspended degree of $(g \circ_j h)$ equals $\|g\| + \|h\|$ and the elements past which the operations must be commuted are the same on both sides.

For (a) (sequential associativity): the two substitutions act on disjoint slots of f , so the spectral variables are independent. The sign $(-1)^{\|g\| \cdot \|h\|}$ arises from interchanging the order in which g and h are commuted past the inputs of f . $\square$

The chiral endomorphism operad encodes multilinear operations with spectral parameters; partial composition encodes nested collisions. But an operad is not yet a cochain complex. To extract the deformation theory of a specific algebra $(A, \{m_k\})$, we must assemble these operation spaces into a single bigraded complex with a differential determined by m .

A.II.2 THE CHIRAL HOCHSCHILD COCHAIN COMPLEX

Definition A.II.3 (Chiral Hochschild cochain complex). The *chiral Hochschild cochain complex* of an A_∞ -chiral algebra $(A, \{m_k\})$ is the graded vector space

$$C_{\text{ch}}^n(A, A) := \prod_{k \geq 0} \text{Hom}\left(A^{\otimes k}, A((\lambda_1)) \cdots ((\lambda_{k-1}))\right)^{n+1-k},$$

equipped with the *bigrading*:

- The *external degree* (or *cochain degree*) is n , the total cohomological degree in the Hochschild complex.
- The *internal degree* is the degree k (the number of inputs).

An element $f \in C_{\text{ch}}^n(A, A)$ is a sequence $f = (f_0, f_1, f_2, \dots)$ where $f_k \in \text{End}_A^{\text{ch}}(k)$ has cohomological degree $n + 1 - k$. The total cochain space is

$$C_{\text{ch}}^\bullet(A, A) = \prod_{n \in \mathbb{Z}} C_{\text{ch}}^n(A, A) = \prod_{k \geq 0} \text{End}_A^{\text{ch}}(k)[1 - k].$$

The *chiral Hochschild differential* is

$$\delta(f) := [m, f],$$

where $m = (m_0, m_1, m_2, \dots)$ is the A_∞ -structure viewed as an element of $C_{\text{ch}}^1(A, A)$ (degree $|m_k| = 2 - k$ gives total degree 1), and $[-, -]$ is the Gerstenhaber bracket defined below in Definition A.II.7.

Remark A.II.4 (Comparison with the geometric definition). The cochain complex of Definition A.II.3 is the algebraic model of the geometric Hochschild complex of §14.4.3 (Theorem 14.2.2). The geometric realization on configuration spaces endows $C_{\text{ch}}^\bullet(A, A)$ with the additional structure of integration over $\text{FM}_n(\mathbb{C})$; the algebraic definition retains only the formal-variable residue operations and is therefore valid over any ground field.

The cochain complex $(C_{\text{ch}}^\bullet(A, A), \delta)$ carries the differential $\delta = [m, -]$, but this uses only the single-insertion bracket. The deeper structure is the full system of multi-insertion operations: given a cochain f and cochains $g_1, \dots, g_r$, one can insert the g_j simultaneously into the slots of f . These are the brace operations, and they encode the obstruction theory for deformations of arbitrary order.

A.II.3 BRACE OPERATIONS ON CHIRAL HOCHSCHILD COCHAINS

Definition A.II.5 (Brace operations). For cochains $f \in C_{\text{ch}}^\bullet(A, A)$ of degree p (i.e., $f \in \text{End}_A^{\text{ch}}(p)$) and $g_1, \dots, g_r$ of degrees $q_1, \dots, q_r$ respectively, the *brace operation*

$$f\{g_1, \dots, g_r\} \in \text{End}_A^{\text{ch}}(p + q_1 + \dots + q_r - r)$$

is defined by the following explicit formula. Set $Q := q_1 + \dots + q_r - r$ (the total number of “extra” inputs contributed by the g_j). Then

$$\begin{aligned} & f\{g_1, \dots, g_r\}(a_1, \dots, a_{p+Q}; \mu_1, \dots, \mu_{p+Q-1}) \\ &= \sum_{1 \leq i_1 < i_2 < \dots < i_r \leq p} \varepsilon(\sigma; f, g_1, \dots, g_r; a_1, \dots, a_{p+Q}) \\ & \quad \times f\left(a_1, \dots, a_{i_1-1+\alpha_0}, g_1(a_{i_1+\alpha_0}, \dots, a_{i_1+\alpha_0+q_1-1}; \mathbf{v}^{(1)}), \right. \\ & \quad \quad a_{i_1+\alpha_0+q_1}, \dots, a_{i_2-1+\alpha_1}, g_2(a_{i_2+\alpha_1}, \dots; \mathbf{v}^{(2)}), \dots, \\ & \quad \quad \left. g_r(\dots, a_{i_r+\alpha_{r-1}+q_{r-1}-1}; \mathbf{v}^{(r)}), a_{i_r+\alpha_{r-1}+q_r}, \dots, a_{p+Q}; \lambda\right), \end{aligned} \tag{A.II}$$

where:

- $\alpha_j := (q_1 - 1) + \dots + (q_j - 1)$ for $j = 0, 1, \dots, r$ (with $\alpha_0 = 0$) counts the accumulated extra inputs from $g_1, \dots, g_j$.
- The *inner spectral variables* $\mathbf{v}^{(j)} = (v_1^{(j)}, \dots, v_{q_j-1}^{(j)})$ for each g_j are determined by the block-substitution rule (A.I0) applied at insertion position i_j .
- The *outer spectral variables* $\lambda = (\lambda_1, \dots, \lambda_{p-1})$ of f are obtained from the μ_ℓ by the same block-substitution, with the slots corresponding to the inner variables of each g_j collapsed.
- The *Koszul sign* is

$$\varepsilon = \prod_{j=1}^r (-1)^{\|g_j\| \cdot \sigma_j}, \tag{A.I2}$$

where the *crossing number* of g_j is

$$\sigma_j := \sum_{s=1}^{i_j-1+\alpha_{j-1}} |a_s| + \sum_{\ell=1}^{j-1} \|g_\ell\|, \tag{A.I3}$$

and $\|g_j\| = |g_j| - 1$ is the suspended degree. The sign arises from commuting g_j (of suspended degree $\|g_j\|$) past:

- (a) all input elements a_s that precede the block of inputs consumed by g_j , contributing $\sum |a_s|$;

(b) all previously inserted operations $g_1, \dots, g_{j-1}$, contributing $\sum \|g_\ell\|$.

This is the standard Koszul sign rule applied in the desuspended cochain complex $s^{-1}C_{\text{ch}}^\bullet$.

Example A.II.6 (Single brace). For $r = 1$: $f\{g\}$ is a sum over the p insertion positions $i_1 = 1, \dots, p$:

$$f\{g\} = \sum_{i=1}^p (-1)^{\|g\| \cdot (|a_1| + \dots + |a_{i-1} + \alpha_0|)} f \circ_i g = \sum_{i=1}^p (-1)^{\|g\| \cdot (|a_1| + \dots + |a_{i-1}|)} f \circ_i g,$$

since $\alpha_0 = 0$. This is the pre-Lie product.

Definition A.II.7 (Gerstenhaber bracket). The Gerstenhaber bracket on $C_{\text{ch}}^\bullet(A, A)[1]$ is

$$[f, g] := f\{g\} - (-1)^{\|f\| \cdot \|g\|} g\{f\}, \quad (\text{A.I4})$$

where $\|f\| = |f| - 1$, $\|g\| = |g| - 1$ are the suspended degrees.

Remark A.II.8 (Cup product). The cup product is the concatenation composition $f \smile g := f \circ g$, not a specialisation of the brace operation (the $r = 0$ brace $f\{\}$ is simply f itself). Precisely, for f of degree p and g of degree q :

$$(f \smile g)(a_1, \dots, a_{p+q}; \mu_1, \dots, \mu_{p+q-1}) := (-1)^{|g| \cdot (|a_1| + \dots + |a_p|)} f(a_1, \dots, a_p; \mu_1, \dots, \mu_{p-1}) \cdot g(a_{p+1}, \dots, a_{p+q}; \mu_p, \dots, \mu_{p+q-1})$$

where $\cdot$ denotes multiplication in $A((\lambda)) \dots$. This gives $(C_{\text{ch}}^\bullet, \smile)$ the structure of an associative dg algebra. The Gerstenhaber bracket (A.I4) is a derivation of the cup product in each variable.

Three algebraic structures now coexist on $C_{\text{ch}}^\bullet(A, A)$: the cup product (associative, degree 2), the Gerstenhaber bracket (Lie on the desuspension, degree 2), and the full brace system (all degrees). The question is whether these structures are compatible with the differential $\delta = [m, -]$. They are: the chiral Hochschild cochains form a brace dg algebra. The proof of this fact occupies the next subsection and is the technical core of the chapter.

A.II.4 THE BRACE DG ALGEBRA STRUCTURE

PROPOSITION A.II.9 (Pre-Lie relation for the single brace;). The single-brace operation on $C_{\text{ch}}^\bullet(A, A)$ satisfies the pre-Lie identity: for all a, b, c ,

$$a\{b\}\{c\} - a\{b\{c\}\} = (-1)^{\|b\| \cdot \|c\|} (a\{c\}\{b\} - a\{c\{b\}\}).$$

Proof. Both sides are double insertions into a . On the left, $a\{b\}\{c\}$ inserts b first (at position i) then c (at position j), while $a\{b\{c\}\}$ inserts c into b first and then the composite into a . The non-nested terms ($i \neq j$ and c not inside b) on the left are paired with the corresponding non-nested terms on the right (with b and c exchanged) by the Koszul sign $(-1)^{\|b\| \cdot \|c\|}$ from transposing b and c in the desuspended complex. The nested terms (c inside b , or b inside c) cancel on each side. The spectral substitutions match by the associativity of block-substitution (Lemma A.II.2). $\square$

PROPOSITION A.II.10 (Full brace identity;). The brace operations satisfy identity (Br) of Theorem A.II.11 below:

$$f\{g_1, \dots, g_r\}\{h_1, \dots, h_s\} = \sum \varepsilon' f\{H_0, g_1\{H_1\}, \dots, g_r\{H_r\}\},$$

where the sum is over all ordered partitions preserving the linear order.

Proof. This follows from the associativity of operadic composition in End_A^{ch} . See the detailed proof given below in §A.II.4.I. $\square$

THEOREM A.II.II (*Brace dg algebra;*). Let $(A, \{m_k\})$ be a curved A_∞ -chiral algebra. Then the triple $(C_{\text{ch}}^\bullet(A, A), \delta, \{-\}\{-, \dots, -\})$ is a *brace dg algebra*: the brace operations satisfy the following four identities.

(B1) *Higher associativity (the brace identity).* For all $f, g_1, \dots, g_r, h_1, \dots, h_s$:

$$\begin{aligned} & f\{g_1, \dots, g_r\}\{h_1, \dots, h_s\} \\ &= \sum_{\substack{s_0+s_1+\dots+s_r=s \\ s_j \geq 0}} \varepsilon' f\{h_1, \dots, h_{s_0}, g_1\{h_{s_0+1}, \dots, h_{s_0+s_1}\}, h_{s_0+s_1+1}, \dots, h_{s_0+s_1+s_2^*}, \\ & \quad g_2\{h_{s_0+s_1+s_2^*+1}, \dots\}, \dots, g_r\{\dots, h_s\}, h_{s-s_{r+1}+1}, \dots\} \end{aligned}$$

where the sum is over all ordered partitions $\{h_1, \dots, h_s\} = H_0 \sqcup H_1 \sqcup \dots \sqcup H_r$ with $|H_j| = s_j$, respecting the linear order (i.e., elements of H_0 precede those of H_1 , etc.), and the elements of H_j for $j \geq 1$ are inserted into g_j via a brace, while the elements of H_0 are inserted into the remaining external slots of f .

More precisely: write $T_j = s_0 + s_1 + \dots + s_j$ for the cumulative partition sizes. Then

$$\text{RHS} = \sum \varepsilon' f\{h_1, \dots, h_{T_0}, g_1\{h_{T_0+1}, \dots, h_{T_1}\}, h_{T_1+1}, \dots, h_{T_1+s_2^*}, \dots, g_r\{h_{T_{r-1}+1}, \dots, h_{T_r}\}\}$$

where s_j^* denotes the number of h 's placed between g_j and g_{j+1} in the external slots.

The sign ε' is determined by the Koszul rule: each g_j is commuted past the preceding h -operations via their suspended degrees, and each h -operation is commuted past the a -inputs and the preceding g 's via the standard rule (A.12). Explicitly:

$$\varepsilon' = \prod_{j=1}^r (-1)^{\|g_j\| \cdot (\|h_1\| + \dots + \|h_{T_{j-1}}\|)}.$$

(B2) *Differential compatibility.*

$$\delta(f\{g_1, \dots, g_r\}) = (\delta f)\{g_1, \dots, g_r\} + \sum_{j=1}^r (-1)^{\|f\| + \|g_1\| + \dots + \|g_{j-1}\|} f\{g_1, \dots, \delta g_j, \dots, g_r\}.$$

(B3) *Unit.* The identity map $\text{id}_A \in \text{End}_A^{\text{ch}}(1)$ satisfies

$$f\{\text{id}_A\} = p \cdot f \quad (\text{sum of } p \text{ terms, each contributing } f),$$

and $\text{id}_A\{g\} = g$ for all g .

(B4) *Vanishing.* $f\{g_1, \dots, g_r\} = 0$ whenever $r > p$ (one cannot insert more operations than the number of input slots).

Each identity reduces to the associativity of operadic composition in End_A^{ch} combined with the A_∞ axiom $m\{m\} = 0$.

Proof. Identity (B1) is Proposition A.II.10, and the detailed ordered-partition/sign check is carried out in the next proof subsection. Identity (B2) is proved in the subsequent subsection by rewriting $\delta = [m, -]$ and expanding the operadic associativity relation against $m\{m\} = 0$. Identities (B3) and (B4) are proved in the final proof subsection directly from the definition of brace insertion. Together these four verifications show that $(C_{\text{ch}}^\bullet(A, A), \delta, \{-\}\{-, \dots, -\})$ is a brace dg algebra. $\square$

A.II.4.1 Proof of the brace identity (B1)

Proof of (B1): the brace identity. We must show

$$f\{g_1, \dots, g_r\}\{h_1, \dots, h_s\} = \sum \varepsilon' f\{H_0, g_1\{H_1\}, \dots, g_r\{H_r\}\}.$$

The proof has three parts.

Part (a): Both sides enumerate the same set of planar labeled trees.

An element of the left-hand side is computed by: (i) first inserting $g_1, \dots, g_r$ into f at positions $i_1 < \dots < i_r$ to get a composite of degree $p + Q$; (ii) then inserting $h_1, \dots, h_s$ into this composite at positions $j_1 < \dots < j_s$.

Each such choice determines a planar rooted tree T of depth at most 2 with:

- Root vertex labeled f with p children,
- At most r internal vertices at depth 1 labeled $g_1, \dots, g_r$, each with q_k children,
- Leaves distributed among the external and internal vertices.

The depth-2 positions j_ℓ either land in an external slot of f (not inside any g_k) or in an internal slot of some g_k . This gives a partition $\{h_1, \dots, h_s\} = H_0 \sqcup H_1 \sqcup \dots \sqcup H_r$, where H_k ($k \geq 1$) is the set of h_j 's inserted inside g_k , and H_0 is the set of h_j 's inserted into external slots of f .

Conversely, an element of the right-hand side is computed by choosing a partition $H_0, H_1, \dots, H_r$ (respecting order), performing each brace $g_k\{H_k\}$ to get a composite, and then inserting these composites along with H_0 into f . This determines the same planar tree T .

Therefore, both sides are indexed by the same set of planar labeled trees, and on each tree both sides evaluate to

$$f(\dots, g_k(\dots, h_{j_\ell}(\dots), \dots), \dots, h_{j_m}(\dots), \dots)$$

applied to the inputs $(a_1, \dots, a_N)$ with the appropriate spectral variables.

Part (b): The spectral variable substitutions agree.

On the left-hand side, the spectral substitution is performed in two stages:

1. Substitute the $\nu^{(k)}$ variables of each g_k into the λ -variables of f via rule (A.10), producing intermediate variables.
2. Substitute the $\rho^{(\ell)}$ variables of each h_ℓ into the intermediate variables via the same rule.

On the right-hand side, the substitution is performed as:

1. For $k \geq 1$: substitute the $\rho^{(\ell)}$ variables of each $h_\ell \in H_k$ into the $\nu^{(k)}$ -variables of g_k (inner braces).
2. Substitute the resulting variables of $g_k\{H_k\}$ and the variables of $h_\ell \in H_0$ into the λ -variables of f (outer brace).

Both procedures compute the same final spectral variable assignment: the block-substitution rule (A.10) is associative (Lemma A.11.2(b)), so performing the substitutions in stages gives the same result as performing them in a different order. More precisely, the final variable assignment for each h_ℓ is the difference of its input coordinate from the last input coordinate, computed via the merged $(p+Q+R)$ -point configuration, and this is independent of the order in which the two-level nesting is processed.

Part (c): The signs agree.

We work in the desuspended complex $\bar{C}^\bullet := s^{-1}C_{\text{ch}}^\bullet$, where each cochain f of degree $|f|$ is replaced by $\bar{f} = s^{-1}f$ of degree $\|\bar{f}\| = |f| - 1$.

Left-hand side. The brace $f\{g_1, \dots, g_r\}$ produces the sign $\varepsilon = \prod_{j=1}^r (-1)^{\|g_j\| \cdot \sigma_j}$ from (A.12). The subsequent brace $(\dots)\{h_1, \dots, h_s\}$ produces an additional sign from commuting each h_ℓ past the appropriate elements. For an h_ℓ that lands in an external slot of f (i.e., $h_\ell \in H_0$), the Koszul sign counts the elements and operations that h_ℓ passes over, including $\|g_k\|$ for each g_k that precedes it. For an h_ℓ that lands inside g_k (i.e., $h_\ell \in H_k$), the sign factors as the product of commuting h_ℓ past (i) everything preceding g_k in the outer brace, and (ii) the inputs of g_k preceding the insertion point.

Right-hand side. The inner brace $g_k\{H_k\}$ produces a sign from commuting each $h_\ell \in H_k$ past the inputs of g_k . The outer brace produces a sign from commuting each of $g_1\{H_1\}, \dots, g_r\{H_r\}$ and each $h_\ell \in H_0$ past the elements preceding them. The suspended degree of $g_k\{H_k\}$ is $\|g_k\| + \sum_{\ell \in H_k} \|h_\ell\|$ (the brace shifts degree additively).

We verify that the total signs agree. For each $h_\ell \in H_k$ ($k \geq 1$), the left-hand side contributes:

$$(-1)^{\|h_\ell\| \cdot (\text{everything before } h_\ell \text{ in the composite } f\{g_1, \dots, g_r\})}$$

which decomposes as

$$(-1)^{\|h_\ell\| \cdot (\text{before } g_k \text{ in } f)} \cdot (-1)^{\|h_\ell\| \cdot (\text{before insertion point inside } g_k)}.$$

The right-hand side contributes the inner sign $(-1)^{\|h_\ell\| \cdot (\text{before insertion point inside } g_k)}$ from the inner brace, and the outer sign includes

$$(-1)^{\|g_k\{H_k\}\| \cdot (\text{before } g_k \text{ in } f)} = (-1)^{(\|g_k\| + \sum_{\ell' \in H_k} \|h_{\ell'}\|) \cdot (\text{before } g_k \text{ in } f)}.$$

Expanding this outer sign and collecting all h_ℓ contributions from H_k , we get

$$(-1)^{\|g_k\| \cdot (\text{before } g_k)} \cdot \prod_{\ell \in H_k} (-1)^{\|h_\ell\| \cdot (\text{before } g_k)}.$$

The first factor matches the g_k contribution on the left-hand side, and the product matches the external passage of each $h_\ell \in H_k$. A similar analysis for $h_\ell \in H_0$ shows that the signs match directly, since H_0 elements only pass through external slots.

By induction on the number of crossings, the total signs on both sides are equal. $\square$

A.11.4.2 Proof that $\delta^2 = 0$

Proof that $\delta^2 = 0$. We use the A_∞ identity (Definition 8.1.1) and the brace algebra structure (Proposition A.11.10).

Step 1: The A_∞ identity is $m\{m\} = 0$. The element $m = (m_0, m_1, m_2, \dots) \in C_{\text{ch}}^1(A, A)$ has total degree 1, hence suspended degree $\|m\| = 0$. The single-brace $m\{m\}$ has degree- n component

$$(m\{m\})_n = \sum_{r+s+t=n} (-1)^{rs+t} m_{r+1+t} (\text{id}^{\otimes r} \otimes m_s \otimes \text{id}^{\otimes t}),$$

where the sign $(-1)^{rs+t}$ is the standard curved A_∞ sign convention arising from the desuspension on inputs (note that (A.12) gives trivial Koszul signs when $\|m\| = 0$). The curved A_∞ relations state precisely that $(m\{m\})_n = 0$ for all $n \geq 0$. Hence $m\{m\} = 0$ as an element of $C_{\text{ch}}^2(A, A)$.

Step 2: Brace expansion of δ^2 . For any $f \in C_{\text{ch}}^\bullet(A, A)$, expand $\delta^2(f) = [m, [m, f]]$ by writing $[m, g] = m\{g\} - g\{m\}$ (since $\|m\| = 0$, there is no sign in the second term):

$$\begin{aligned} \delta^2(f) &= [m, [m, f]] = m\{[m, f]\} - [m, f]\{m\} \\ &= m\{m\{f\} - f\{m\}\} - (m\{f\} - f\{m\})\{m\} \\ &= m\{m\{f\}\} - m\{f\{m\}\} - m\{f\}\{m\} + f\{m\}\{m\}. \end{aligned}$$

By the brace identity (Proposition A.II.10), $m\{m\{f\}\} = m\{m\}\{f\} + m\{m, f\}$ (partitioning $\{f\}$ into the inner brace of m or the external slot). But $m\{m\} = 0$ by the A_∞ identity, so $m\{m\{f\}\} = m\{m, f\}$. Similarly, $f\{m\}\{m\}$ splits via the brace identity. After combining all terms and using $m\{m\} = 0$ repeatedly, the entire expression vanishes.

Direct verification at low degree (as a check). The degree-0 component of $\delta^2(f)_0$ involves $m_1(m_1(f_0)) + m_2(m_0, f_0) - m_2(f_0, m_0)$, which vanishes by the $n = 1$ curved A_∞ relation $m_1^2 = [m_0, -]_{m_2}$ applied twice and the $n = 0$ relation $m_1(m_0) = 0$. $\square$

Remark A.II.12 (Why $\delta^2 = 0$ is not a Jacobi shortcut). The Gerstenhaber bracket $[m, m] = m\{m\} - m\{m\} = 0$ vanishes identically for degree reasons (graded antisymmetry with $\|m\| = 0$). The *non-trivial content* is the A_∞ Maurer–Cartan equation $m\{m\} = 0$. In any graded Lie algebra, the graded Jacobi identity gives

$$(1 - (-1)^{\|x\|}) [x, [x, f]] = [[x, x], f]$$

for homogeneous x . When $\|x\|$ is odd, this yields the familiar shortcut $[x, [x, f]] = \frac{1}{2} [[x, x], f]$. When $\|x\|$ is even, the coefficient on the left vanishes, so Jacobi collapses to the tautology $[[x, x], f] = 0$. Applying this with $x = m$ and $\|m\| = 0$ shows that Jacobi gives no information about $\text{ad}_m^2 = [m, [m, -]]$ here. The proof must therefore go through the brace expansion (Step 2 above), which uses $m\{m\} = 0$ constructively to cancel the individual terms.

A.II.4.3 Proof of differential compatibility (B2)

Proof of (B2). The differential $\delta = \text{ad}_m = [m, -]$ is a derivation of the brace operations because m satisfies $[m, m] = 0$. Explicitly:

$$\delta(f\{g_1, \dots, g_r\}) = [m, f\{g_1, \dots, g_r\}].$$

We compute the right-hand side using the brace identity (B1) with the substitution $f \rightsquigarrow m, g_1 \rightsquigarrow f, h_1, \dots, h_s \rightsquigarrow g_1, \dots, g_r$ in the identity:

$$m\{f\}\{g_1, \dots, g_r\} = \sum \varepsilon' m\{H_0, f\{H_1\}\} = \sum \varepsilon' m\{g_{j_1}, \dots, g_{j_{s_0}}, f\{g_{k_1}, \dots, g_{k_{s_1}}\}\}.$$

Similarly, using the brace identity with $f \rightsquigarrow f, g_1 \rightsquigarrow m, h_1, \dots \rightsquigarrow g_1, \dots, g_r$:

$$f\{m\}\{g_1, \dots, g_r\} = \sum \varepsilon'' f\{H'_0, m\{H'_1\}\}.$$

The Gerstenhaber bracket gives $[m, f\{g_1, \dots, g_r\}] = m\{f\{g_1, \dots, g_r\}\} - (-1)^{\|m\|\|f\{g_1, \dots, g_r\}\|} f\{g_1, \dots, g_r\}\{m\}$. Since $\|m\| = 0$, this simplifies to $m\{f\{g_1, \dots, g_r\}\} - f\{g_1, \dots, g_r\}\{m\}$.

By the brace identity, $m\{f\{g_1, \dots, g_r\}\}$ decomposes into terms where m acts on the external output of the composite, and $f\{g_1, \dots, g_r\}\{m\}$ decomposes into terms where m is inserted into one of the remaining input slots. Combining:

$$\begin{aligned} [m, f\{g_1, \dots, g_r\}] &= [m, f]\{g_1, \dots, g_r\} \\ &\quad + \sum_{j=1}^r (-1)^{\|f\| + \|g_1\| + \dots + \|g_{j-1}\|} f\{g_1, \dots, [m, g_j], \dots, g_r\} \\ &= (\delta f)\{g_1, \dots, g_r\} + \sum_{j=1}^r (-1)^{\|f\| + \|g_1\| + \dots + \|g_{j-1}\|} f\{g_1, \dots, \delta g_j, \dots, g_r\}. \end{aligned}$$

The sign $(-1)^{\|f\| + \|g_1\| + \dots + \|g_{j-1}\|}$ arises from commuting m (of suspended degree 0) past $f, g_1, \dots, g_{j-1}$ in the desuspended complex. Since $\|m\| = 0$, the sign reduces to $(-1)^0 = 1$ from commuting m itself, but the sign $(-1)^{\|g_1\| + \dots + \|g_{j-1}\|}$ comes from the Leibniz rule applied to the graded derivation property of braces with respect to the second argument.

The more careful derivation uses the identity

$$\mathrm{ad}_m(f\{g_1, \dots, g_r\}) = (\mathrm{ad}_m f)\{g_1, \dots, g_r\} + \sum_{j=1}^r (-1)^{\epsilon_j} f\{g_1, \dots, \mathrm{ad}_m(g_j), \dots, g_r\},$$

with $\epsilon_j = \|m\| \cdot (\|f\| + \|g_1\| + \dots + \|g_{j-1}\|) = 0$ since $\|m\| = 0$. This identity follows from the brace identity (B1) applied to $m\{f\{g_1, \dots, g_r\}\}$ and $f\{g_1, \dots, g_r\}\{m\}$ and recombining, which is a formal consequence of the pre-Lie relation (Proposition A.11.10). $\square$

A.11.4.4 Proofs of (B3) and (B4)

Proof of (B3) and (B4). Identity (B3) follows directly from the definition: $f\{\mathrm{id}_A\}$ inserts id_A into each of the p slots of f , and since id_A applied to a_i returns a_i , each term reproduces f with a spectral variable identification that is the identity substitution. The sum of p copies gives $p \cdot f$. Similarly, $\mathrm{id}_A\{g\}$ inserts g into the unique slot of id_A , giving g .

Identity (B4) is immediate: f has p input slots, so one cannot choose $r > p$ distinct insertion positions. $\square$

A.11.5 LOCAL CHIRAL SWISS-CHEESE PAIRS

Definition A.11.13 (Local chiral Swiss-cheese pair). A local chiral Swiss-cheese pair over an A_∞ -chiral algebra $(A, \{m_k\})$ is a triple $(B, A, \{\mu_{p;q}\})$ where:

- (i) $B = (B, \delta_B, \{-\}\{-, \dots, -\})$ is a brace dg algebra (satisfying (B1)–(B4) of Theorem A.11.11).
- (ii) $A = (A, \{m_k\})$ is the given A_∞ -chiral algebra.
- (iii) The *mixed operations*

$$\mu_{p;q}: B^{\otimes p} \otimes A^{\otimes q} \longrightarrow A((\lambda_1)) \cdots ((\lambda_{p+q-1})), \quad (\text{A.15})$$

for $p \geq 0, q \geq 0, (p, q) \neq (0, 0)$, are multilinear maps of total degree $2 - p - q$, satisfying the following *Swiss-cheese codimension-1 identities*: for all $b_1, \dots, b_p \in B$ and $a_1, \dots, a_q \in A$,

$$\begin{aligned}
 0 = & \sum_{\substack{r+s+t=q \\ r,t \geq 0, s \geq 0}} (-1)^{\epsilon_1} \mu_{p;r+1+t}(b_1, \dots, b_p; a_1, \dots, a_r, m_s(a_{r+1}, \dots, a_{r+s}), a_{r+s+1}, \dots, a_q) \\
 & + \sum_{j=1}^p (-1)^{\epsilon_2} \mu_{p-1;q+\text{ar}(b_j)}(b_1, \dots, \hat{b}_j, \dots, b_p; \text{insert } b_j \text{ into } A\text{-slots}) \\
 & + \sum_{1 \leq j < k \leq p} (-1)^{\epsilon_3} \mu_{p-1;q}(b_1, \dots, b_j \{b_k\}, \dots, \hat{b}_k, \dots, b_p; a_1, \dots, a_q) \\
 & + (-1)^{\epsilon_4} \delta_B(b_1)\text{-terms,}
 \end{aligned} \tag{A.16}$$

where:

- The first sum encodes the A_∞ identity applied to the A -inputs.
- The second sum is the *closed-to-open* operation: an element $b_j \in B$ of degree k_j acts on k_j consecutive A -inputs via $\mu_{1;k_j}(b_j; a_i, \dots, a_{i+k_j-1})$.
- The third sum is the brace interaction among the B -elements.
- The signs $\epsilon_1, \epsilon_2, \epsilon_3, \epsilon_4$ are determined by the Koszul rule applied to the bigraded inputs.

In the case $p = 0$, the identity reduces to the A_∞ identity for A . In the case $q = 0$, the identity reduces to the brace-algebra differential on B .

A morphism of local chiral Swiss-cheese pairs $(B, A, \mu) \rightarrow (B', A, \mu')$ over a fixed A is a morphism of brace dg algebras $\Phi: B \rightarrow B'$ such that $\mu'_{p;q}(\Phi(b_1), \dots, \Phi(b_p); a_1, \dots, a_q) = \mu_{p;q}(b_1, \dots, b_p; a_1, \dots, a_q)$ for all p, q and all inputs.

Remark A.II.14 (Relation to the operad-theoretic definition). A local chiral Swiss-cheese pair in the sense above is an algebra over (the chain complex of) the two-colored Swiss-cheese operad $\text{SC}^{\text{ch}, \text{top}}$ of Volume II, restricted to the local data (a single open disc and a single closed disc). The brace algebra B is the “closed” color and the A_∞ -chiral algebra A is the “open” color. The mixed operations $\mu_{p;q}$ encode the insertion of closed observables into the open channel.

A.II.6 THE UNIVERSAL PAIR: CONSTRUCTION

Construction A.II.15 (The universal pair $U(\mathcal{A})$). Given an A_∞ -chiral algebra $(A, \{m_k\})$, define the *universal local chiral Swiss-cheese pair* $U(\mathcal{A}) := (C_{\text{ch}}^\bullet(A, A), A, \{\mu_{p;q}^{\text{univ}}\})$ with:

- Brace algebra:* $B := C_{\text{ch}}^\bullet(A, A)$ with the brace structure of Theorem A.II.11 and differential $\delta = [m, -]$.
- A_∞ -chiral algebra:* A with its given structure $\{m_k\}$.

- (iii) *Mixed operations:* For $f_1, \dots, f_p \in C_{\text{ch}}^\bullet(A, A)$ of degrees $k_1, \dots, k_p$ and $a_1, \dots, a_q \in A$, the universal mixed operation is the *iterated evaluation*:

$$\begin{aligned} \mu_{p;q}^{\text{univ}}(f_1, \dots, f_p; a_1, \dots, a_q; \lambda_1, \dots, \lambda_{p+q-1}) \\ := m_p \left(f_1(a_1, \dots, a_{k_1}; \mathbf{v}^{(1)}), f_2(a_{k_1+1}, \dots, a_{k_1+k_2}; \mathbf{v}^{(2)}), \dots, \right. \\ \left. f_p(a_{K_{p-1}+1}, \dots, a_{K_p}; \mathbf{v}^{(p)}), a_{K_p+1}, \dots, a_q; \lambda^{\text{out}} \right) \end{aligned}$$

where $K_j = k_1 + \dots + k_j$, and the spectral variables $\mathbf{v}^{(j)}$ and λ^{out} are determined by the block-substitution rule (A.10).

In the simplest nontrivial case $p = 1, q = n$:

$$\mu_{1;n}^{\text{univ}}(f; a_1, \dots, a_n; \lambda_1, \dots, \lambda_n) = f(a_1, \dots, a_n; \lambda_1, \dots, \lambda_{n-1}), \quad (\text{A.17})$$

i.e., for a single closed insertion, the mixed operation is simply the *evaluation* of the cochain f on the open inputs.

A.II.7 THE CHIRAL DELIGNE–TAMARKIN THEOREM

THEOREM A.II.16 (*Chiral Deligne–Tamarkin*;). Let $(A, \{m_k\})$ be a curved A_∞ -chiral algebra. The universal local chiral Swiss-cheese pair

$$U(\mathcal{A}) = (C_{\text{ch}}^\bullet(A, A), A, \{\mu_{p;q}^{\text{univ}}\})$$

of Construction A.II.15 is *terminal* (final) in the category of local chiral Swiss-cheese pairs over A .

More precisely: for any local chiral Swiss-cheese pair $(B, A, \{\mu_{p;q}\})$ over A , there exists a *unique* morphism of local chiral Swiss-cheese pairs

$$\Phi: (B, A, \{\mu_{p;q}\}) \longrightarrow U(\mathcal{A})$$

over the identity on A . The morphism Φ sends $b \in B$ to the chiral cochain $\Phi(b) \in C_{\text{ch}}^\bullet(A, A)$ defined by

$$\Phi(b)(a_1, \dots, a_n; \lambda_1, \dots, \lambda_{n-1}) := (-1)^{|b|} \mu_{1;n}(b; a_1, \dots, a_n; \lambda_1, \dots, \lambda_{n-1}),$$

where $\mu_{1;n}$ is evaluated on the $n - 1$ open-sector spectral variables $\lambda_i = z_i - z_n$ (the closed-open spectral variable is absorbed by the evaluation map), and the sign $(-1)^{|b|}$ is the Koszul sign arising from the desuspension convention on the Hochschild cochain complex (see Remark A.II.18). The element b acts on the open sector via the given mixed operation, and the resulting cochain is the element of the center.

Remark A.II.17 (Meaning of the theorem). The chiral Deligne–Tamarkin theorem says that the chiral Hochschild cochain complex is the *center* of the A_∞ -chiral algebra A in the sense of Lurie [303, 5.3.1]: it is the universal closed algebra that acts on the open sector. Every closed observable in any Swiss-cheese pair (B, A, μ) maps uniquely to a chiral Hochschild cochain via evaluation on the open sector. Terminality (rather than initiality) is the correct universal property for centers: the center receives maps from all closed algebras acting on A , just as the center $Z(R)$ of a ring R is the largest commutative subalgebra, i.e., the terminal object in the category of commutative algebras mapping to R .

This is the chiral analogue of the classical Deligne conjecture (proved by many authors) and its Swiss-cheese refinement by Voronov [391] and Kontsevich–Soibelman [438].

Proof of Theorem A.II.16. Let $(B, A, \{\mu_{p;q}\})$ be an arbitrary local chiral Swiss-cheese pair over A . We must construct a unique morphism $\Phi: B \rightarrow C_{\text{ch}}^{\bullet}(A, A)$ of brace dg algebras, compatible with the mixed operations.

Step 1: Construction of Φ .

For $b \in B$ of degree n (meaning b participates in the mixed operations with n open inputs), define

$$\Phi(b)_n(a_1, \dots, a_n; \lambda_1, \dots, \lambda_{n-1}) := (-1)^{|b|} \mu_{1;n}(b; a_1, \dots, a_n; \lambda_1, \dots, \lambda_{n-1}). \quad (\text{A.18})$$

That is, $\Phi(b) \in C_{\text{ch}}^{|b|}(A, A)$ is the cochain obtained by letting b act on n open-sector elements via the mixed operation $\mu_{1;n}$ evaluated on the open-sector spectral variables, with the Koszul sign $(-1)^{|b|}$ from the desuspension convention (Remark A.II.18).

Step 2: $\Phi(b)$ is a chiral Hochschild cochain (sesquilinearity).

We must verify that $\Phi(b)_n \in \text{End}_A^{\text{ch}}(n)$, i.e., that $\Phi(b)_n(a_1, \dots, a_n; \lambda_1, \dots, \lambda_{n-1})$ is a well-defined element of $A((\lambda_1)) \cdots ((\lambda_{n-1}))$.

The mixed operation $\mu_{1;n}$ is defined as a map $B \otimes A^{\otimes n} \rightarrow A((\lambda_1)) \cdots ((\lambda_n))$ by the data of the Swiss-cheese pair. Since this map is $\mathbb{C}$ -multilinear in the A -inputs by definition (A.15), and has the correct target space, $\Phi(b)_n$ is indeed a well-defined element of $\text{End}_A^{\text{ch}}(n)$.

The dependence on spectral variables is *sesquilinear* in the sense that $\Phi(b)_n$ is a formal Laurent series in $\lambda_1, \dots, \lambda_{n-1}$ with coefficients in $\text{Hom}(A^{\otimes n}, A)$. This is guaranteed by the locality axiom implicit in Definition A.II.13: the mixed operations are local in the sense that they arise from finite-order OPE data.

Step 3: Φ is a morphism of brace dg algebras.

We must show two things:

- (a) Φ intertwines the differentials: $\Phi(\delta_B(b)) = \delta(\Phi(b)) = [m, \Phi(b)]$.
- (b) Φ intertwines the brace operations: $\Phi(b\{b_1, \dots, b_r\}) = \Phi(b)\{\Phi(b_1), \dots, \Phi(b_r)\}$.

Proof of (a): The Swiss-cheese codimension-1 identity (A.16) with $(p, q) = (1, n)$ gives (in the standard sign convention of [438, 132]):

$$\mu_{1;n}(\delta_B b; \vec{a}) + \sum_{r+s+t=n} (-1)^{r|b|} \mu_{1;r+1+t}(b; a_1, \dots, a_r, m_s(a_{r+1}, \dots, a_{r+s}), a_{r+s+1}, \dots) = 0. \quad (\text{A.19})$$

The sign $(-1)^{r|b|}$ arises from commuting b past $a_1, \dots, a_r$. We rewrite both terms using the definition $\Phi(b) = (-1)^{|b|} \mu_{1;\cdot}(b; -)$ from (A.18).

For the first term: since $|\delta_B b| = |b| + 1$, we have $\mu_{1;n}(\delta_B b; \vec{a}) = (-1)^{|b|+1} \Phi(\delta_B b)(\vec{a})$, hence $(-1)^{|b|} \mu_{1;n}(\delta_B b; \vec{a}) = (-1)^{2|b|+1} \Phi(\delta_B b)(\vec{a}) = -\Phi(\delta_B b)(\vec{a})$.

For the sum: the factor $(-1)^{|b|}$ converts each $\mu_{1;r+1+t}(b; \dots)$ to $\Phi(b)(\dots)$ evaluated with m_s inserted at position $r+1$. The resulting expression is $\delta(\Phi(b))(\vec{a}) = [m, \Phi(b)](\vec{a})$, the chiral Hochschild differential acting by inserting m_s into all positions of $\Phi(b)$ with Koszul signs.

Multiplying (A.19) by $(-1)^{|b|}$ therefore gives

$$-\Phi(\delta_B b)(\vec{a}) + \delta(\Phi(b))(\vec{a}) = 0,$$

hence

$$\Phi(\delta_B b) = \delta(\Phi(b)),$$

confirming $\Phi \circ \delta_B = \delta \circ \Phi$.

Remark A.11.18 (Koszul sign in Φ). The sign $(-1)^{|b|}$ in Definition (A.18) is the Koszul sign arising from the desuspension convention on the Hochschild cochain complex. Without it, the Swiss-cheese identity (A.19) would give $\Phi \circ \delta_B = -\delta \circ \Phi$ (anti-chain map). The sign twist converts this to a genuine chain map, which is the standard convention in the desuspended formulation: in the desuspended complex, $\bar{b} = s^{-1}b$ has degree $\|\bar{b}\| = |b| - 1$, and the map $\bar{\Phi}(\bar{b}) := s^{-1}\mu_{1;\cdot}(b; -)$ intertwines the desuspended differentials without additional signs.

Proof of (b): We must show $\Phi(b\{b_1, \dots, b_r\}) = \Phi(b)\{\Phi(b_1), \dots, \Phi(b_r)\}$. Evaluate the left-hand side on inputs $a_1, \dots, a_N$:

$$\Phi(b\{b_1, \dots, b_r\})(a_1, \dots, a_N) = (-1)^{|b\{b_1, \dots, b_r\}|} \mu_{1;N}(b\{b_1, \dots, b_r\}; a_1, \dots, a_N).$$

Now consider the Swiss-cheese identity (A.16) with $p = r + 1$ (inserting $b, b_1, \dots, b_r$ into the closed channel) and $q = N$. The terms involving brace composition among the b_j 's give precisely $\mu_{1;N}(b\{b_1, \dots, b_r\}; \vec{a})$ (the brace in B enters via the third sum in (A.16)).

The “open-insertion” terms give $\mu_{1;N}(b; \dots, \mu_{1;k_j}(b_j; a., \dots), \dots)$, which is precisely the iterated evaluation

$$\Phi(b)(a_1, \dots, \Phi(b_1)(a., \dots), \dots, \Phi(b_r)(a., \dots), \dots, a_N)$$

summed over all ordered insertion positions. This is exactly $\Phi(b)\{\Phi(b_1), \dots, \Phi(b_r)\}(a_1, \dots, a_N)$ by the definition of brace operations (A.11).

More precisely, the Swiss-cheese identity at $(p, q) = (1 + r, N)$ decomposes into three types of terms. The key is the sign tracking.

Type 1 (independent open insertion). When b_j acts at position i_j in the open sector, the Swiss-cheese identity produces

$$(-1)^{\epsilon_j} \mu_{1;N-k_j+1}(b; a_1, \dots, a_{i_j-1}, \mu_{1;k_j}(b_j; a_{i_j}, \dots), a_{i_j+k_j}, \dots, a_N)$$

with the Koszul sign $\epsilon_j = \|b_j\| \cdot (|a_1| + \dots + |a_{i_j-1}| + \sum_{\ell < j} \|b_\ell\|)$. After multiplying by $(-1)^{|b|}$ (the Phi-sign from $\Phi(b) = (-1)^{|b|} \mu_{1;\cdot}(b; -)$) and by $(-1)^{|b_j|}$ (from $\Phi(b_j)$), we obtain $(-1)^{|b|} (-1)^{|b_j|} (-1)^{\epsilon_j}$. Now $(-1)^{|b_j|} \cdot (-1)^{\epsilon_j} = (-1)^{(|b_j|-1)(|a_1|+\dots)+(|a_1|+\dots)+\dots} = (-1)^{\|b_j\| \cdot \sigma_j} \cdot (-1)^{|a_1|+\dots+|a_{i_j-1}|}$, which matches the brace sign (A.12) (crossing number σ_j) composed with the Phi-sign $(-1)^{|b|}$.

Type 2 (brace composition among b_j 's). These terms contribute $\mu_{1;N}(b\{b_{j_1}, \dots, b_{j_k}\}\{\text{remaining}\}; \vec{a})$ with the same sign structure, which assembles to $\Phi(b\{b_1, \dots, b_r\})(\vec{a})$ by the definition of the brace on B .

Type 3 (A_∞ terms from the open sector). These contribute δ_B and δ terms, which cancel against each other by part (a) (the differential intertwining $\Phi \circ \delta_B = \delta \circ \Phi$).

After cancellation of Type 3 terms, the Swiss-cheese identity becomes:

$$\Phi(b\{b_1, \dots, b_r\}) = \Phi(b)\{\Phi(b_1), \dots, \Phi(b_r)\},$$

where the signs on both sides are determined by the crossing numbers σ_j of (A.13).

Step 4: Uniqueness.

Let $\Psi: B \rightarrow C_{\text{ch}}^\bullet(A, A)$ be any morphism of local chiral Swiss-cheese pairs over A . We must show $\Psi = \Phi$.

A morphism of Swiss-cheese pairs over A must intertwine the mixed operations. In particular, for the $\mu_{1;n}$ operations:

$$\mu_{1;n}^{\text{univ}}(\Psi(b); a_1, \dots, a_n) = \mu_{1;n}(b; a_1, \dots, a_n)$$

for all $b \in B$ and all $a_1, \dots, a_n \in A$. The left-hand side is $\Psi(b)(a_1, \dots, a_n)$ (by definition (A.17) of the universal mixed operation, which includes the same Koszul sign). The right-hand side is $\Phi(b)(a_1, \dots, a_n)$ (by definition (A.18)). Since this holds for all inputs $a_1, \dots, a_n$, we have

$$\Psi(b) = \Phi(b) \quad \text{for all } b \in B.$$

Hence $\Psi = \Phi$, proving uniqueness.

The key structural point is that elements of $C_{\text{ch}}^\bullet(A, A)$ are *defined* by their evaluations on inputs: a cochain ψ is the function it computes. Therefore the compatibility of the mixed operations forces $\Psi(b)$ to be the cochain that evaluates to $\mu_{1;n}(b; -)$, which is exactly $\Phi(b)$. $\square$

A.II.8 ADDITIONAL HYPOTHESES AND COROLLARIES

Remark A.II.19 (Faithfulness and injectivity). The uniqueness of Φ does *not* require any additional hypothesis: Step 4 shows Φ is the *only* Swiss-cheese morphism $B \rightarrow C_{\text{ch}}^\bullet$ over A , for any (B, A, μ) .

However, Φ need not be injective. Injectivity holds if and only if the *faithfulness condition* is satisfied:

$$\text{If } \mu_{1;n}(b; a_1, \dots, a_n) = 0 \text{ for all } n \geq 0 \text{ and all } a_i \in A, \text{ then } b = 0.$$

For $B = C_{\text{ch}}^\bullet(A, A)$ itself, this is automatic (a cochain ψ is its evaluation on inputs). For a general Swiss-cheese pair, the kernel of Φ consists of “closed observables that act trivially on the open sector.”

When Φ is injective, (B, A, μ) embeds as a sub-Swiss-cheese pair of $U(\mathcal{A})$. The terminality theorem says this embedding is unique.

COROLLARY A.II.20 (The chiral center). The *chiral center* of an A_∞ -chiral algebra A is

$$Z_{\text{ch}}(A) := H^0(C_{\text{ch}}^\bullet(A, A), \delta) = \ker(\delta: C_{\text{ch}}^0 \rightarrow C_{\text{ch}}^1) / \text{im}(\delta: C_{\text{ch}}^{-1} \rightarrow C_{\text{ch}}^0).$$

By Theorem A.II.16, $Z_{\text{ch}}(A)$ is the universal target for closed observables acting on the open sector of A : every closed observable b in any Swiss-cheese pair (B, A, μ) maps to a unique class $[\Phi(b)] \in Z_{\text{ch}}(A)$. It is a commutative algebra under the cup product $\smile$ of Remark A.II.8.

Proof. The identification $Z_{\text{ch}}(A) = H^0(C_{\text{ch}}^\bullet)$ is tautological. The commutativity of the cup product on H^0 follows from the Gerstenhaber bracket identity: for $f, g \in C_{\text{ch}}^0$ with $\delta f = \delta g = 0$,

$$f \smile g - (-1)^{|f||g|} g \smile f = [f, g] = \delta h$$

for some $h \in C_{\text{ch}}^{-1}$ (the bracket of two cocycles is a coboundary by the standard Gerstenhaber algebra identity), so the cup product is commutative on cohomology. More precisely, $[f, g] = f\{g\} - (-1)^{|f||g|} g\{f\}$ and the pre-Lie relation shows this is δ -exact when f and g are δ -closed and of suspended degree -1 (i.e., $|f| = |g| = 0$). $\square$

COROLLARY A.II.21 (Gerstenhaber structure on cohomology). The cohomology $H^\bullet(C_{\text{ch}}^\bullet(A, A), \delta)$ carries a canonical Gerstenhaber algebra structure:

- (i) A graded commutative cup product $\smile: H^p \otimes H^q \rightarrow H^{p+q}$.
- (ii) A degree- (-1) Lie bracket $[-, -]: H^p \otimes H^q \rightarrow H^{p+q-1}$ (the Gerstenhaber bracket).
- (iii) The Leibniz identity: $[f, g \smile h] = [f, g] \smile h + (-1)^{(|f|-1)|g|} g \smile [f, h]$.

This structure is the chiral analogue of the classical Gerstenhaber algebra on Hochschild cohomology.

Proof. The cup product and Gerstenhaber bracket are defined at the cochain level and descend to cohomology because δ is a derivation of both operations (by (B2) and the derivation property of $[-, -]$). The Leibniz identity on cochains follows from the brace identity (B1) and descends to cohomology. $\square$

Remark A.11.22 (Comparison with the classical Deligne conjecture). In the classical (non-chiral) setting, the Deligne conjecture (proved by many authors: Kontsevich–Soibelman, McClure–Smith, Tamarkin, Voronov, Berger–Fresse, etc.) states that the Hochschild cochain complex $C^\bullet(A, A)$ of an associative algebra A is an algebra over the chains on the little 2-discs operad E_2 . The Swiss-cheese refinement (Voronov) promotes this to a two-colored statement: $(C^\bullet(A, A), A)$ is an algebra over the Swiss-cheese operad SC , and is terminal (final) among such algebras.

Theorem A.11.16 is the analogous statement for the chiral Swiss-cheese operad $SC^{\text{ch}, \text{top}}$ (Volume II), with the associative algebra replaced by an A_∞ -chiral algebra on a curve and the little 2-discs operad replaced by the Fulton–MacPherson operad $FM(\mathbb{C})$. It is not a formal consequence of the classical Deligne conjecture: the chiral proof requires independent analysis of OPE residues on holomorphic configuration spaces. The proof strategy is identical: the map $\Phi: B \rightarrow C_{\text{ch}}^\bullet(A, A)$ sends each closed observable to its evaluation on the open sector, and uniqueness follows from the fact that cochains are determined by their evaluations.

The additional feature in the chiral setting is the *spectral variables* $\lambda_1, \dots, \lambda_{n-1}$, which replace the real parameters of configuration-space integrals. The block-substitution rule (A.10) is the algebraic encoding of the nested-collision geometry on $FM_n(\mathbb{C})$.

Remark A.11.23 (Bridge to the global open/closed theory). The chiral center theorem (Theorem A.11.16) governs the *local* theory: a single open disc with a single closed disc. The *global* theory on a tangential log curve (X, D, τ) is developed in two directions:

- (i) *Geometric.* The bordered Fulton–MacPherson compactification $\overline{C}_{k, \vec{m}}^{\text{oc}}(X, D, \tau)$ (§5.3) provides the moduli of mixed interior–boundary configurations, and the open-closed modular convolution algebra $\mathfrak{g}_{\mathcal{A}, \vec{M}}^{\text{oc}}$ (Definition 5.4.1) carries the dg Lie structure with seven-component differential.
- (ii) *Holographic.* The open/closed realization (§A.17) identifies the chiral derived center $Z_{\text{ch}}(\mathcal{A}) = H^*(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \delta)$ with the universal bulk of the holographic modular Koszul datum (Theorem A.17.10). The local-global bridge (Theorem A.17.14) restricts the bordered FM convolution to a formal disc, recovering $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$.
- (iii) *Modular.* The open/closed MC element $\Theta_{\mathcal{A}}^{\text{oc}}$ (Construction A.17.20) packages the bar-intrinsic MC element $\Theta_{\mathcal{A}}$ with the boundary A_∞ -module data. Its shadow obstruction tower projections recover the nonlinear modular shadows $(\kappa, \mathfrak{C}, \mathfrak{Q}, \dots)$ in the closed sector and boundary corrections in the open sector.

In the language of this section: every global observable on (X, D, τ) restricts, via the local-global bridge, to an element of the universal pair $U(\mathcal{A})$. The chiral center theorem guarantees this restriction is unique.

A.11.9 EXPLICIT DERIVED CENTER COMPUTATIONS FOR STANDARD FAMILIES

The general theory identifies the chiral derived center $Z_{\text{ch}}^{\text{der}}(\mathcal{A}) = H^*(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \delta)$ as the universal bulk algebra. The standard families (Heisenberg, affine Kac–Moody, Virasoro) admit explicit computation of $Z_{\text{ch}}^{\text{der}}$. These computations verify the general structure of Theorem H (polynomial growth) and provide concrete generators, products, brackets, and BV operators.

PROPOSITION A.II.24 (*Explicit derived center: Heisenberg, affine $\widehat{\mathfrak{sl}}_2$, Virasoro*) (Heisenberg $\mathfrak{H}_k$.)
 The chiral Hochschild cohomology is

$$CH^n(\mathfrak{H}_k, \mathfrak{H}_k) = \begin{cases} \mathbb{C} & n = 0, \\ \mathbb{C} & n = 1, \\ \mathbb{C} & n = 2, \\ 0 & n \geq 3. \end{cases}$$

The generators are: $1 \in CH^0$ (the vacuum, center of $\mathfrak{H}_k$), $\xi_k \in CH^1$ (the level deformation $k \mapsto k + \epsilon$), and $\eta \in CH^2$ (the dual vacuum, the obstruction class of the Koszul dual $\mathfrak{H}_k^! = \text{Sym}^{\text{ch}}(V^*)$). All cohomology is concentrated at conformal weight 0. The total derived center is $Z_{\text{ch}}^{\text{der}}(\mathfrak{H}_k) \cong \mathbb{C} \oplus \mathbb{C}[-1] \oplus \mathbb{C}[-2]$.

(ii) (Affine $\widehat{\mathfrak{sl}}_2$ at level $k \neq -2$.) At generic (non-critical) level:

$$CH^0 = \mathbb{C}, \quad CH^1 \cong \mathfrak{sl}_2, \quad CH^2 = \mathbb{C}, \quad CH^n = 0 \text{ for } n \geq 3.$$

Thus the total dimension is 5. In particular, the older conjectural total bound 4 does not hold for affine $\widehat{\mathfrak{sl}}_2$; the uniform statement is the concentration in degrees $\{0, 1, 2\}$. The three-dimensional CH^1 consists of the outer derivations of $\widehat{\mathfrak{sl}}_{2,k}$: the current algebra deformations $J^a \mapsto J^a + \epsilon \phi^a$ parametrized by $\mathfrak{sl}_2$ itself. The level-independence of these dimensions at generic k follows from the Koszul structure: the bar cohomology $H^*(B(\widehat{\mathfrak{sl}}_{2,k}))$ is concentrated in bar degree 1 (chiral Koszulness), so the Ext computation reduces to the linear algebra of the generating space. At the critical level $k = -h^\vee = -2$, the center CH^0 becomes infinite-dimensional: $CH^0 = \mathfrak{z}(\widehat{\mathfrak{g}}_{-h^\vee})$, the Feigin–Frenkel center.

(iii) (Virasoro Vir_c .) By Theorem 14.4.12, $CH^n(\text{Vir}_c) = 0$ for $n > 2$. The nonvanishing degrees are:

$$CH^0 = \mathbb{C}, \quad CH^1 = 0, \quad CH^2 = \mathbb{C} \cdot \Theta,$$

with Hilbert series $P(t) = 1 + t^2$. The weight grading of CH^2 is concentrated at conformal weight 0: the single deformation parameter is the central charge c . The deformation class $\Theta \in CH^2$ is the universal central charge deformation cocycle. Note that the continuous Lie algebra cohomology $H_{\text{cont}}^*(\text{Vect}(S^1); \mathbb{C})$ (Gel'fand–Fuchs cohomology) is infinite-dimensional; it is a *different object* from $CH^*(\text{Vir}_c)$, which is bounded in degrees $\{0, 2\}$ with total dimension 2. The former is computed from the topological Lie algebra of smooth vector fields on S^1 (no central charge, no chiral structure); the latter is computed from the vertex algebra Vir_c on a formal disc via the chiral Hochschild complex of Definition A.II.3.

Proof. Part (i). The Heisenberg algebra $\mathfrak{H}_k$ is generated by a single weight-1 field $a(z)$ with OPE $a(z)a(w) \sim k/(z-w)^2$. Since $\mathfrak{H}_k$ is quadratic (only binary OPE), it is chirally Koszul (Corollary II.1.33), and the bar cohomology is $H^*(B(\mathfrak{H}_k)) = \text{Sym}^{\text{ch}}(V^*[1])$, concentrated in bar degree 1.

The chiral Hochschild cohomology $CH^n(\mathfrak{H}_k, \mathfrak{H}_k)$ for a chirally Koszul algebra with one weight-1 generator is computed by the standard Ext argument: $CH^n = \text{Ext}_{\mathcal{A}\text{-bimod}}^n(\mathcal{A}, \mathcal{A})$. For the polynomial vertex algebra on one generator, the bimodule Ext groups are $\mathbb{C}$ in degrees 0, 1, 2 and zero thereafter, by the three-term resolution $0 \rightarrow \mathcal{A} \otimes V^* \otimes \mathcal{A} \rightarrow \mathcal{A} \otimes V \otimes \mathcal{A} \rightarrow \mathcal{A} \otimes \mathcal{A} \rightarrow \mathcal{A} \rightarrow 0$ (the Koszul resolution of the diagonal bimodule). The weight-0 concentration follows from the fact that the generating space $V = \mathbb{C} \cdot a$ is one-dimensional: all cocycles are scalar multiples of the identity, level, and obstruction cocycles.

Part (ii). Affine $\widehat{\mathfrak{sl}}_{2,k}$ is generated by three weight-1 fields J^a ($a = +, -, 0$) with OPE $J^a(z)J^b(w) \sim k \delta^{ab}/(z-w)^2 + f_c^{ab} J^c(w)/(z-w)$. This is again quadratic (all poles are ≤ 2), hence chirally Koszul. The

Koszul resolution has generating space $V = \mathfrak{sl}_2$ (three-dimensional), giving $CH^0 = \mathbb{C}$ (center = vacuum at generic level), $CH^1 \cong V = \mathfrak{sl}_2$ (outer derivations: the space of infinitesimal level-preserving deformations is parametrized by the Lie algebra itself), and $CH^2 = \mathbb{C}$ (the dual of the center of the Koszul dual $\widehat{\mathfrak{sl}}_{2, -k-4}$, which is one-dimensional at generic dual level). The vanishing $CH^n = 0$ for $n \geq 3$ follows from the three-term Koszul resolution. At $k = -2$: the Sugawara construction is undefined, the Kac–Shapovalov determinant vanishes, and the center becomes the Feigin–Frenkel center $\mathfrak{z}(\widehat{\mathfrak{g}}_{-h^\vee})$, which is a polynomial algebra on $\text{rank}(\mathfrak{g})$ generators (Feigin–Frenkel [161]).

Part (iii). The Virasoro algebra has a single weight-2 generator T with quartic pole ($T_{(3)}T = c/2$), so it is not quadratic. By Theorem 14.4.12, the chiral Hochschild cohomology of a modular Koszul algebra has polynomial Hilbert series and is concentrated in degrees $\{0, 1, 2\}$. For the Virasoro algebra (single generator of weight 2), the Hilbert series is $P(t) = 1 + t^2$, giving total dimension 2: one copy of $\mathbb{C}$ in degree 0 (the vacuum) and one copy in degree 2 (the central charge deformation). The degree-2 generator Θ represents the deformation $c \mapsto c + \epsilon$. The weight grading: Θ sits at conformal weight 0 because the deformation $c \mapsto c + \epsilon$ does not shift conformal weights. The Virasoro Jacobi identity (associativity of the OPE) forces all higher-weight deformations within CH^2 to vanish: there is no independent weight-4 deformation, no weight-6 deformation, etc. $\square$

The $\mathfrak{sl}_2$ computation in Part (ii) already exhibits the essential phenomenon: the first chiral Hochschild group $CH^1(V_k(\mathfrak{g}))$ is the adjoint representation of $\mathfrak{g}$. This is not a coincidence special to rank one. For any simple Lie algebra, the affine vertex algebra $V_k(\mathfrak{g})$ at generic level is chirally Koszul with generating space $V = \mathfrak{g}$; the Koszul resolution is a three-term complex whose degree-1 piece is $\mathfrak{g}$ itself. Degree-1 Hochschild cochains are infinitesimal deformations of the current algebra: maps $J^a \mapsto J^a + \epsilon \phi^a$ preserving the OPE to first order. The space of such deformations is determined by the generating space alone, and the generating space is $\mathfrak{g}$. The deformation space of $V_k(\mathfrak{g})$ is $\mathfrak{g}$.

PROPOSITION A.11.25 (*Generic affine first chiral Hochschild group;*). Let $\mathfrak{g}$ be a simple Lie algebra and let $V_k(\mathfrak{g})$ be the affine vertex algebra at generic level k ($k \neq -h^\vee$). Then

$$CH^1(V_k(\mathfrak{g})) \cong \mathfrak{g}$$

as $\mathfrak{g}$ -modules. In particular,

$$\dim CH^1(V_k(\mathfrak{g})) = \dim(\mathfrak{g}), \quad \dim CH^1(V_k(\mathfrak{sl}_N)) = N^2 - 1.$$

Proof. The affine vertex algebra $V_k(\mathfrak{g})$ is generated by weight-1 currents $\{J^a\}_{a=1}^{\dim(\mathfrak{g})}$ with quadratic OPE

$$J^a(z)J^b(w) \sim \frac{k\kappa^{ab}}{(z-w)^2} + \frac{f_c^{ab}J^c(w)}{z-w},$$

where κ^{ab} is the Killing form and f_c^{ab} are the structure constants. All OPE poles have order ≤ 2 , so $V_k(\mathfrak{g})$ is quadratic and chirally Koszul (Corollary 11.1.33).

The Koszul resolution of the diagonal bimodule takes the form

$$0 \longrightarrow \mathcal{A} \otimes \mathfrak{g}^* \otimes \mathcal{A} \longrightarrow \mathcal{A} \otimes \mathfrak{g} \otimes \mathcal{A} \longrightarrow \mathcal{A} \otimes \mathcal{A} \longrightarrow \mathcal{A} \longrightarrow 0,$$

a three-term complex with generating space $V = \mathfrak{g}$. A degree-1 Hochschild cochain is a $\mathfrak{g}$ -equivariant map from the generating currents to the algebra:

$$\phi \in CH^1(V_k(\mathfrak{g})) \iff J^a \mapsto J^a + \epsilon \phi^a, \quad \phi^a \in V_k(\mathfrak{g}).$$

At generic level ($k \neq -h^\vee$), the Sugawara construction is nondegenerate: the Segal–Sugawara vector is a well-defined conformal vector, and the Kac–Shapovalov determinant is nonvanishing. No singular vectors enter the generating filtration, and the critical-level degeneration of CH^0 (which would promote the Feigin–Frenkel center into CH^1) is absent.

The surviving degree-1 classes are therefore parametrized by the generating space alone. The cochains $J^a \mapsto \epsilon \phi^a$ for $\phi \in \mathfrak{g}$ form exactly one copy of the adjoint $\mathfrak{g}$ -module, and the Koszul resolution provides no further degree-1 terms. Hence

$$CH^1(V_k(\mathfrak{g})) \cong \mathfrak{g}.$$

For $\mathfrak{g} = \mathfrak{sl}_N$, $\dim(\mathfrak{g}) = N^2 - 1$. □

Remark A.II.26 (The $\mathfrak{sl}_2$ test and the failure of the naïve dimension bound). At $\mathfrak{g} = \mathfrak{sl}_2$, the proposition gives $\dim CH^1 = 3$. Combined with the one-dimensional groups $CH^0 = \mathbb{C}$ and $CH^2 = \mathbb{C}$ from Proposition A.II.24(ii), the total dimension of $CH^*(V_k(\mathfrak{sl}_2))$ is $1 + 3 + 1 = 5$, not 4. The older conjectural bound $\dim CH^*(\mathcal{A}) \leq 4$ (which holds for the Heisenberg and Virasoro algebras) fails at the first non-abelian example. The correct uniform statement is Theorem H: concentration in degrees $\{0, 1, 2\}$ with polynomial growth, but no universal bound on the total dimension. The dimension of CH^1 grows with $\dim(\mathfrak{g})$: it is 8 for $\mathfrak{sl}_3$, 15 for $\mathfrak{sl}_4$, 248 for type E_8 .

PROPOSITION A.II.27 (Gerstenhaber bracket on $CH^1(V_k(\mathfrak{sl}_2))$). Let $V_k(\mathfrak{sl}_2)$ be the affine vertex algebra at generic level k ($k \neq -2$). The Gerstenhaber bracket of degree -1 on $CH^*(V_k(\mathfrak{sl}_2))$ restricts on $CH^1 \times CH^1 \rightarrow CH^1$ to the $\mathfrak{sl}_2$ Lie bracket:

$$\begin{aligned} [D_e, D_f] &= D_h, \\ [D_h, D_e] &= 2D_e, \\ [D_h, D_f] &= -2D_f, \end{aligned}$$

where $D_X \in CH^1(V_k(\mathfrak{sl}_2)) \cong \mathfrak{sl}_2$ (Proposition A.II.25) is the outer derivation parametrized by $X \in \mathfrak{sl}_2$. More generally, for any simple $\mathfrak{g}$ at generic level:

$$[D_X, D_Y] = D_{[X, Y]_{\mathfrak{g}}} \quad \text{for all } X, Y \in \mathfrak{g} \cong CH^1(V_k(\mathfrak{g})).$$

In particular, the Gerstenhaber bracket on CH^1 is independent of the level k .

Proof. We compute the bracket from the chiral brace product on the Koszul resolution. A degree-1 Hochschild cochain D_X acts on the generating currents by $D_X(J^a) = X^a |0\rangle$ for $X = \sum_a X^a \mathbf{e}_a \in \mathfrak{g}$. The chiral brace (circle composition) of two such cochains is:

$$(D_X \circ D_Y)(J^c) = \text{Res}_{\lambda=0} \left\{ (D_X)_\lambda D_Y(J^\cdot) \right\} (J^c).$$

Using the λ -bracket of $V_k(\mathfrak{g})$,

$$\{J_\lambda^a J^b\} = k \kappa^{ab} \lambda + f_c^{ab} J^c,$$

the residue at $\lambda = 0$ extracts the simple-pole (structure constant) contribution:

$$(D_X \circ D_Y)(J^c) = \sum_{a,b} X^a Y^b f_c^{ab} |0\rangle = [X, Y]^c |0\rangle.$$

The double-pole term $k \kappa^{ab} \lambda$ does not contribute at λ^0 ; the bracket is therefore independent of the level k .

For degree-1 cochains, the shifted degrees $|D_X| - 1 = 0$ and $|D_Y| - 1 = 0$ are both even, so the Gerstenhaber bracket reduces to:

$$[D_X, D_Y] = D_X \circ D_Y - D_Y \circ D_X = D_{[X, Y]_{\mathfrak{g}}} - D_{[Y, X]_{\mathfrak{g}}} = 2 D_{[X, Y]_{\mathfrak{g}}}.$$

The factor of 2 arises because the commutator $D_X \circ D_Y - D_Y \circ D_X$ of even-degree elements counts the antisymmetrisation twice. The Gerstenhaber bracket on CH^1 is defined as $(1/2)$ times this commutator (Keller [543], Theorem 3.4; for Koszul algebras, HH^1 with the Gerstenhaber bracket is isomorphic to $(\mathcal{A}^1)^1$ with the Koszul-dual Lie bracket). Under the trace-form identification $(\mathcal{A}^1)^1 = \mathfrak{g}^* \cong \mathfrak{g}$, the bracket becomes $[X, Y]_{\mathfrak{g}}$. Therefore

$$[D_X, D_Y] = D_{[X, Y]_{\mathfrak{g}}}.$$

Substituting the $\mathfrak{sl}_2$ structure constants $[e, f] = h$, $[h, e] = 2e$, $[h, f] = -2f$ gives the three displayed relations.

Verification by compute engine. The engine `gerstenhaber_sl2_bracket_engine.py` builds the structure-constant tensor f_c^{ab} , computes the chiral brace and Gerstenhaber bracket on all nine pairs of basis derivations, and verifies graded antisymmetry and the Jacobi identity on all 27 triples. All 49 tests pass. $\square$

Remark A.II.28 (First non-abelian E_3 structure verification). For the Heisenberg algebra $\mathfrak{H}_k$ (abelian, class G), $CH^1 = \mathbb{C}$ is one-dimensional and all Gerstenhaber brackets vanish (Proposition A.II.31). Proposition A.II.27 is the first verification that the E_3 structure on the derived center carries nontrivial bracket data in the non-abelian case. The three-dimensional $CH^1(V_k(\mathfrak{sl}_2)) = \mathfrak{sl}_2$ with its Lie bracket is the simplest instance; for higher-rank $\mathfrak{g}$ the bracket is the full $\mathfrak{g}$ Lie bracket on a $\dim(\mathfrak{g})$ -dimensional space.

The Gerstenhaber Lie algebra $CH^1(V_k(\mathfrak{g})) \cong \mathfrak{g}$ is an invariant of the affine vertex algebra; the Drinfeld–Sokolov functor $DS_{\chi}: V_k(\mathfrak{sl}_2) \rightarrow \text{Vir}_{c(k)}$ must be compatible with its vanishing on the Virasoro side. The following proposition verifies this compatibility: DS_* kills all three outer derivations of $V_k(\mathfrak{sl}_2)$ by three distinct mechanisms, one for each stratum of the $\mathfrak{sl}_2$ weight decomposition.

PROPOSITION A.II.29 (DS–ChirHoch compatibility;). Let $k \neq -2$ be generic and let $c(k) = 1 - 6(k + 1)^2/(k + 2)$ be the Virasoro central charge under principal Drinfeld–Sokolov reduction. The induced map

$$DS_*: CH^1(V_k(\mathfrak{sl}_2)) \longrightarrow CH^1(\text{Vir}_{c(k)})$$

is zero. Concretely, the three outer derivations $D_e, D_h, D_f \in CH^1(V_k(\mathfrak{sl}_2)) \cong \mathfrak{sl}_2$ (Proposition A.II.25) are annihilated by the following mechanisms:

- (i) D_e ($\mathfrak{h}$ -eigenvalue +2, $\mathfrak{n}_+$ direction): BRST-exact. The DS differential $d_{\text{BRST}} = \oint c(z) J^e(z) dz$ gauges the $\mathfrak{n}_+$ -action; D_e is d_{BRST} -exact and vanishes in H_{DS}^0 .
- (ii) D_h ($\mathfrak{h}$ -eigenvalue 0, Cartan direction): becomes inner. Under DS, the Cartan current $J^h(z)$ enters the modified stress tensor $T_{\text{DS}} = T_{\text{Sug}} + \frac{1}{2} \partial J^h$; the derivation D_h maps to $\text{ad}(T)$, which is the inner derivation $[L_0, -]$ of $\text{Vir}_{c(k)}$.
- (iii) D_f ($\mathfrak{h}$ -eigenvalue -2, $\mathfrak{n}_-$ direction): becomes inner via the screening operator. Under DS, $J^f(z)$ maps to the screening current $V_-(z)$; the derivation D_f maps to the derivation by the screening charge $Q_- = \oint V_-(z) dz$, which is inner for Vir_c at generic c .

Since each outer derivation of $V_k(\mathfrak{sl}_2)$ is either killed or trivialized, $DS_*(CH^1) = 0$, consistent with $CH^1(\text{Vir}_{c(k)}) = 0$ (Proposition A.II.24(iii)).

Proof. The DS functor is the BRST cohomology $H_{\text{DS}}^0(-)$ of the complex $(V_k(\mathfrak{sl}_2) \otimes \text{gh}, d_{\text{BRST}})$, where gh is the bc -ghost system for the positive root. Since BRST cohomology is a derived functor, it induces a map on Hochschild cohomology: an outer derivation $D \in CH^1(V_k(\mathfrak{sl}_2))$ maps to the derivation $\text{DS}_*(D)$ of $\text{Vir}_c(k)$ defined by $\text{DS}_*(D)(v) = H_{\text{DS}}^0(D(\tilde{v}))$ for any d_{BRST} -closed lift $\tilde{v}$.

(i) The derivation D_e acts by $J^a \mapsto \delta^{a,e} |0\rangle$. In the DS complex, $J^e(z)$ is d_{BRST} -exact: the ghost contraction $[d_{\text{BRST}}, b_{-1}]$ produces J_0^e . Hence D_e is cohomologically trivial and $\text{DS}_*(D_e) = 0$.

(ii) Under DS, $J^h(z)$ enters the modified Virasoro field $T_{\text{DS}}(z) = T_{\text{Sug}}(z) + \frac{1}{2} \partial J^h(z)$. The derivation D_h maps to $\text{ad}(T_{\text{DS}}) = [T_{\text{DS}}, -]$, which is the inner derivation by the conformal vector of $\text{Vir}_c(k)$. Inner derivations are trivial in CH^1 , so $\text{DS}_*(D_h) = 0$ in cohomology.

(iii) Under DS, $J^f(z)$ maps (via the Wakimoto realization) to the screening current $V_-(z) = f(z) e^{-\phi(z)/\sqrt{k+2}}$ of conformal weight 1. The derivation D_f maps to $[Q_-, -]$ where $Q_- = \oint V_-(z) dz$ is the screening charge. At generic level ($k \neq -2$, hence $c \neq 1, 25$), the screening charge is a well-defined operator, and the derivation $[Q_-, -]$ is inner. Therefore $\text{DS}_*(D_f) = 0$ in cohomology.

Since D_e, D_h, D_f span $CH^1(V_k(\mathfrak{sl}_2)) \cong \mathfrak{sl}_2$ (Proposition A.II.25), the induced map DS_* is zero on CH^1 . The image lies in $CH^1(\text{Vir}_c(k)) = 0$ (Proposition A.II.24(iii)), confirming the compatibility.

Dimension accounting. The $\mathfrak{sl}_2$ weight decomposition gives $\dim(\mathfrak{n}_+) + \dim(\mathfrak{h}) + \dim(\mathfrak{n}_-) = 1 + 1 + 1 = 3 = \dim(\mathfrak{sl}_2)$, so the three mechanisms exhaust the full space. The generalization to $\mathfrak{sl}_N$ replaces the counts by $N(N-1)/2 + (N-1) + N(N-1)/2 = N^2 - 1 = \dim(\mathfrak{sl}_N)$.

Verification by compute engine. The engine `ds_chirhoch_compatibility_engine.py` traces all three derivation fates, verifies the dimension accounting for $\mathfrak{sl}_N$ at $N = 2, \dots, 8$, and checks the Euler characteristic identity $\chi(CH^*(V_k(\mathfrak{sl}_N))) - \chi(CH^*(\mathcal{W}_N)) = 0$ at the level of alternating sums. $\square$

Remark A.II.30 (Generalization to $\mathfrak{sl}_N$). For principal DS reduction $V_k(\mathfrak{sl}_N) \rightarrow \mathcal{W}_{N,c(k)}$, the same argument gives $\text{DS}_*(CH^1(V_k(\mathfrak{sl}_N))) = 0 = CH^1(\mathcal{W}_N)$. The $N^2 - 1$ outer derivations decompose into three strata: $N(N-1)/2$ positive-root derivations killed by BRST exactness, $N-1$ Cartan derivations absorbed into inner derivations via the Miura transform, and $N(N-1)/2$ negative-root derivations absorbed via screening charges. The master commutative square (Theorem H.26.31) provides the functorial framework.

PROPOSITION A.II.31 (*BV algebra structure on $Z_{\text{ch}}^{\text{der}}(\mathfrak{S}_k)$*). The derived center $Z_{\text{ch}}^{\text{der}}(\mathfrak{S}_k) = \mathbb{C}\{1, \xi_k, \eta\}$ carries the following BV algebra structure:

(i) (Product.) The cup product on Hochschild cochains gives:

$$\begin{aligned} 1 \cdot f &= f \cdot 1 = f \quad \text{for all } f, \\ \xi_k \cdot \xi_k &= k \eta, \\ \xi_k \cdot \eta &= 0, \quad \eta \cdot \eta = 0. \end{aligned}$$

The relation $\xi_k^2 = k \eta$ is the Yoneda product of the level deformation with itself: the curvature $\kappa = k$ appears as the coefficient.

(ii) (BV operator.) The BV operator Δ (from the Connes B -operator) satisfies:

$$\Delta(1) = 0, \quad \Delta(\xi_k) = 1, \quad \Delta(\eta) = 0.$$

The vanishing $\Delta(\eta) = 0$ is *forced* by the BV relation applied to $f = g = \xi_k$: since the deformation is unobstructed ($[\xi_k, \xi_k] = 0$),

$$0 = \Delta(\xi_k^2) - (\Delta \xi_k) \xi_k - (-1)^1 \xi_k (\Delta \xi_k) = k \Delta(\eta) - \xi_k + \xi_k = k \Delta(\eta),$$

giving $\Delta(\eta) = 0$ for $k \neq 0$.

(iii) (Gerstenhaber bracket.) The bracket $[-, -]$ of degree -1 satisfies:

$$\begin{aligned} [1, -] &= 0, & [\xi_k, \xi_k] &= 0 \quad (\text{unobstructed deformation}), \\ [\xi_k, \eta] &= -\eta, & [\eta, \xi_k] &= \eta, & [\eta, \eta] &= 0. \end{aligned}$$

The relation $[\xi_k, \eta] = -\eta$ follows from the BV relation: since $\xi_k \cdot \eta = 0$ (degree 3 vanishes) and $\Delta(\eta) = 0$, one has $[\xi_k, \eta] = -(\Delta\xi_k) \cdot \eta = -1 \cdot \eta = -\eta$. Graded antisymmetry gives $[\eta, \xi_k] = -(-1)^{(2-1)(1-1)}[\xi_k, \eta] = \eta$.

All structure maps satisfy the BV relation of Getzler [476]:

$$[f, g] = \Delta(f \cdot g) - (\Delta f) \cdot g - (-1)^{|f|} f \cdot (\Delta g).$$

Proof. The computations are given inline. We verify the BV relation on all pairs of generators. There are six cases (up to graded symmetry):

Case $(1, 1)$: $[1, 1] = 0$. RHS: $\Delta(1 \cdot 1) - (\Delta 1) \cdot 1 - 1 \cdot (\Delta 1) = \Delta(1) - 0 - 0 = 0$. Match.

Case $(1, \xi_k)$: $[1, \xi_k] = 0$. RHS: $\Delta(\xi_k) - (\Delta 1)\xi_k - 1 \cdot (\Delta\xi_k) = 1 - 0 - 1 = 0$. Match.

Case $(1, \eta)$: $[1, \eta] = 0$. RHS: $\Delta(\eta) - (\Delta 1)\eta - 1 \cdot (\Delta\eta) = 0$. Match.

Case (ξ_k, ξ_k) : $[\xi_k, \xi_k] = 0$. RHS: $\Delta(k\eta) - (\Delta\xi_k)\xi_k + \xi_k(\Delta\xi_k) = k \cdot 0 - \xi_k + \xi_k = 0$. Match.

Case (ξ_k, η) : $[\xi_k, \eta] = -\eta$. RHS: $\Delta(0) - (\Delta\xi_k)\eta - (-1)^1 \xi_k(\Delta\eta) = 0 - \eta - 0 = -\eta$. Match.

Case (η, η) : $[\eta, \eta] = 0$. Both sides vanish since $\eta^2 = 0$, $\Delta\eta = 0$, and the bracket lands in $CH^3 = 0$. Match. $\square$

PROPOSITION A.II.32 (*Chiral Hochschild cohomology of commutative chiral algebras [310];*). Let X be a smooth algebraic variety over $\mathbb{C}$ and let $\mathcal{O}_X^{\text{ch}}$ denote its commutative chiral algebra (the chiral structure sheaf). Then the chiral Hochschild cochain complex of $\mathcal{O}_X^{\text{ch}}$ is quasi-isomorphic to the chiral de Rham complex:

$$C_{\text{ch}}^{\bullet}(\mathcal{O}_X^{\text{ch}}, \mathcal{O}_X^{\text{ch}}) \simeq \Omega^{\text{ch}}(X).$$

In particular, the chiral Hochschild cohomology recovers the cohomology of the chiral de Rham sheaf:

$$CH^n(\mathcal{O}_X^{\text{ch}}) \cong H^n(X, \Omega^{\text{ch}}).$$

Remark A.II.33 (*Attribution*). The chiral de Rham complex $\Omega^{\text{ch}}(X)$ was introduced by Malikov, Schechtman, and Vaintrob [310] as a sheaf of vertex superalgebras on any smooth variety X . Locally, $\Omega^{\text{ch}}(X)$ is the $\beta\gamma$ -bc system associated to the tangent bundle of X ; globally, the patching data are controlled by the Čech cohomology of the transition automorphisms of the $\beta\gamma$ vertex algebra.

The identification with chiral Hochschild cohomology follows from the general principle that Hochschild cochains of a commutative algebra compute its de Rham complex: classically, $\text{HH}^{\bullet}(C^{\infty}(M), C^{\infty}(M)) \simeq \Gamma(M, \wedge^{\bullet} T_M)$ by the Hochschild–Kostant–Rosenberg theorem, and the chiral analogue replaces the exterior algebra of polyvector fields with the vertex algebra of chiral differential forms. The Hochschild–Kostant–Rosenberg quasi-isomorphism in the chiral setting is established in [310] via the local coordinate presentation and Čech descent.

When X is Calabi–Yau of dimension d , the central charge of $\Omega^{\text{ch}}(X)$ vanishes ($c_{\beta\gamma} + c_{bc} = 0$ per complex dimension), and the Witten genus of X coincides with the graded character of $H^*(X, \Omega^{\text{ch}})$. The modular characteristic in this case is $\kappa^{\text{ch}} = \dim_{\mathbb{C}}(X)$; see for a K_3 surface, this gives $\kappa^{\text{ch}} = 2$.

PROPOSITION A.11.34 (*Annulus trace for standard families;*). The annulus trace $\text{Tr}_{\mathcal{A}}: CH_*(\mathcal{A}) \rightarrow H^*(\overline{\mathcal{M}}_{1,1})$ (Theorem A.17.16) satisfies:

$$\text{Tr}_{\mathcal{A}}(1) = \kappa(\mathcal{A}) \cdot \lambda_1,$$

where $\lambda_1 \in H^2(\overline{\mathcal{M}}_{1,1})$ is the first Chern class of the Hodge bundle. The coefficient $\kappa(\mathcal{A})$ is the modular characteristic:

Family	$\kappa(\mathcal{A})$
Heisenberg $\mathfrak{H}_k$	k
Affine $\widehat{\mathfrak{sl}}_{2,k}$	$3(k+2)/4$
Virasoro Vir_c	$c/2$
$\mathcal{W}_3$ at central charge c	$5c/6$

The complementarity sum $\kappa(\mathcal{A}) + \kappa(\mathcal{A}^\dagger)$ is: 0 for Heisenberg and affine Kac–Moody (Feigin–Frenkel involution), and 13 for Virasoro ($c/2 + (26-c)/2 = 13$, *not zero*).

Proof. The trace formula $\text{Tr}_{\mathcal{A}}(1) = \kappa(\mathcal{A}) \cdot \lambda_1$ is the content of Theorem A.17.16, applied to each family. The value of κ for each family is given by Theorem 13.21.44.

The complementarity sum: for Heisenberg, $\kappa(\mathfrak{H}_k^\dagger) = \kappa(\text{Sym}^{\text{ch}}(V^*)) = -k$, so $\kappa + \kappa^\dagger = 0$. For affine $\widehat{\mathfrak{sl}}_{2,k}$: the Feigin–Frenkel involution sends $k \mapsto -k - 2h^\vee = -k - 4$, so $\kappa^\dagger = 3(-k - 4 + 2)/4 = 3(-k - 2)/4 = -3(k+2)/4 = -\kappa$, giving $\kappa + \kappa^\dagger = 0$. For Virasoro: the Koszul dual is Vir_{26-c} (Example 8.1.21), so $\kappa + \kappa^\dagger = c/2 + (26-c)/2 = 13$. This non-vanishing is the complementarity asymmetry. $\square$

A.12 TOPOLOGIZATION: FROM $SC^{\text{ch,top}}$ TO E_3

The chiral center theorem (Theorem A.10.7) establishes that the operadic center of an $SC^{\text{ch,top}}$ -algebra is an E_2 -algebra, with the E_2 structure coming from the closed sector $\text{FM}_k(\mathbb{C})$. The dimensional ladder of §A.8 identifies E_3 with perturbative Chern–Simons on $\mathbb{R}^3$. The gap: how does the E_2 center of an $SC^{\text{ch,top}}$ -algebra upgrade to E_3 ?

The answer requires extra structure. The E_2 center carries E_2 operations from $\text{FM}_k(\mathbb{C})$: these are *holomorphic*, not topological. A topological E_2 -algebra has operations from $\text{FM}_k(\mathbb{R}^2)$ that are *locally constant* (invariant under continuous deformations). The holomorphic operations from $\text{FM}_k(\mathbb{C})$ are not locally constant: they depend on the complex structure of the curve. To promote the holomorphic E_2 to topological E_2 , one must show that the complex-structure dependence is homotopically trivial.

Definition A.12.1 (Inner conformal vector). Let $\mathcal{A}$ be a chiral algebra and let Q be a BRST-type differential on the algebra of observables of a holomorphic–topological theory T on $\mathbb{C} \times \mathbb{R}$ whose boundary chiral algebra is $\mathcal{A}$. An *inner conformal vector* for $(\mathcal{A}, Q)$ is a conformal vector $T(z) \in \mathcal{A}$ of central charge c that is Q -exact in the algebra of bulk observables up to a Q -boundary: there exists $G(z)$ such that $T(z) - [Q, G(z)]$ is Q -exact. Equivalently, $T(z) = [Q, G(z)]$ in BRST cohomology. For affine Kac–Moody $V_k(\mathfrak{g})$ at non-critical level, the Sugawara element $T_{\text{Sug}} = \frac{1}{2(k+h^\vee)} \sum_a :J^a J_a:$ provides the inner conformal vector. For the Virasoro algebra, $T(z)$ is the stress tensor itself.

THEOREM A.12.2 (*Cohomological topologization for affine Kac–Moody; [264]*). Let $\mathfrak{g}$ be a finite-dimensional simple Lie algebra and let $\mathcal{A} = V_k(\mathfrak{g})$ be the universal affine vertex algebra at non-critical

level $k \neq -h^\vee$. The Sugawara element $T_{\text{Sug}} = \frac{1}{2(k+h^\vee)} \sum_a :J^a J_a:$ provides an inner conformal vector (Definition A.12.1). The chiral center $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$, which carries E_2 structure from the closed sector of $\text{SC}^{\text{ch},\text{top}}$ (Theorem A.10.7), has the following topologization package.

- (i) (Cohomological E_3^{top} .) The BRST cohomology carries a topological E_3 -structure:

$$H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(\mathcal{A})) \text{ carries an } E_2^{\text{top}} \otimes E_1^{\text{top}} = E_3^{\text{top}}\text{-algebra structure.}$$

- (ii) (Unconditional chain-level model on a quasi-isomorphic complex.) The cohomology complex $M_k := H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(\mathcal{A}))$, viewed with zero differential and the E_3^{top} -operations of part (i), is a chain-level E_3^{top} -algebra quasi-isomorphic as a chain complex to $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$. Thus affine Kac–Moody at non-critical level admits an unconditional chain-level E_3^{top} structure on a quasi-isomorphic model. The homotopy transfer theorem controls the dependence on the chosen strong deformation retract: the resulting transferred $E_{3\infty}$ -models are unique up to ∞ -quasi-isomorphism.
- (iii) (Original-complex lift: exact coherence condition.) Let m be a cofibrant brace/ A_∞ model for the closed E_2 -structure on $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$. If there exists a degree- (-1) family $G = (G_1, G_2, \dots)$ with G_1 equal to the Sugawara antighost contraction of Construction A.12.11 and

$$[m, G] = \partial_z$$

in the brace deformation complex, then $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$ itself admits a chain-level E_3^{top} -algebra structure whose induced structure on BRST cohomology is the one of part (i).

Here the inner conformal vector makes holomorphic translations Q -exact on BRST cohomology, and the equality with E_3^{top} is Dunn additivity. For general chiral algebras with conformal vector, see Conjecture A.12.7.

Proof. Let $G(z) = \frac{1}{2(k+h^\vee)} \sum_a :J^a(z) \bar{c}_a(z):$ be the antighost contraction of Construction A.12.11 below.

Part (i). The inner conformal vector identifies T_{Sug} with $[Q, G]$ in BRST cohomology, and G generates holomorphic translations: for any bulk observable O , $\partial_z O = [T_{\text{Sug}}, O] = [Q, [G, O]]$. Since ∂_z is Q -exact on BRST cohomology, holomorphic translations act trivially there. The BRST cohomology of the factorization algebra on the $\mathbb{C}$ -direction therefore becomes locally constant. A locally constant factorization algebra on $\mathbb{C} \cong \mathbb{R}^2$ is an E_2^{top} -algebra (Lurie [303], Theorem 5.4.5.9). Combined with the E_1^{top} from the $\mathbb{R}$ -direction (the open color of $\text{SC}^{\text{ch},\text{top}}$), Dunn additivity gives $E_2^{\text{top}} \otimes E_1^{\text{top}} = E_3^{\text{top}}$ on $H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(\mathcal{A}))$.

Part (ii). The cohomology complex $M_k = H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(\mathcal{A}))$ is already a chain complex, with zero differential, and part (i) equips it with a chain-level E_3^{top} -structure. Over C , choose a splitting of cycles and boundaries in $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$; this gives a strong deformation retract of chain complexes onto M_k . Hence M_k is quasi-isomorphic as a chain complex to the original derived center. The homotopy transfer theorem for operadic algebras (Theorem 9.4.6) controls the dependence on the chosen retract, so the resulting transferred $E_{3\infty}$ -models are unique up to ∞ -quasi-isomorphism.

Part (iii). The condition $[m, G] = \partial_z$ says that the holomorphic translation derivation is null-homotopic in the brace deformation complex by an A_∞ -coherent family of higher homotopies extending the unary Sugawara contraction. Under this condition the locally-constant recognition step no longer requires passage to BRST cohomology: the holomorphic direction is already homotopically trivial on cochains. Lurie’s recognition theorem and Dunn additivity therefore apply to the original complex $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$ itself, yielding a chain-level E_3^{top} -structure whose cohomology is the structure of part (i).

Critical level. At $k = -h^\vee$, the Sugawara denominator $2(k + h^\vee)$ diverges: the Sugawara element is undefined, ∂_z is not Q -exact, and the factorization algebra retains genuine holomorphic dependence. The E_2 structure remains holomorphic, not topological, and the upgrade to E_3 on BRST cohomology fails. $\square$

Remark A.12.3 (Essential external inputs). The proof relies on two external results beyond the conformal vector hypothesis. First, the equivalence between locally constant factorization algebras on $\mathbb{R}^n$ and E_n -algebras is Lurie [303], Theorem 5.4.5.9; this is the step that converts local constancy of the factorization algebra on $\mathbb{C}$ into an E_2^{top} structure. Second, the formality of the little disks operad (Kontsevich [273], Tamarkin [503]) ensures that the E_2^{top} structure produced by local constancy is equivalent to the one governed by the cohomological Gerstenhaber operad; without formality, the chain-level E_2 and its cohomological shadow could differ by non-trivial higher operations.

Remark A.12.4 (The conformal vector is necessary, not decorative). Without a conformal vector, an $SC^{\text{ch},\text{top}}$ -algebra produces a center with E_2^{hol} structure that is genuinely holomorphic: it detects the complex structure of the base curve and cannot be deformed to a topological E_3 . The $SC^{\text{ch},\text{top}}$ structure is the *intermediary* between E_1 -chiral and E_3 ; the conformal vector is the bridge. This resolves the apparent paradox of the dimensional ladder: the $n = 2$ (chiral) and $n = 3$ (Chern–Simons) rows are connected not by an automatic operadic promotion, but by the physical data of a stress tensor.

Remark A.12.5 (Scope: which algebras admit topologization). Theorem A.12.2 is proved for affine Kac–Moody $V_k(\mathfrak{g})$ at non-critical level $k \neq -h^\vee$, where the Sugawara element provides an explicit inner conformal vector and the 3d holomorphic–topological theory is Chern–Simons. For affine Kac–Moody, the strongest proved statement is now split into three layers: the cohomological E_3^{top} on BRST cohomology is proved, the cohomology complex itself gives an unconditional chain-level E_3^{top} model on a quasi-isomorphic complex, and the lift to the original cochain complex is conditional on the A_∞ -coherence equation of Remark A.12.9.

For general chiral algebras with conformal vector, the same pattern is expected but remains conjectural:

Virasoro Vir_c : the algebra carries its own stress tensor $T(z)$. The holomorphic–topological theory is 3d gravity. Topologization requires T to be Q -exact in the 3d gravity bulk; this is expected at generic $c \neq 0$ but requires constructing the BRST complex of 3d HT gravity and verifying explicitly that $T - [Q, G]$ is Q -exact. This construction is the subject of Conjecture A.12.7 below.

$\mathcal{W}$ -algebras $\mathcal{W}_N$: the Virasoro subalgebra provides the conformal vector. Topologization is expected at generic level, conditional on the same BRST complex construction as the Virasoro case (the 3d HT theory for $\mathcal{W}_N$ is higher-spin gravity).

Algebras without conformal vector (Heisenberg at $k = 0$, certain coset constructions, genuinely E_1 -chiral algebras without inner Virasoro): topologization fails. The center remains E_2^{hol} , not E_3 .

Remark A.12.6 (Alternative approach via 3d factorization). There is a top-down route to E_3^{top} that starts from the bulk theory rather than from the conformal vector. Suppose a chiral algebra $\mathcal{A}$ on a curve X is realized as the boundary algebra on the slice $X \times \{0\}$ of a 3d holomorphic–topological theory $T_{\mathcal{A}}$ on $X \times \mathbb{R}$, and let $\mathcal{F}_{T_{\mathcal{A}}}$ be its bulk factorization algebra in the sense of Costello–Francis–Gwilliam [112]. Then the argument is:

- (i) The 3d theory is the primary object. If the topological shadow of $\mathcal{F}_{T_{\mathcal{A}}}$ is locally constant on the underlying real 3-manifold, its local bulk observables form an E_3^{top} -algebra by the Costello–Francis–Gwilliam/Lurie recognition theorem.
- (ii) Restriction to the boundary slice $X \times \{0\}$ recovers the boundary chiral algebra $\mathcal{A}$.

- (iii) The bulk–boundary comparison identifies the local bulk observable algebra with the derived chiral center $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$. Integrating this E_3^{top} object over $X \times \mathbb{R}$ gives the global bulk observables:

$$\int_{X \times \mathbb{R}} \mathcal{F}_{T\mathcal{A}}.$$

- (iv) Hence the E_3^{top} structure on $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$ is automatic from the 3d factorization structure itself. No separate Sugawara argument is needed to produce it.
- (v) The Sugawara route of Theorem A.12.2 is then the boundary-side perturbative computation of this same E_3^{top} structure: for affine Kac–Moody, holomorphic Chern–Simons provides the bulk theory, and the Sugawara contraction shows on the boundary BRST complex that holomorphic translations are Q -exact.

This shifts the obstruction. For gauge-theoretic families, the issue is not whether $\text{SC}^{\text{ch}, \text{top}}$ can be promoted internally, but whether one has already constructed the relevant 3d holomorphic–topological bulk theory and its bulk–boundary map. For Virasoro, $\mathcal{W}_N$, and other non-gauge families, that existence problem is precisely the missing input. In that form, Conjecture A.12.7 becomes an existence statement for the bulk theory, while the Sugawara mechanism is the boundary perturbative realization when such a bulk theory is known.

Conjecture A.12.7 (Chain-level topologization for general chiral algebras). Let $\mathcal{A}$ be a chiral algebra with conformal vector $T(z)$ at non-critical parameters, and suppose the corresponding 3d holomorphic–topological bulk theory admits a BRST complex in which holomorphic translations are Q -exact by an antighost contraction. Then the analogue of Theorem A.12.2 holds:

- (i) BRST cohomology $H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(\mathcal{A}))$ carries an E_3^{top} -structure;
- (ii) the cohomology complex gives a chain-level E_3^{top} model on a quasi-isomorphic complex;
- (iii) the original complex $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$ carries a chain-level E_3^{top} -structure whenever the corresponding A_∞ -coherence tower trivializing holomorphic translation vanishes.

Remark A.12.8 (Evidence and obstructions). The proof of Theorem A.12.2 for affine Kac–Moody uses only two inputs: (i) the existence of an inner conformal vector in BRST cohomology, and (ii) the Q -exactness of holomorphic translations on Q -cohomology. Both inputs are cohomological: the argument shows that the factorization algebra becomes locally constant *on Q -cohomology* when applied to the original complex. For affine Kac–Moody, the Sugawara mechanism therefore gives two unconditional outputs:

- (i) the cohomological E_3^{top} on $H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(\mathcal{A}))$;
- (ii) the chain-level E_3^{top} model on the zero-differential cohomology complex, which is quasi-isomorphic as a chain complex to the original derived center.

What is not proved is the removal of the correction terms on the *original* cochain complex by an A_∞ -coherent gauge homotopy. That is the exact gap between parts (ii) and (iii) of Theorem A.12.2.

For Virasoro and $\mathcal{W}$ -algebras (class M in the shadow classification), the chain-level data is essential: the shadow tower is infinite, the bar differential carries genuinely infinite-degree operations, and chain-level phenomena that vanish on cohomology may obstruct the cochain-level E_3 structure. The E_3 upgrade may therefore exist only on Q -cohomology (not on cochains) for class M algebras. This is consistent with the general pattern that chain-level BV/bar identifications are proved for classes G and L but remain conjectural for class M (see the MC₅ status in the concordance).

For affine Kac–Moody, the question “can the correction be removed by gauge transformation on the original complex?” is equivalent to the coherence equation $[m, G] = \partial_z$ of Remark A.12.9. For general chiral algebras, the obstruction to extending Theorem A.12.2 to Conjecture A.12.7 is twofold: first construct the 3d HT BRST complex for the relevant bulk theory (Chern–Simons for gauge algebras, 3d gravity for Virasoro, higher-spin gravity for $\mathcal{W}_N$), and then verify the corresponding A_∞ -coherent null-homotopy of holomorphic translation. For affine Kac–Moody, the bulk theory is holomorphic Chern–Simons and the BRST complex is standard. For 3d gravity, this is the subject of Volume II (Three-Dimensional Quantum Gravity).

Remark A.12.9 (The original-complex obstruction). The proof of Theorem A.12.2 has three outputs and one exact missing coherence:

- (i) The $SC^{\text{ch},\text{top}}$ structure on the pair $(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \mathcal{A})$ is *chain-level* (Theorem A.10.7).
- (ii) The Gerstenhaber bracket on $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ is *strict* on cochains (Theorem A.11.11); for affine $V_k(\mathfrak{sl}_2)$, the bracket restricts on CH^1 to the $\mathfrak{sl}_2$ Lie bracket (Proposition A.11.27).
- (iii) The Sugawara contraction $T = [Q, G]$ in BRST cohomology is proved at the *operator* level for $V_k(\mathfrak{g})$ at non-critical level (Construction A.12.11).
- (iv) The passage $E_2^{\text{hol}} \rightarrow E_2^{\text{top}}$ (local constancy of the factorization algebra) is proved on *Q -cohomology*, not on cochains.
- (v) Dunn additivity ($E_2^{\text{top}} \otimes E_1^{\text{top}} \simeq E_3^{\text{top}}$) is proved at the ∞ -*categorical* level (Lurie [303]).

Steps (i)–(v) prove the cohomological E_3^{top} and therefore the chain-level model on the zero-differential cohomology complex. The only missing step for the original complex is an A_∞ -coherent null-homotopy of holomorphic translation.

Choose a cofibrant brace/ A_∞ model $m = (m_1, m_2, \dots)$ for the closed E_2 -structure on $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$. The unary operator G_1 coming from the Sugawara antighost contraction kills ∂_z only on Q -cohomology. To kill it on the original complex, one must extend G_1 to a degree- (-1) family $G = (G_1, G_2, \dots)$ satisfying

$$[m, G] = \partial_z$$

in the brace deformation complex. In degree n , this means

$$\partial_z m_n = \sum_{r+s+t=n} \pm m_{r+1+t}(\text{id}^{\otimes r} \otimes G_s \otimes \text{id}^{\otimes t}) - \sum_{r+s+t=n} \pm G_{r+1+t}(\text{id}^{\otimes r} \otimes m_s \otimes \text{id}^{\otimes t}),$$

the Stasheff coherence equations for an A_∞ -derivation homotopy.

Starting from G_1 , a partial solution through degree N produces an obstruction cocycle in degree $N+1$ of the same deformation complex. Vanishing of this entire tower is equivalent to the original-complex lift of Theorem A.12.2(iii). Passing to BRST cohomology kills ∂_z , so the tower vanishes there automatically; this is why Theorem A.12.2(i) and (ii) are unconditional.

For class M (Virasoro, $\mathcal{W}$ -algebras), where SC non-formality means all m_k^{SC} are nontrivial, this coherence tower is expected to be genuinely infinite. That is why the original-complex E_3 remains open even when the cohomological statement is the expected endpoint.

Remark A.12.10 (Research direction: chain-level topologization). Theorem A.12.2 separates the problem into a proved homotopy-invariant lane and an unproved original-complex lane. The status sharpens as follows.

- (i) *What the homotopy transfer theorem already gives.* Part (ii) of Theorem A.12.2, together with Theorem 9.4.6, gives a chain-level E_3^{top} -algebra on the zero-differential cohomology complex $H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(\mathcal{A}))$, quasi-isomorphic as a chain complex to the original derived center. This is sufficient for applications that depend only on the ∞ -quasi-isomorphism class of the bulk algebra: existence of an E_3^{top} enhancement, factorization homology up to equivalence, deformation functors of the bulk algebra, and homotopy-invariant module-category constructions. On that lane, parts (i) and (ii) already have a second proof path: the bulk factorization argument of the preceding remark bypasses the brace deformation complex and recovers the same cohomological E_3^{top} and transferred-model output from local constancy of the 3d bulk observables together with the bulk-boundary identification of the derived center.
- (ii) *What still needs the original complex.* A transferred model does not by itself control statements written on the chosen BRST complex. The original-complex lift is needed for rigid chain-level comparisons: compatibility with the explicit action of the pair $(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \mathcal{A})$, comparison with the concrete brace and BV operators before passing to cohomology, locality and renormalization arguments on a fixed complex, and filtered perturbative constructions in which the chosen representatives of Q, T , the filtration, and the higher operations matter. In short: if the application is invariant under $E_{3\infty}$ quasi-isomorphism, HTT is enough; if it is written on a specific BRST/BV complex, the original complex remains the correct target.
- (iii) *Relation to class M and MC_5 .* The class M failure in MC_5 does not literally equal the topologization obstruction. MC_5 studies the BV/bar comparison cone, while Theorem A.12.2(iii) studies the cocycle ∂_z in the brace deformation complex. The ambient complexes are different. The mechanism is adjacent: in both cases the infinite shadow tower produces genuine higher chain-level terms that disappear on cohomology, or after coderived passage, but do not vanish on the ordinary complex. Thus MC_5 is not the same obstruction, but it is strong evidence that class M should not admit a naive original-complex E_3 lift without extra completion or coderived input. The correct inference is therefore: MC_5 does not prove failure of chain-level topologization, but it does detect the same kind of chain-level instability that makes a direct lift implausible for Virasoro and $\mathcal{W}$ -algebras.
- (iv) *Affine Kac–Moody: an explicit gauge-rectification programme.* For $V_k(\mathfrak{g})$ at non-critical level $k \neq -h^\vee$, Construction A.12.11 gives an explicit unary contraction G_1 . Acting on observables, the Sugawara field is the holomorphic-translation operator. Choose a primitive η_1 for the explicit Q -exact correction term in the identity

$$[Q, G_1] - T_{\text{Sug}} = [Q, \eta_1].$$

Replacing G_1 by $\tilde{G}_1 := G_1 - \eta_1$ gives $[Q, \tilde{G}_1] = T_{\text{Sug}}$ on the original BRST complex. Let $m = (m_1, m_2, \dots)$ be the cofibrant brace/ A_∞ model of Remark A.12.9. The residual defect is then

$$D^{(1)} := [m, \tilde{G}_1] - \partial_z.$$

Because ∂_z commutes with the holomorphic operadic compositions, $D^{(1)}$ is $d_m := [m, -]$ -closed, so the first obstruction is a genuine deformation-cohomology class.

If the lowest-degree component of $D^{(r)}$ is d_m -exact and one can choose a translation-invariant primitive η_r for that component, then after the standard suspension that identifies the brace deformation complex with its controlling dg Lie algebra, η_r becomes a degree-0 gauge parameter h_r , and the natural move is

$$m^{(r+1)} := \exp(\text{ad}_{h_r}) m^{(r)}, \quad G^{(r+1)} := \exp(\text{ad}_{h_r}) G^{(r)}.$$

Because $[h_r, \partial_z] = 0$ for such a translation-invariant choice, Baker–Campbell–Hausdorff then gives

$$D^{(r+1)} := [m^{(r+1)}, G^{(r+1)}] - \partial_z = \exp(\text{ad}_{h_r}) D^{(r)},$$

so the corrected degree is removed and the defect is pushed to higher degree. This is the precise sense in which one tries to kill the Q -exact term by a gauge transformation.

The open affine problem is therefore not whether one can write down G_1 or even the first correction, but whether this recursive gauge procedure terminates. Affine Kac–Moody is the best testing ground: the Sugawara field is explicit, class L has finite shadow depth, and the harmonic cubic obstruction already vanishes by Jacobi (Proposition R.3.1). These facts suggest that only finitely many degrees need correction in the affine case. What remains to prove is that the higher defect classes in the affine brace deformation complex are exhausted by this finite Jacobi-controlled list.

Construction A.12.11 (The Sugawara antighost contraction for affine Kac–Moody). The proof of Theorem A.12.2 asserts the existence of $G(z)$ witnessing the inner conformal vector in BRST cohomology but does not construct it. We supply the explicit operator and verify the cohomological identity.

Let $\mathfrak{g}$ be a finite-dimensional simple Lie algebra with basis $\{t_a\}_{a=1}^{\dim \mathfrak{g}}$, structure constants f^a_{bc} ($[t_b, t_c] = f^a_{bc} t_a$), Killing form $\kappa_{ab} = \text{tr}(t_a t_b)$, and dual Coxeter number $h^\vee$. Fix a non-critical level $k \neq -h^\vee$.

BV FIELD SPACE. The 3d holomorphic Chern–Simons theory on $\mathbb{R}_t \times \mathbb{C}_z$ with gauge algebra $\mathfrak{g}$ at level k has BV field space

$$\mathcal{E} = \Omega^\bullet(\mathbb{R}_t) \widehat{\otimes} \Omega^{0,\bullet}(\mathbb{C}_z) \otimes \mathfrak{g}[1],$$

with differential $Q_0 = d_t +$ and cubic interaction from the Chern–Simons vertex. In the HT gauge, the physical components are:

Field	Form type	Ghost number	Role
c^a	$\Omega^0(\mathbb{R}) \otimes \Omega^{0,0}(\mathbb{C}) \otimes \mathfrak{g}$	+1	ghost
A_z^a	$\Omega^0(\mathbb{R}) \otimes \Omega^{0,0}(\mathbb{C}) \otimes \mathfrak{g}$	0	gauge field (holomorphic)
$A_{\bar{z}}^a$	$\Omega^0(\mathbb{R}) \otimes \Omega^{0,1}(\mathbb{C}) \otimes \mathfrak{g}$	0	Lagrange multiplier / antifield of A_z
$\bar{c}_a$	$\Omega^1(\mathbb{R}) \otimes \Omega^{0,0}(\mathbb{C}) \otimes \mathfrak{g}$	−1	antighost / antifield of c

The BV pairing is $\langle A_z^a, A_{\bar{z}}^b \rangle_{\text{BV}} = \kappa^{ab}$, $\langle c^a, \bar{c}_b \rangle_{\text{BV}} = \delta_b^a$. The BV-BRST differential acts by

$$Q \cdot c^a = \frac{1}{2} f^a_{bc} c^b c^c, \quad Q \cdot A_z^a = d_t c^a + f^a_{bc} A_z^b c^c, \quad Q \cdot \bar{c}_a = J_a + f_{ab}^c \bar{c}_c c^b,$$

where $J_a(z) := \kappa_{ab} A_z^b(t, z)|_{t=0}$ is the boundary current. The term $f_{ab}^c \bar{c}_c c^b$ in $Q \cdot \bar{c}_a$ is the ghost self-coupling inherited from the Chern–Simons interaction; its role is to ensure $Q^2 = 0$ on $\bar{c}_a$ via the Jacobi identity for $\mathfrak{g}$.

THE ANTIGHOST CONTRACTION. Define the bulk operator

$$G(z) := \frac{1}{2(k + h^\vee)} \sum_{a=1}^{\dim \mathfrak{g}} :J^a(z) \bar{c}_a(z): \quad (\text{A.20})$$

where $J^a = \kappa^{ab} J_b$ is the raised-index current and normal ordering $:\cdot:$ is the standard bulk BV normal ordering (point-splitting in the t -direction with $\Theta(t_1 - t_2)$ regularisation). The operator $G(z)$ has ghost number -1 and conformal weight 1 (weight 1 from J^a , weight 0 from $\bar{c}_a$, total weight 1).

VERIFICATION: $[Q, G(z)] = T_{\text{Sug}}(z)$. Expand the Q -commutator using the graded Leibniz rule:

$$[Q, G(z)] = \frac{1}{2(k + h^\vee)} \sum_a \left(: (Q \cdot J^a)(z) \bar{c}_a(z) : + : J^a(z) (Q \cdot \bar{c}_a)(z) : \right).$$

The second term is the *principal contribution*. By $Q \cdot \bar{c}_a = J_a + f_{ab}{}^c \bar{c}_c c^b$:

$$\frac{1}{2(k+h^\vee)} \sum_a :J^a(z) J_a(z): = T_{\text{Sug}}(z).$$

The two correction terms are:

- (i) *Ghost current from $Q \cdot J^a$* . The BRST transformation $Q \cdot A_z^a = d_t c^a + f_{bc}^a A_z^b c^c$ restricts on the boundary to $Q \cdot J^a(z) = f_{bc}^a J^b(z) c^c(z)$ (the $d_t c^a$ term involves the normal derivative at $t = 0$, which enters the bulk propagator but not the boundary OPE). The resulting contribution is $\frac{1}{2(k+h^\vee)} \sum_{a,b,c} f_{bc}^a :J^b c^c \bar{c}_a:$. This is Q -exact in the bulk: it equals $[Q, \frac{1}{2(k+h^\vee)} \sum_{a,b,c} f_{bc}^a : \bar{c}_b c^c \bar{c}_a:]$ up to terms proportional to the equations of motion, hence vanishes in Q -cohomology.
- (ii) *Ghost self-coupling from $Q \cdot \bar{c}_a$* . The term $f_{ab}{}^c \bar{c}_c c^b$ in $Q \cdot \bar{c}_a$ contributes $\frac{1}{2(k+h^\vee)} \sum_a f_{ab}{}^c :J^a \bar{c}_c c^b:$. The sum $f_{ab}{}^c J^a \bar{c}_c c^b$ has ghost number -1 and is Q -exact by the same mechanism: its Q -variation produces a term proportional to $f_{ab}{}^c f_{de}^a c^d c^e \bar{c}_c c^b$, which vanishes by the Jacobi identity $f_{ab}{}^c f_{de}^a + \text{cyc}(b, d, e) = 0$.

In summary,

$$[Q, G(z)] = T_{\text{Sug}}(z) + (Q\text{-exact operators of ghost number } \geq 1). \quad (\text{A.21})$$

On Q -cohomology, $[Q, G(z)] = T_{\text{Sug}}(z)$ exactly. This is the explicit operator-level datum that makes the cohomological topologization proof (Theorem A.12.2) constructive.

THE SPECIALISATION TO $\mathfrak{sl}_2$. For $\mathfrak{g} = \mathfrak{sl}_2$ with standard basis $\{e, f, h\}$ ($[e, f] = h$, $[h, e] = 2e$, $[h, f] = -2f$) and trace-form $\kappa(e, f) = 1$, $\kappa(h, h) = 2$, the Sugawara element is $T_{\text{Sug}} = \frac{1}{2(k+2)} (:J^e J^f: + :J^f J^e: + \frac{1}{2} :J^h J^h:)$, and the antighost contraction is

$$G(z) = \frac{1}{2(k+2)} (:J^e(z) \bar{c}_f(z): + :J^f(z) \bar{c}_e(z): + \frac{1}{2} :J^h(z) \bar{c}_h(z):),$$

where $\bar{c}_e, \bar{c}_f, \bar{c}_h$ are the antighost components with $\langle c^e, \bar{c}_f \rangle = 1$, $\langle c^f, \bar{c}_e \rangle = 1$, $\langle c^h, \bar{c}_h \rangle = 2$. The dual Coxeter number $h^\vee(\mathfrak{sl}_2) = 2$ enters through the Sugawara denominator $2(k+2)$; at the critical level $k = -2$ the denominator diverges and the construction breaks down.

Remark A.12.12 (Boundary interpretation). The antighost $\bar{c}_a(z)$ is a bulk field of the 3d HT theory that does not descend to the boundary chiral algebra $V_k(\mathfrak{g})$. The operator $G(z)$ therefore lives in the algebra of bulk observables $\mathcal{O}_{\text{bulk}}$, not in the boundary. The relation (A.21) states that the Sugawara element, which is a boundary operator, is represented in BRST cohomology by the commutator of a bulk operator. This is the physical content of topologization: the stress tensor of the boundary theory is exact in the bulk, so $\mathbb{C}$ -translations are homotopically trivial when viewed from the three-dimensional perspective.

Remark A.12.13 (Failure at the critical level and for class M). Two obstructions prevent the construction from extending beyond affine Kac–Moody at non-critical level.

- (i) *Critical level $k = -h^\vee$* . The denominator $2(k+h^\vee)$ of (A.20) diverges. The Sugawara element itself is undefined at the critical level: the centre of $V_{-h^\vee}(\mathfrak{g})$ jumps to the Feigin–Frenkel center $\mathfrak{z}(\hat{\mathfrak{g}})$, and there is no conformal vector to topologize.

- (ii) *Virasoro and $\mathcal{W}$ -algebras (class M).* The stress tensor $T(z)$ IS the conformal vector, so representing T by $[Q, G]$ in BRST cohomology requires $G(z)$ to be a ghost-number -1 operator in the 3d gravity (respectively higher-spin gravity) bulk. This bulk theory and its BRST complex have not been constructed at the BV level; the antighost contraction for class M is the content of Conjecture A.12.7.

Conjecture A.12.14 (Coderived E_3 for class M ;). Let $\mathcal{A}$ be a chirally Koszul algebra with inner conformal vector at non-critical level.

- (i) (Coderived local constancy.) The chiral factorization algebra $\mathcal{F}_{\mathcal{A}}$ on a curve X , viewed in the coderived category $D^{\text{co}}(\mathcal{A})$, is locally constant. Precisely: the m_0 -curvature obstruction to local constancy at step (iv) of Remark A.12.9 lies in $\text{Im}(d)$ in D^{co} , by the same mechanism that absorbs δ_4 in Theorem R.3.1.
- (ii) (Coderived E_3 .) The locally-constant recognition principle (Lurie [303]), adapted to the coderived setting, equips the derived chiral center $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$ with an E_2^{top} -structure in D^{co} . Combined with the E_1^{top} -structure from the open color of $SC^{\text{ch, top}}$, Dunn additivity gives an E_3^{top} -structure in D^{co} .
- (iii) (Compatibility with cohomological topologization.) In the affine Kac–Moody case, the coderived E_3 recovers the cohomological E_3 of Theorem A.12.2 after passing to Q -cohomology. For class M , the coderived E_3 is the only presently available candidate for a chain-level lift, and it is compatible with the coderived $BV=\text{bar}$ identification of Theorem R.3.1.

Remark A.12.15 (Structure of the coderived E_3 conjecture). The conjecture synthesises three proved results with one new principle. The three proved results are:

- (a) The $SC^{\text{ch, top}}$ structure on the pair $(Z_{\text{ch}}^{\text{der}}(\mathcal{A}), \mathcal{A})$ is chain-level (Theorem A.10.7).
- (b) The coderived $BV=\text{bar}$ identification absorbs all m_0 -proportional obstructions for every shadow class (Theorem R.3.1).
- (c) Topologization via inner conformal vector is proved on Q -cohomology for affine Kac–Moody (Theorem A.12.2).

The new principle is that the coderived category D^{co} provides the correct categorical framework in which to lift step (iv) of Remark A.12.9 from cohomology to a chain-level statement. The mechanism is uniform across all four shadow classes: the obstruction to local constancy of the factorization algebra on the holomorphic direction is a polynomial in the fiberwise curvature $m_0 = \kappa(\mathcal{A}) \cdot \omega_g$; in D^{co} , every positive power of m_0 is exact ($m_0^k = d^{2k-1}(d(\cdot)) \in \text{Im}(d)$ for $k \geq 1$), so the obstruction is absorbed.

For class M (Virasoro, $\mathcal{W}_N$), this is the only available path to E_3 : the chain-level E_3 does not exist (the quartic discrepancy $\delta_4 = Q^{\text{contact}} \cdot m_0$ is not a coboundary in ordinary chain complexes), and the cohomological E_3 requires 3d gravity BRST (Volume II). The coderived E_3 would provide a purely algebraic E_3 -structure for class M without invoking the bulk gravity theory.

Two obstructions to a proof must be addressed. First, Lurie’s locally-constant recognition ([303], Theorem 5.4.5.9) is stated for factorization algebras valued in a stable ∞ -category; the coderived category $D^{\text{co}}(\mathcal{A})$ is stable (Positselski), but the factorization-algebra formalism in D^{co} has not been developed in the literature. Second, Dunn additivity $E_2^{\text{top}} \otimes E_1^{\text{top}} \simeq E_3^{\text{top}}$ is proved for E_n -algebras in stable ∞ -categories; its compatibility with the coderived tensor product requires verification.

Remark A.12.16 (Obstruction analysis for the coderived E_3). The two obstructions of Remark A.12.15 can be analysed in more detail, reducing Conjecture A.12.14 to a purely categorical question about factorisation algebras valued in a coderived ∞ -category. The content-level (i.e., chiral-algebraic) input is already available; only the categorical receptacle is missing.

Step 1: DG enhancement and stability. For a conilpotent CDG-coalgebra (C, d, h) with finite-dimensional graded pieces, Positselski [350, Theorem 5.3, Corollary 4.4] identifies the coderived category with the homotopy category of injective CDG-comodules: $D^{\text{co}}(C\text{-comod}) \simeq K_{\text{inj}}(C\text{-comod})$. The category of injective CDG-comodules is a pretriangulated DG-category, providing a DG enhancement of D^{co} . Via the Lurie–Cohn nerve construction, this DG enhancement presents D^{co} as a *stable* ∞ -category, which is the categorical input required by both Lurie’s locally-constant recognition theorem ([303], Theorem 5.4.5.9) and Dunn additivity ([303], Theorem 5.1.2.2). For the chiral bar complex $\bar{B}^{(g)}(\mathcal{A})$ of a chirally Koszul algebra, conilpotence and finite-dimensionality of graded pieces are guaranteed by the PBW filtration (Proposition K.7.1(b)), so this enhancement is unconditionally available.

Step 2: Obstruction absorption via coacyclicity. The chain-level obstruction to local constancy of the factorisation algebra $\mathcal{F}_{\mathcal{A}}$ on the holomorphic direction involves the infinite coherence tower $[m, G] = \partial_z$ of Remark A.12.9: the obstruction at degree $N+1$ to extending the Sugawara null-homotopy $G = (G_1, \dots, G_N)$ lands in the brace deformation complex. For class M, this obstruction does not vanish on the nose. The same harmonic-factorisation mechanism of Theorem R.3.1(iv) applies: the only available harmonic insertions at each degree pass through the curvature direction $m_0 = \kappa(\mathcal{A}) \cdot \omega_g$, so the obstruction cocycle at degree $N+1$ is proportional to $m_0^{\lfloor (N+1)/2 \rfloor}$. In the coderived category D^{co} , every m_0 -power-torsion object is coacyclic (Positselski [350, Proposition 3.5]; the same bounded-below filtered criterion used in the proof of Theorem R.3.1). Hence every degree obstruction is absorbed, and the full coherence tower collapses in D^{co} .

This step is a direct consequence of proved results and requires no new input beyond the identification of the degree- N obstruction with an m_0 -power, which follows from the proof of Proposition R.3.1.

Step 3: The categorical gap. Steps 1 and 2 provide the raw ingredients: a stable ∞ -category D^{co} in which the holomorphic-translation obstruction vanishes. To complete the proof of Conjecture A.12.14, two categorical constructions are needed:

- (a) A theory of *factorisation algebras valued in D^{co}* . Costello–Gwilliam [92] and Lurie [303] develop factorisation algebras valued in chain complexes (equivalently, in a presentable stable ∞ -category). The DG-enhanced coderived category is stable but its presentability status depends on the coalgebra: for the conilpotent case with finite-dimensional graded pieces, $\text{Ind}(D^{\text{co}}_c)$ is presentable (where D^{co}_c is the full subcategory of compact objects). The factorisation-algebra formalism in this Ind-completion has not been developed, but no obstruction of principle is visible.
- (b) *Dunn additivity for the coderived tensor product.* The cotensor product $\square_C$ of Positselski provides a monoidal structure on D^{co} , and its compatibility with the E_n -operad actions required by Dunn’s theorem ([303], Theorem 5.1.2.2) must be verified. This is a standard but non-trivial check: one must show that the cotensor product preserves coacyclic objects in each variable and that the resulting monoidal ∞ -category satisfies the conditions of [303, Remark 5.1.2.4].

Neither obstruction involves new chiral-algebraic content: both are questions about the categorical framework. In particular, if a presentable symmetric monoidal stable ∞ -category C with a functor $D^{\text{co}} \rightarrow C$ preserving the relevant structure is constructed, then the obstruction absorption of Step 2 produces the coderived E_3 in C .

Summary. Conjecture A.12.14 decomposes into (i) a proved content-level input (obstruction absorption, Step 2, following from Theorem R.3.1 and Proposition R.3.1), (ii) a proved structural input (DG enhancement providing stability, Step 1), and (iii) an unproved categorical input (factorisation algebras and Dunn additivity in D^{co} , Step 3). The claim remains conjectural because of (iii), but the gap is categorical infrastructure, not chiral-algebraic substance. For class M, no alternative path to a chain-level E_3 is available:

the ordinary chain-level E_3 fails (Remark A.12.9, step (iv)), the cohomological E_3 requires 3d gravity BRST (Conjecture A.12.7), and the coderived E_3 requires only the categorical completion of (iii).

PROPOSITION A.12.17 (E_3^{top} via Dunn additivity, bypassing the Higher Deligne Conjecture). Let $\mathfrak{g}$ be a finite-dimensional simple Lie algebra and $\mathcal{A} = V_k(\mathfrak{g})$ the universal affine vertex algebra at non-critical level $k \neq -h^\vee$. The BRST cohomology of the derived chiral centre $H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(\mathcal{A}))$ carries an E_3^{top} -algebra structure by a route that does not invoke the Higher Deligne Conjecture.

The three inputs are:

- (i) (Costello–Gwilliam factorisation algebra.) The 3d holomorphic–topological Chern–Simons theory on $\mathbb{R}_t \times \mathbb{C}_z$ produces a factorisation algebra $\mathcal{F}_k^{\text{CS}}$ on $\mathbb{R} \times \mathbb{C}$ whose algebraic structure decomposes as E_1^{top} along the $\mathbb{R}$ -direction and E_2^{hol} along the $\mathbb{C}$ -direction (Costello–Gwilliam [92]). On the chiral centre, the E_2^{hol} factor encodes the chiral Gerstenhaber bracket from the $SC^{\text{ch},\text{top}}$ structure (Theorem A.10.7).
- (ii) (Topologisation of the holomorphic factor.) By Theorem A.12.2, the Sugawara element $T_{\text{Sug}} = \frac{1}{2(k+h^\vee)} \sum_a :J^a J_a:$ makes holomorphic translations Q -exact. On BRST cohomology the factorisation algebra on $\mathbb{C}$ becomes locally constant, so the E_2^{hol} upgrades to E_2^{top} by Lurie’s locally-constant recognition ([303], Theorem 5.4.5.9).
- (iii) (Transverse E_1^{top} .) The E_1^{top} from the $\mathbb{R}$ -direction is topological from the outset: no conformal vector is needed for this factor, since $\mathbb{R}$ carries no complex structure. The topologisation of the $\mathbb{C}$ -direction does not disturb this transverse structure.

Dunn additivity (Lurie [303], Theorem 5.1.2.2) gives an equivalence $E_2^{\text{top}} \otimes E_1^{\text{top}} \simeq E_3^{\text{top}}$. Combining the three inputs:

$$H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g}))) \text{ carries } E_2^{\text{top}} \otimes E_1^{\text{top}} = E_3^{\text{top}}.$$

Proof. The factorisation algebra $\mathcal{F}_k^{\text{CS}}$ of holomorphic Chern–Simons theory on $\mathbb{R}_t \times \mathbb{C}_z$ at level k is constructed in [92] and [93]. The product decomposition $\mathbb{R} \times \mathbb{C}$ equips $\mathcal{F}_k^{\text{CS}}$ with the structure of a factorisation algebra on $\mathbb{R}$ valued in factorisation algebras on $\mathbb{C}$: the $\mathbb{R}$ -direction carries E_1^{top} (a topological factorisation algebra on a 1-manifold) and the $\mathbb{C}$ -direction carries E_2^{hol} (a holomorphic factorisation algebra on a 2-manifold). The bulk observables of the 3d theory on the $\mathbb{C}$ -slice reproduce the derived chiral centre $Z_{\text{ch}}^{\text{der}}(\mathcal{A})$ by the holomorphic descent identification of [93], Chapter 5.

The Sugawara element T_{Sug} at non-critical level provides the inner conformal vector (Definition A.12.1), which is Q -exact in the bulk: $T_{\text{Sug}} = [Q, G]$ in BRST cohomology, where $G = \frac{1}{2(k+h^\vee)} \sum_a :J^a \bar{c}_a:$ is the antighost contraction of Construction A.12.11. Since $\partial_z \mathcal{O} = [T_{\text{Sug}}, \mathcal{O}] = [Q, [G, \mathcal{O}]]$ for any bulk observable $\mathcal{O}$, holomorphic translations act trivially on $H_Q^\bullet$. The factorisation algebra on $\mathbb{C}$ therefore becomes locally constant on BRST cohomology. By Lurie’s recognition theorem ([303], Theorem 5.4.5.9), a locally constant factorisation algebra on $\mathbb{C} \cong \mathbb{R}^2$ is an E_2^{top} -algebra.

The E_1^{top} from the $\mathbb{R}$ -direction was topological throughout: the $\mathbb{R}$ -direction is the topological direction of the HT theory, and no step in the topologisation of the $\mathbb{C}$ -direction alters the $\mathbb{R}$ -factor.

Dunn additivity ([303], Theorem 5.1.2.2) now applies. The two structures act on the same object $H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(\mathcal{A}))$ and come from orthogonal geometric directions ($\mathbb{R}$ and $\mathbb{C} \cong \mathbb{R}^2$), so the hypotheses of the Dunn equivalence are satisfied. The result is an E_3^{top} -algebra structure on $H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g})))$ as claimed. $\square$

Remark A.12.18 (Comparison of the two E_3 constructions). Two independent routes produce E_3 -structures on the derived chiral centre of $V_k(\mathfrak{g})$ at non-critical level:

- (a) (HDC route, Theorem A.12.19(i).) The curve geometry provides an E_2 structure on the bar coalgebra $\overline{B}^\Sigma(V_k(\mathfrak{g}))$. The Higher Deligne Conjecture (Lurie [303], Francis [168]) promotes Hochschild cochains of an E_2 -algebra to an E_3 -algebra: $E_2 + 1 = E_3$. This route is purely algebraic; it does not reference the 3d bulk theory and works for any E_∞ -chiral algebra whose symmetric bar coalgebra carries an E_2 structure. The resulting E_3 is algebraic and need not be topological without additional data.
- (b) (Dunn route, Proposition A.12.17.) The Costello–Gwilliam factorisation algebra on $\mathbb{R} \times \mathbb{C}$ provides $E_1^{\text{top}} \times E_2^{\text{hol}}$; topologisation converts the E_2^{hol} to E_2^{top} ; Dunn additivity gives E_3^{top} . This route uses the 3d bulk theory and Sugawara explicitly. The output is topological by construction.

For affine Kac–Moody at non-critical level, both routes apply. The HDC route gives an algebraic E_3 that the Sugawara element can subsequently topologize (Theorem A.12.19(iv)); the Dunn route produces E_3^{top} directly without the intermediate algebraic E_3 or the Hochschild cochain machinery. The two E_3^{top} -structures on $H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g})))$ agree: both are determined by the unique E_3^{top} -deformation of $C^*(\mathfrak{g})$ classified by $(k + h^\vee)H^3(\mathfrak{g})[[k + h^\vee]]$ (Theorem A.12.20).

The Dunn route has two advantages: it avoids the Higher Deligne Conjecture (a deep result in higher algebra whose chain-level content is controlled by formality), and it makes the physical origin of E_3 manifest as Dunn additivity for the product $\mathbb{R} \times \mathbb{C} \cong \mathbb{R}^3$. The HDC route has the advantage of working for any E_∞ -chiral algebra (no 3d bulk theory required), and it gives E_3 without the Sugawara hypothesis.

On the original complex, both routes remain cohomological: the Dunn route uses local constancy only after passing to BRST cohomology, and the HDC route uses formality to compare chain-level operations with their cohomological shadow. For affine Kac–Moody, Theorem A.12.2 adds the stronger statement that the cohomology complex itself is an unconditional chain-level E_3^{top} model on a quasi-isomorphic complex. What remains open is the lift to the original cochain complex, governed by the A_∞ -coherence equation $[m, G] = \partial_z$ of Remark A.12.9. For class M algebras, even the cohomological route still depends on the conjectural bulk BRST construction (Conjecture A.12.7), and the coderived alternative remains Conjecture A.12.14.

THEOREM A.12.19 (*The E_3 -algebra and Chern–Simons*). Let $\mathfrak{g}$ be a simple finite-dimensional Lie algebra and $V_k(\mathfrak{g})$ the affine Kac–Moody vertex algebra at level k .

- (i) (The E_3 structure.) The curve geometry provides the E_2 structure on $\overline{B}^\Sigma(V_k(\mathfrak{g}))$. By the Higher Deligne Conjecture (Lurie [303], Francis [168]), the derived chiral centre $Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g})) = \text{HH}^*(\overline{B}^\Sigma(V_k(\mathfrak{g})), \overline{B}^\Sigma(V_k(\mathfrak{g})))$ carries a natural E_3 -algebra structure ($E_2 + 1 = E_3$).
- (ii) (Deformation classification.) The space of E_3 -deformations is non-canonically isomorphic to $(k + h^\vee)H^3(\mathfrak{g})[[k + h^\vee]]$. For simple $\mathfrak{g}$, $H^3(\mathfrak{g})$ is one-dimensional.
- (iii) (Comparison with CFG.) The same space classifies perturbative CS quantisations, filtered E_3 -algebras deforming $C^*(\mathfrak{g})$, braided monoidal deformations of $\text{Rep}_{\text{fin}}(\mathfrak{g})$, and quasi-triangular quasi-Hopf deformations of $U(\mathfrak{g})$ (Costello–Francis–Gwilliam).
- (iv) (Topological enhancement.) The Sugawara Virasoro element at non-critical level upgrades the holomorphic E_2 to topological E_2 ; Dunn additivity gives E_3^{top} (Theorem A.12.2). At $k = -h^\vee$, the enhancement fails.

THEOREM A.12.20 (*Costello–Francis–Gwilliam [112]*). Let $\mathfrak{g}$ be a simple finite-dimensional Lie algebra. BV quantisation of Chern–Simons theory on $\mathbb{R}^3$ with gauge algebra $\mathfrak{g}$ and coupling λ yields a filtered E_3 -algebra $\mathcal{A}^\lambda$ on $C^*(\mathfrak{g}) = \text{Sym}(\mathfrak{g}^\vee[-1])$.

- (i) Classical observables: $C^*(\mathfrak{g})$, commutative.

- (ii) Quantum observables: $\mathcal{A}^\lambda$, filtered E_3 -algebra with deformation space $(k + h^\vee)H^3(\mathfrak{g})[[k + h^\vee]]$.
- (iii) $\text{Mod}_{\mathcal{A}^\lambda}$ is braided monoidal; filtered Koszul duality gives $\text{Perf}_{C^*(\mathfrak{g})} \simeq \text{Rep}_{\text{fin}}(\mathfrak{g})^{\text{dg}}$, recovering the Drinfeld–Jimbo quantum group.
- (iv) (Theorem 1.4 of [112].) Canonical bijection between perturbative CS quantisations, filtered E_3 -deformations, braided monoidal deformations, and quasi-triangular quasi-Hopf algebras.

LEMMA A.12.21 (*Formality reduction for E_n -deformations of commutative algebras*). Let $n \geq 2$ and let V be a commutative algebra in chain complexes (equivalently an E_∞ -algebra). Write $P_n = H_*(E_n)$ for the n -Poisson operad (commutative product + degree- $(1-n)$ Lie bracket satisfying Leibniz). Suppose E_n is formal over $\mathbb{R}$, i.e., there exists a quasi-isomorphism of operads $E_n \xrightarrow{\sim} P_n$ in chain complexes. Then the space of E_n -algebra structures on V deforming the given commutative structure, modulo E_n -quasi-isomorphisms, is equivalent to the space of P_n -algebra structures on $H^*(V)$ deforming the commutative structure:

$$\pi_0(E_n\text{-Alg}^{\text{def}}(V)) \simeq \pi_0(P_n\text{-Alg}^{\text{def}}(H^*(V))).$$

In particular, for $V = \text{Sym}(W)$ free commutative, the P_n deformations are classified by degree- $(1-n)$ Lie brackets on W satisfying the Leibniz rule with respect to the symmetric product (P_n biderivations).

Proof. The argument proceeds in three steps.

Step 1: operadic transfer. A quasi-isomorphism of dg operads $\phi: \mathcal{P} \xrightarrow{\sim} \mathcal{Q}$ induces a Quillen equivalence of model categories $\phi_!: \mathcal{P}\text{-Alg} \rightleftarrows \mathcal{Q}\text{-Alg} : \phi^*$ (Fresse [460], Vol. II, Theorem 16.1.1; Loday–Vallette [299], Theorem 11.4.7 for the Koszul case). At the ∞ -categorical level, the induced functor on ∞ -categories of algebras is an equivalence (Lurie [303], Theorem 5.1.4.7, applied to the symmetric monoidal ∞ -category of chain complexes).

Applying this to the formality quasi-isomorphism $\phi: E_n \xrightarrow{\sim} P_n$ (which exists for $n \geq 2$ by Fresse–Willwacher [459]), we obtain an equivalence between the ∞ -categories of E_n -algebras and P_n -algebras in chain complexes.

Step 2: deformation equivalence. Fix a commutative algebra V , viewed as a P_n -algebra with zero Lie bracket. Under the equivalence of Step 1, V qua P_n -algebra corresponds to $\phi^*(V)$ qua E_n -algebra, which is V with its commutative (hence E_n) structure. The equivalence restricts to the formal neighbourhoods of these base points: filtered deformations of V as an E_n -algebra correspond bijectively to filtered deformations of V as a P_n -algebra (on the level of equivalence classes).

Step 3: biderivation reduction. For $V = \text{Sym}(W)$ free commutative, a P_n -algebra structure consists of the commutative product (which is fixed) and a degree- $(1-n)$ Lie bracket $\{-, -\}: V \otimes V \rightarrow V$ satisfying the Leibniz rule: $\{a, bc\} = \{a, b\}c + (-1)^{|a||b|} b\{a, c\}$. Such a bracket is a biderivation, uniquely determined by its restriction to generators $W \otimes W \rightarrow V$. By the universal property of $\text{Sym}(W)$, the Jacobi identity on $\text{Sym}(W)$ is equivalent to the Jacobi identity on generators (extend by Leibniz), so P_n -deformations are classified by degree- $(1-n)$ Lie brackets on W extended as biderivations. $\square$

Two constructions produce E_3 -deformation families of $C^*(\mathfrak{g}) = \text{Sym}(\mathfrak{g}^\vee[-1])$: the derived chiral centre $Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g}))$ (Theorem A.12.19) and the Costello–Francis–Gwilliam algebra $\mathcal{A}^\lambda$ from perturbative Chern–Simons quantisation (Theorem A.12.20). Both are parametrised by $(k + h^\vee)H^3(\mathfrak{g})[[k + h^\vee]]$. For simple $\mathfrak{g}$, $\dim H^3(\mathfrak{g}) = 1$, so the deformation base is one-dimensional at each order: the two families must coincide.

THEOREM A.12.22 (*Identification of E_3 -deformation families*). Let $\mathfrak{g}$ be a simple finite-dimensional Lie algebra and $V_k(\mathfrak{g})$ the affine Kac–Moody vertex algebra at level k . Writing $\lambda = k + h^\vee$ for the departure

from critical level, the derived chiral centre $Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g}))$ of Theorem A.12.19(i) and the CFG E_3 -algebra $\mathcal{A}^\lambda$ of Theorem A.12.20 are isomorphic as formal deformation families of E_3 -algebras:

$$\{Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g}))\}_{k+h^\vee \in \lambda C[[\lambda]]} \simeq \{\mathcal{A}^\lambda\}_{\lambda \in \lambda H^3(\mathfrak{g})[[\lambda]]} \quad (\text{A.22})$$

over the base $\lambda H^3(\mathfrak{g})[[\lambda]]$ (with $\lambda = k + h^\vee$).

- (i) (Matching deformation spaces.) Both families are parametrised by $(k + h^\vee)H^3(\mathfrak{g})[[k + h^\vee]]$: for the derived chiral centre, the deformation parameter is the departure from critical level; for the CFG algebra, it is the Chern–Simons coupling.
- (ii) (Base point mismatch.) At critical level $k = -h^\vee$, the derived chiral centre $Z_{\text{ch}}^{\text{der}}(V_{-h^\vee}(\mathfrak{g}))$ is related to the Feigin–Frenkel centre $\text{Fun}(\text{Op}_{\mathfrak{g}^\vee}(D))$ (opers on the formal disk), not directly to $C^*(\mathfrak{g})$. The isomorphism is perturbative: it holds in the formal neighbourhood of critical level, order by order in $\lambda = k + h^\vee$.
- (iii) (Order-by-order uniqueness.) For simple $\mathfrak{g}$, $H^3(\mathfrak{g}) \cong C$ is one-dimensional, so the deformation base is one-dimensional at each order in λ . The isomorphism (A.22) is forced by the matching of associated graded algebras (both $C^*(\mathfrak{g})$), matching P_3 brackets on the formal disk (Theorem A.12.37(ii)), and the one-dimensionality of the obstruction space at each order.
- (iv) (Sugawara constraint.) The topological enhancement (Theorem A.12.19(iv)) holds at generic k but fails at $k = -h^\vee$, where the Sugawara element is undefined. The perturbative identification holds order by order in $(k + h^\vee)$, since the Sugawara element exists at any nonzero departure from critical level.

Proof. We construct an isomorphism of E_3 -algebras order by order in $\lambda = k + h^\vee$. The key input is E_3 formality, which reduces the chain-level matching to a cohomological computation in P_3 deformations.

Step 1: formality reduction. Both $Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g}))$ and $\mathcal{A}^\lambda$ are filtered E_3 -algebras deforming $C^*(\mathfrak{g}) = \text{Sym}(\mathfrak{g}^\vee[-1])$ over the base $\lambda H^3(\mathfrak{g})[[\lambda]]$, with $\lambda = k + h^\vee$ (Theorem A.12.19(ii) and Theorem A.12.20(iv) respectively). Both filtrations are complete and exhaustive with associated graded $C^*(\mathfrak{g})$. By E_n formality for $n = 3$ (Proposition A.6.10; Fresse–Willwacher [459]), E_3 -deformations of the commutative algebra $C^*(\mathfrak{g})$ are classified by P_3 -deformations. The precise citation chain is: Kontsevich [275] first observed that operadic formality implies deformation classification at $n = 2$; Tamarkin [503] gave the first complete proof of E_2 formality; Fresse–Willwacher [459] proved intrinsic formality of E_n for all $n \geq 2$ over $\mathbb{R}$; Lemma A.12.21 (via Fresse [460], Vol. II, Theorem 16.1.1 and Lurie [303], Theorem 5.1.4.7) deduces that the operad-level formality quasi-isomorphism $E_n \xrightarrow{\sim} P_n$ induces an equivalence of deformation theories for algebras. Applying Lemma A.12.21 at $n = 3$ with $V = C^*(\mathfrak{g}) = \text{Sym}(\mathfrak{g}^\vee[-1])$: the formality quasi-isomorphism $C_*(E_3; \mathbb{R}) \xrightarrow{\sim} H_*(E_3; \mathbb{R})$ identifies chain-level E_3 structures on $C^*(\mathfrak{g})$, up to quasi-isomorphism, with P_3 -algebra structures on $H^*(C^*(\mathfrak{g})) = C^*(\mathfrak{g})$. Since $C^*(\mathfrak{g}) = \text{Sym}(\mathfrak{g}^\vee[-1])$ is free commutative, the biderivation reduction (Lemma A.12.21, Step 3) shows that a P_3 bracket is determined by a degree -2 Lie bracket on generators $\mathfrak{g}^*[-1] \subset C^*(\mathfrak{g})$. The space of $\mathfrak{g}$ -equivariant such brackets is $\text{Hom}_{\mathfrak{g}}(\Lambda^2 \mathfrak{g}^*, C)[-2] \cong H^3(\mathfrak{g})[-2]$, one-dimensional for simple $\mathfrak{g}$ (Costello–Francis–Gwilliam [112], Theorem 1.4 establish the matching of deformation spaces; the one-dimensionality itself is Whitehead’s lemma: $H^3(\mathfrak{g}) = H_{\text{CE}}^3(\mathfrak{g}; C) \cong C$ for simple $\mathfrak{g}$).

Step 2: induction on order. We construct the isomorphism $\varphi: Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g})) \xrightarrow{\sim} \mathcal{A}^\lambda$ as a compatible family of isomorphisms φ_p modulo λ^{p+1} , by induction on p .

Base case ($p = 0$): both associated graded algebras are $C^*(\mathfrak{g})$ (Theorem A.12.37(i)), so $\varphi_0 = \text{id}_{C^*(\mathfrak{g})}$.

Inductive step: suppose φ_p is an E_3 -isomorphism modulo λ^{p+1} . The obstruction to extending φ_p to an isomorphism modulo λ^{p+2} lies in $H^3(\mathfrak{g})$ (Step 1). For simple $\mathfrak{g}$, $H^3(\mathfrak{g}) = C$ is generated by the Cartan

three-form $\omega_3(X, Y, Z) = (X, [Y, Z])$, so two E_3 -deformations of $C^*(\mathfrak{g})$ agreeing modulo λ^{p+1} differ at order $p + 1$ by a scalar multiple of ω_3 .

It remains to show that both constructions select the *same* scalar at each order. By E_3 formality (Step 1), this scalar is determined by the P_3 bracket on generators: the degree -2 bracket $\{-, -\}: \mathfrak{g}^*[-1] \otimes \mathfrak{g}^*[-1] \rightarrow C[-2]$. On the formal disk $D = \text{Spec } C[[z]]$, the restriction functor $\Gamma(D, -)$ is symmetric monoidal and preserves E_3 -structures (Theorem A.12.37, proof, Step 1). By Theorem A.12.37(ii), the chiral P_3 bracket restricted to D recovers the CFG P_3 bracket at every order: both give $\{\phi_a, \phi_b\} = h_{\text{KZ}} \cdot (\phi_a, \phi_b)$ on generators (with $h_{\text{KZ}} = 1/(k + h^\vee)$, the KZ coupling constant). Since the P_3 bracket on generators determines the full E_3 deformation class (biderivation property, Lemma A.12.34, Step 2), and the space of $\mathfrak{g}$ -equivariant corrections at each order is one-dimensional (spanned by the Killing-form pairing $(a, b) \mapsto k(a, b)$), the two constructions agree at order $p + 1$.

Step 3: passage to the limit. The compatible family $\{\varphi_p\}_{p \geq 0}$ determines an isomorphism $\varphi = \varprojlim_p \varphi_p$ of filtered E_3 -algebras over $\lambda H^3(\mathfrak{g})[[\lambda]]$, completing the proof of (A.22). Part (iv) is immediate: the topological enhancement (Theorem A.12.19(iv)) requires the Sugawara element, which exists for $\lambda \neq 0$ and is compatible with φ order by order (the Sugawara element at order p depends only on the data modulo λ^{p+1} , where the two families already agree).

Verification at $\mathfrak{sl}_2$. Proposition A.12.26 computes the P_3 bracket on $Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{sl}_2))$ explicitly: $\{X, Y\} = h_{\text{KZ}} \cdot (X, Y) = (X, Y)/(k + 2)$ for $X, Y \in \mathfrak{sl}_2 = \text{HH}^1$ (equation (A.24)). This matches the CFG P_3 bracket (Theorem A.12.37(ii)) and confirms that the obstruction-theoretic argument of Steps 1–3 produces the correct isomorphism, with the KZ coupling $h_{\text{KZ}} = 1/(k + 2)$ as the deformation parameter. $\square$

Remark A.12.23 (Non-simple Lie algebras). For simple $\mathfrak{g}$, the identification theorem exploits $\dim H^3(\mathfrak{g}) = 1$ to force uniqueness at each order. For reductive $\mathfrak{g}$ with simple summands $\mathfrak{g} = \mathfrak{g}_1 \oplus \cdots \oplus \mathfrak{g}_r \oplus \mathfrak{z}$ (where $\mathfrak{z}$ is the centre), the E_3 deformation theory is controlled by the space of $\mathfrak{g}$ -invariant symmetric bilinear forms $\text{Sym}^2(\mathfrak{g}^*)^{\mathfrak{g}}$, which classifies P_3 biderivations on $C^*(\mathfrak{g}) = \text{Sym}(\mathfrak{g}^\vee[-1])$ via the formality reduction (Lemma A.12.21). For semisimple $\mathfrak{g}$, the Cartan map $B \mapsto \omega_B(X, Y, Z) = B(X, [Y, Z])$ gives an isomorphism $\text{Sym}^2(\mathfrak{g}^*)^{\mathfrak{g}} \xrightarrow{\sim} H^3(\mathfrak{g})$, so $\dim \text{Sym}^2(\mathfrak{g}^*)^{\mathfrak{g}} = r$ (one Killing form per simple summand). When $\mathfrak{z} \neq 0$, the Cartan map has a kernel: any bilinear form pairing central elements with central elements maps to zero under $B \mapsto B(-, [-, -])$, since $[\mathfrak{z}, \mathfrak{z}] = 0$. The dimension of the deformation space is therefore $\dim \text{Sym}^2(\mathfrak{g}^*)^{\mathfrak{g}} = r + \binom{\dim \mathfrak{z} + 1}{2}$, which exceeds $\dim H^3(\mathfrak{g}) = r + \binom{\dim \mathfrak{z}}{3}$ when $\mathfrak{z} \neq 0$. The uniqueness argument requires matching all $\dim \text{Sym}^2(\mathfrak{g}^*)^{\mathfrak{g}}$ independent scalars at each order in λ , not merely $\dim H^3(\mathfrak{g})$ of them.

Remark A.12.24 (Obstruction analysis for $\mathfrak{gl}_N$). We carry out the uniqueness argument of Theorem A.12.22 for $\mathfrak{g} = \mathfrak{gl}_N = \mathfrak{sl}_N \oplus \mathfrak{gl}_1$, where the deformation space is two-dimensional at each order.

Step 1: invariant bilinear forms. The space of $\mathfrak{gl}_N$ -invariant symmetric bilinear forms has basis

$$B_{\text{tr}}(X, Y) = (XY), \quad B_{\text{ab}}(X, Y) = (X)(Y).$$

Both are $\mathfrak{gl}_N$ -invariant (conjugation-invariant). Under the Cartan map $B \mapsto \omega_B(X, Y, Z) = B(X, [Y, Z])$: the form B_{tr} maps to the Cartan three-form $\omega_3(X, Y, Z) = (X[Y, Z])$, which generates $H^3(\mathfrak{sl}_N) \cong \mathbb{C}$; the form B_{ab} maps to $(X)([Y, Z]) = 0$, since the trace vanishes on commutators. Hence $\dim H^3(\mathfrak{gl}_N) = 1$ while $\dim \text{Sym}^2(\mathfrak{gl}_N^*)^{\mathfrak{gl}_N} = 2$. The abelian form B_{ab} is invisible to H^3 but visible to the P_3 deformation theory.

Step 2: two-parameter P_3 bracket. The vertex algebra $V_{k_1, k_2}(\mathfrak{gl}_N)$ carries two independent levels: k_1 for the $\mathfrak{sl}_N$ summand and k_2 for $\mathfrak{gl}_1$. The PVA λ -bracket on generators J^a of $\mathfrak{gl}_N$ is

$$\{J^a_\lambda J^b\} = f^{ab}_c J^c + (k_1 B_{\text{tr}}(a, b) + k_2 B_{\text{ab}}(a, b)) \lambda,$$

where f^{ab}_c are the $\mathfrak{gl}_N$ structure constants. On the chiral Chevalley–Eilenberg complex, the induced P_3 bracket (Construction A.12.30) is

$$\{\phi_a, \phi_b\}^{\text{ch}} = f^{ab}_c \phi_c + (k_1 B_{\text{tr}}(a, b) + k_2 B_{\text{ab}}(a, b)) \cdot \partial. \quad (\text{A.23})$$

At each order in the two-parameter deformation $(\lambda_1, \lambda_2) = (k_1 + N, k_2)$ (the departure from critical level for $\mathfrak{sl}_N$ is $k_1 + h^\vee = k_1 + N$; the Heisenberg factor has $h^\vee = 0$), the correction space is $\text{Sym}^2(\mathfrak{gl}_N^*)^{\mathfrak{gl}_N} \cong C^2$, spanned by B_{tr} and B_{ab} .

Step 3: formal disk determination of both parameters. Theorem A.12.37(ii) matches the chiral P_3 bracket restricted to the formal disk with the CFG P_3 bracket. On the formal disk, the bracket (A.23) yields

$$\{\phi_a, \phi_b\}_{\text{CFG}} = f^{ab}_c \phi_c + (k_1 B_{\text{tr}}(a, b) + k_2 B_{\text{ab}}(a, b)) \cdot \delta_0.$$

The two bilinear forms B_{tr} and B_{ab} are *linearly independent* as elements of $\text{Sym}^2(\mathfrak{gl}_N^*)$: choosing $a, b \in \mathfrak{sl}_N$ with $(a) = (b) = 0$ and $(ab) \neq 0$ extracts k_1 ; choosing $a = b = I_N/N$ (a scalar matrix) extracts k_2 . The formal disk comparison therefore determines both k_1 and k_2 independently.

Step 4: the identification extends. The inductive argument of Theorem A.12.22, Steps 1–3, goes through for $\mathfrak{gl}_N$: at each order in (λ_1, λ_2) , the two-dimensional correction space $C \cdot B_{\text{tr}} \oplus C \cdot B_{\text{ab}}$ is fully determined by the P_3 bracket on the formal disk (Step 3 above). Both the derived chiral centre $Z_{\text{ch}}^{\text{der}}(V_{k_1, k_2}(\mathfrak{gl}_N))$ and the CFG algebra $\mathcal{A}^{\lambda_1, \lambda_2}$ (perturbative Chern–Simons with gauge algebra $\mathfrak{gl}_N$ and two coupling constants) have matching associated graded $C^*(\mathfrak{gl}_N) = \text{Sym}(\mathfrak{gl}_N^\vee[-1])$ and matching P_3 brackets on the formal disk. Since the correction at each order is a *linear* function of the invariant bilinear form, and the formal disk data determines both components, the isomorphism

$$\{Z_{\text{ch}}^{\text{der}}(V_{k_1, k_2}(\mathfrak{gl}_N))\} \simeq \{\mathcal{A}^{\lambda_1, \lambda_2}\}$$

of filtered E_3 -algebras holds over the two-dimensional base $(\lambda_1, \lambda_2) \in C^2$, order by order in the joint (λ_1, λ_2) -adic filtration.

The Sugawara constraint (Theorem A.12.22(iv)) requires separate analysis: the Sugawara element for $\mathfrak{gl}_N$ at levels (k_1, k_2) involves only the $\mathfrak{sl}_N$ factor at non-critical level $k_1 \neq -N$; the $\mathfrak{gl}_1$ factor contributes independently to the stress tensor. The topological enhancement holds at generic (k_1, k_2) with $k_1 \neq -N$.

A.12.1 EXPLICIT E_3 OPERATIONS FOR $V_k(\mathfrak{sl}_2)$

The abstract E_3 structure of Theorem A.12.19 acquires concrete content for $\mathfrak{g} = \mathfrak{sl}_2$: the five-dimensional derived chiral centre $C \oplus \mathfrak{sl}_2[-1] \oplus C[-2]$ carries an explicit cup product, Gerstenhaber bracket, P_3 bracket, and BV operator, all computable from the OPE.

The underlying graded vector space. By Theorem A.12.19 and Proposition A.11.24(ii), the derived chiral centre of $V_k(\mathfrak{sl}_2)$ at generic level $k \neq -2$ is the graded vector space

$$Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{sl}_2)) = \underbrace{C}_{= \text{HH}^0} \oplus \underbrace{\mathfrak{sl}_2[-1]}_{= \text{HH}^1} \oplus \underbrace{C[-2]}_{= \text{HH}^2},$$

with total dimension $1 + 3 + 1 = 5$. Write $\mathbf{1}$ for the generator of $\text{HH}^0 = C$ (the vacuum), $\{e, f, h\}$ for the standard basis of $\text{HH}^1 = \mathfrak{sl}_2$ (outer derivations: infinitesimal level-preserving deformations parametrised by $\mathfrak{g}$ itself), and η for the generator of $\text{HH}^2 = C$ (the central charge deformation cocycle). The $\mathfrak{sl}_2$ -module structure is: HH^0 trivial, HH^1 adjoint, HH^2 trivial.

Conventions. The Killing form normalisation is $(e, f) = (f, e) = 1$, $(h, h) = 2$, all other pairings zero. Structure constants: $[e, f] = h$, $[h, e] = 2e$, $[h, f] = -2f$. The inverse Casimir is $\Omega = e \otimes f + f \otimes e + \frac{1}{2} h \otimes h$, and $h^\vee = 2$. The KZ coupling constant is $h_{\text{KZ}} = 1/(k + h^\vee) = 1/(k + 2)$.

Remark A.12.25 (Convention for $\hbar$). Throughout this paper, $\hbar$ denotes the KZ coupling constant

$$\hbar = h_{\text{KZ}} = \frac{1}{k + h^\vee},$$

the normalisation in the KZ connection $\nabla = d + \hbar \sum \Omega_{ij} dz_{ij}$. It vanishes as $k \rightarrow \infty$ (weak-coupling limit) and diverges at the critical level $k = -h^\vee$. In the $\mathfrak{sl}_2$ computations, $h^\vee = 2$, so $\hbar = 1/(k + 2)$. The *departure from critical level* is the inverse quantity $k + h^\vee = 1/\hbar$; we always write this explicitly as $k + h^\vee$ rather than introducing a separate symbol. Critical level corresponds to $k + h^\vee = 0$ (equivalently, $\hbar \rightarrow \infty$); weak coupling corresponds to $k + h^\vee \rightarrow \infty$ (equivalently, $\hbar \rightarrow 0$). For the quantum group parameter: $q = e^{2\pi i \hbar}$.

An E_3 -algebra carries three levels of operations:

- Level 0 (E_∞): a graded-commutative product $\mu: \text{HH}^p \otimes \text{HH}^q \rightarrow \text{HH}^{p+q}$.
- Level 1 (E_2 beyond E_1): the Gerstenhaber bracket $[-, -]: \text{HH}^p \otimes \text{HH}^q \rightarrow \text{HH}^{p+q-1}$ of degree -1 , derived from the fundamental class of $S^1 = C_2(\mathbb{R}^2)/\mathbb{R}^+$.
- Level 2 (E_3 beyond E_2): the P_3 bracket $\{-, -\}: \text{HH}^p \otimes \text{HH}^q \rightarrow \text{HH}^{p+q-2}$ of degree -2 , derived from the fundamental class of $S^2 = C_2(\mathbb{R}^3)/\mathbb{R}^+$.

We compute each in turn.

PROPOSITION A.12.26 (*Explicit E_3 operations on $Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{sl}_2))$*). Let $k \neq -2$. The E_3 -algebra structure on $Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{sl}_2))$ is determined by the following data.

(I) Cup product (E_∞ level).

- (a) $\mathbf{1}$ is the unit: $\mathbf{1} \cdot f = f \cdot \mathbf{1} = f$ for all f .
- (b) $\mu(X, Y) = 0$ for all $X, Y \in \text{HH}^1 = \mathfrak{sl}_2$.
- (c) $\mu(X, \eta) = 0$ for all $X \in \text{HH}^1$, and $\eta \cdot \eta = 0$.

(II) Gerstenhaber bracket (E_2 level, degree -1).

$$\begin{aligned} [\mathbf{1}, -] &= 0, & [X, Y] &= 0 \quad \text{for all } X, Y \in \text{HH}^1 = \mathfrak{sl}_2, \\ [X, \eta] &= 0 \quad \text{for all } X \in \text{HH}^1, & [\eta, \eta] &= 0. \end{aligned}$$

(III) The P_3 bracket (E_3 level, degree -2).

$$\begin{aligned} \{X, Y\} &= h_{\text{KZ}} \cdot (X, Y) = \frac{1}{k + h^\vee} (X, Y) \quad \text{for } X, Y \in \text{HH}^1, \\ \{X, \eta\} &= 0 \quad \text{for } X \in \text{HH}^1, \\ \{\mathbf{1}, -\} &= 0, \\ \{\eta, \eta\} &= 0, \end{aligned} \tag{A.24}$$

where (X, Y) denotes the normalised Killing form and $h_{\text{KZ}} = 1/(k + h^\vee) = 1/(k + 2)$ is the KZ coupling constant (Remark A.12.25).

Proof. We establish each level by $\mathfrak{sl}_2$ -equivariance, degree counting, and the BV relation.

Cup product. The cup product $\mu: \mathrm{HH}^p \otimes \mathrm{HH}^q \rightarrow \mathrm{HH}^{p+q}$ is graded-commutative: $\mu(a, b) = (-1)^{pq} \mu(b, a)$. For $X, Y \in \mathrm{HH}^1$, this gives $\mu(X, Y) = -\mu(Y, X)$: the restriction to $\mathrm{HH}^1 \otimes \mathrm{HH}^1 \rightarrow \mathrm{HH}^2 = C$ is an $\mathfrak{sl}_2$ -invariant antisymmetric bilinear form on the adjoint representation valued in the trivial representation. Since $\Lambda^2(\mathfrak{sl}_2)^{\mathfrak{sl}_2} \cong \mathrm{Hom}_{\mathfrak{sl}_2}(\Lambda^2(\mathrm{ad}), C) = 0$ (the exterior square of the adjoint decomposes as $\Lambda^2(\mathrm{ad}) \cong \mathrm{ad}$, which has no trivial summand), the cup product $\mu(X, Y) = 0$ for all $X, Y \in \mathrm{HH}^1$.

The products $\mu(\mathrm{HH}^1, \mathrm{HH}^2) \subset \mathrm{HH}^3 = 0$ and $\mu(\mathrm{HH}^2, \mathrm{HH}^2) \subset \mathrm{HH}^4 = 0$ vanish for degree reasons.

BV operator. The framed E_2 structure on $\overline{B}^\Sigma(V_k(\mathfrak{sl}_2))$ (from genus-1 sewing) equips the derived centre with a BV operator $\Delta: \mathrm{HH}^n \rightarrow \mathrm{HH}^{n-1}$ satisfying $\Delta^2 = 0$ and the BV relation

$$[f, g] = \Delta(f \cdot g) - (\Delta f) \cdot g - (-1)^{|f|} f \cdot (\Delta g). \quad (\text{A.25})$$

The component $\Delta: \mathrm{HH}^1 \rightarrow \mathrm{HH}^0$ is an $\mathfrak{sl}_2$ -equivariant linear map from the adjoint representation to the trivial representation. Since the adjoint is irreducible and non-trivial, $\Delta|_{\mathrm{HH}^1} = 0$.

The component $\Delta: \mathrm{HH}^2 \rightarrow \mathrm{HH}^1$ is an $\mathfrak{sl}_2$ -equivariant linear map from the trivial to the adjoint. Again, $\Delta|_{\mathrm{HH}^2} = 0$.

All other components vanish trivially ($\Delta|_{\mathrm{HH}^0}$ lands in $\mathrm{HH}^{-1} = 0$; $\Delta|_{\mathrm{HH}^n} = 0$ for $n \geq 3$). Therefore $\Delta = 0$ on the entire derived centre.

Gerstenhaber bracket. With $\Delta = 0$ and $\mu|_{\mathrm{HH}^1 \otimes \mathrm{HH}^1} = 0$, the BV relation (A.25) gives: for $X, Y \in \mathrm{HH}^1$,

$$[X, Y] = \Delta(\mu(X, Y)) - (\Delta X) \cdot Y + X \cdot (\Delta Y) = \Delta(0) - 0 + 0 = 0.$$

For $X \in \mathrm{HH}^1, \eta \in \mathrm{HH}^2$: $[X, \eta] = \Delta(\mu(X, \eta)) - (\Delta X) \cdot \eta - (-1)^1 X \cdot (\Delta \eta) = 0 - 0 + 0 = 0$ (since $\mu(X, \eta) \in \mathrm{HH}^3 = 0, \Delta X = 0, \Delta \eta = 0$). Similarly $[\eta, \eta] \in \mathrm{HH}^3 = 0$.

The vanishing of the Gerstenhaber bracket on the derived centre is a structural consequence of the $\mathfrak{sl}_2$ -equivariance constraints: the adjoint representation provides no equivariant maps to or from the trivial representation. This is specific to the *derived centre* $\mathrm{HH}^*(\overline{B}^\Sigma, \overline{B}^\Sigma)$; the Gerstenhaber bracket on the full Hochschild cochain complex $C^*(\overline{B}^\Sigma, \overline{B}^\Sigma)$ is non-trivial (it carries the commutator of derivations at the cochain level).

P₃ bracket. The degree-(-2) bracket $\{-, -\}: \mathrm{HH}^p \otimes \mathrm{HH}^q \rightarrow \mathrm{HH}^{p+q-2}$ satisfies the graded symmetry

$$\{a, b\} = -(-1)^{(|a|-2)(|b|-2)} \{b, a\} \quad (\text{A.26})$$

of a degree-(-2) Lie bracket, together with the Leibniz rule $\{a, b \cdot c\} = \{a, b\} \cdot c + (-1)^{(|a|-2)|b|} b \cdot \{a, c\}$.

Step 1: $\{\mathbf{1}, -\} = 0$. The Leibniz rule applied to $\mathbf{1} = \mathbf{1} \cdot \mathbf{1}$ gives $\{\mathbf{1}, f\} = 2\{\mathbf{1}, f\}$ for all f ; hence $\{\mathbf{1}, f\} = 0$.

Step 2: $\{X, Y\} = h_{\mathrm{KZ}}(X, Y)$. For $X, Y \in \mathrm{HH}^1, \{X, Y\} \in \mathrm{HH}^0 = C$. The symmetry (A.26) at $|X| = |Y| = 1$ gives $\{X, Y\} = -(-1)^{(-1)(-1)} \{Y, X\} = -(-1)^1 \{Y, X\} = \{Y, X\}$: the bracket is *symmetric* on $\mathrm{HH}^1 \otimes \mathrm{HH}^1$. By $\mathfrak{sl}_2$ -equivariance, $\{X, Y\}$ is an invariant symmetric bilinear form on the adjoint representation valued in C . The space of such forms is one-dimensional, spanned by the Killing form (X, Y) . Hence $\{X, Y\} = \alpha \cdot (X, Y)$ for a scalar α depending on k .

The scalar α is determined by the r -matrix residue, independently of any comparison with the CFG construction. The P_3 bracket on the derived chiral centre $Z_{\mathrm{ch}}^{\mathrm{der}}(V_k(\mathfrak{g})) = \mathrm{HH}^*(\overline{B}^\Sigma(V_k(\mathfrak{g})), \overline{B}^\Sigma(V_k(\mathfrak{g})))$ is the E_2 -Hochschild cohomology operation derived from the fundamental class of $S^2 \subset C_2(\mathbb{R}^3)$. At

degree 2, this operation is the residue of the classical r -matrix paired with the fundamental class of $S^1 \subset C_2(C)$. In the KZ normalisation (see (??) and the conventions of §A.12.7):

$$r(z) = \frac{\Omega}{(k + h^\vee)z}, \quad \text{Res}_{z=0}[r(z)] = \frac{\Omega}{k + h^\vee}. \quad (\text{A.27})$$

The residue acts on $X \otimes Y \in \mathfrak{g} \otimes \mathfrak{g}$ by contraction with the inverse Casimir: $\Omega(X \otimes Y) = (X, Y)$ (the normalised Killing form). The P_3 bracket on $HH^1 \cong \mathfrak{g}$ is therefore

$$\{X, Y\} = \text{Res}_{z=0}[r(z)(X \otimes Y)] = \frac{(X, Y)}{k + h^\vee} = h_{\text{KZ}} \cdot (X, Y),$$

giving $\alpha = h_{\text{KZ}} = 1/(k + h^\vee)$. For $\mathfrak{sl}_2$, $h^\vee = 2$ and $\alpha = 1/(k + 2)$.

Verification: at $k \rightarrow \infty$, $h_{\text{KZ}} \rightarrow 0$ and the bracket vanishes (the weak-coupling limit is the abelian E_3). At the critical level $k = -h^\vee$, h_{KZ} diverges (the bracket degenerates, reflecting the Feigin–Frenkel singularity). Both limits are consistent with the behaviour of the KZ connection.

Step 3: $\{X, \eta\} = 0$. The bracket $\{X, \eta\} \in HH^1 = \mathfrak{sl}_2$ for $X \in HH^1$, $\eta \in HH^2$ is an $\mathfrak{sl}_2$ -equivariant map $\text{ad} \otimes C \rightarrow \text{ad}$, hence $\{X, \eta\} = \beta X$ for some scalar β . The P_3 Jacobi identity applied to $X, Y \in HH^1$ and $\eta \in HH^2$, combined with $\{X, Y\} = h_{\text{KZ}}(X, Y) \in HH^0$, gives $\{\{X, \eta\}, \eta\} = 0$ (since $\{\{X, \eta\}, \eta\} \in HH^{-1} = 0$) and $\{\eta, \{X, \eta\}\} \in HH^{-1} = 0$, while $\{X, \{\eta, \eta\}\} = \{X, 0\} = 0$. The Jacobi identity is thus satisfied for all β ; the constraint comes instead from the self-consistency of the E_3 deformation. At the cohomological level, one applies the iterated Jacobi identity to $X, Y \in HH^1$ and η :

$$\begin{aligned} \{\{X, Y\}, \eta\} &= \{X, \{Y, \eta\}\} - (-1)^{(|X|-2)(|Y|-2)} \{Y, \{X, \eta\}\} \\ &= \{X, \beta Y\} - (-1)^1 \{Y, \beta X\} \\ &= \beta h_{\text{KZ}}(X, Y) + \beta h_{\text{KZ}}(Y, X) \\ &= 2\beta h_{\text{KZ}}(X, Y). \end{aligned}$$

The left side: $\{\{X, Y\}, \eta\} = \{h_{\text{KZ}}(X, Y) \mathbf{1}, \eta\} = h_{\text{KZ}}(X, Y) \{1, \eta\} = 0$. Hence $2\beta h_{\text{KZ}}(X, Y) = 0$ for all X, Y . Since $(e, f) = 1 \neq 0$ and $h_{\text{KZ}} \neq 0$ at generic k , we conclude $\beta = 0$.

Step 4: $\{\eta, \eta\} = 0$. The bracket $\{\eta, \eta\} \in HH^2 = C$ and the symmetry (A.26) at $|\eta| = 2$ gives $\{\eta, \eta\} = -(-1)^{0 \cdot 0} \{\eta, \eta\} = -\{\eta, \eta\}$, hence $\{\eta, \eta\} = 0$. $\square$

Remark A.12.27 (The Killing form as the E_3 shadow of the Cartan 3-form). The bracket (A.24) has a transparent topological origin. The E_3 -deformation space is $(k + h^\vee) H^3(\mathfrak{sl}_2)[[k + h^\vee]] \cong (k + h^\vee) C[[k + h^\vee]]$, one-dimensional at each order in $(k + h^\vee)$ (Theorem A.12.20(iv)). The generator of $H^3(\mathfrak{sl}_2)$ is the Cartan 3-form

$$\omega_3(X, Y, Z) = (X, [Y, Z]),$$

the unique (up to scalar) $\mathfrak{sl}_2$ -invariant element of $\Lambda^3(\mathfrak{sl}_2^*)$. The degree- (-2) bracket $\{X, Y\}$ is the E_3 -operation induced by this deformation class scaled by $\hbar = 1/(k + h^\vee)$:

$$\{X, Y\} = \hbar \cdot (X, Y).$$

The mechanism is *not* literal contraction of the antisymmetric 3-form ω_3 ; the P_3 bracket is symmetric on HH^1 (by the graded symmetry (A.26) at $|X| = |Y| = 1$), while any contraction of ω_3 in two slots is antisymmetric. The connection is indirect: the one-dimensional deformation space $H^3(\mathfrak{sl}_2)$, generated by ω_3 , parametrises E_3 -deformations of $C^*(\mathfrak{g})$ (Theorem A.12.20(iv)); on cohomology, $\mathfrak{sl}_2$ -equivariance

forces the induced P_3 bracket on $HH^1 \cong \mathfrak{sl}_2$ to be proportional to the Killing form (X, Y) , the unique invariant symmetric bilinear form. The coefficient $h_{KZ} = 1/(k + h^\vee)$ is fixed by the r -matrix residue (equation (A.27)), not by comparison with CFG. The P_3 bracket on $Z_{\text{ch}}^{\text{der}}$ is the binary shadow of the ternary Cartan deformation class, with the Killing form appearing through equivariance rather than through direct contraction.

A.12.2 QUANTUM CORRECTIONS FROM THE VERTEX R -MATRIX: E_3 OPERATIONS FOR THE EK QUANTUM VOA

The classical $V_k(\mathfrak{sl}_2)$ has trivial braiding $S(z) = \text{id}$; the Etingof–Kazhdan quantum VOA V_{EK} has $S(z) = \text{id} + h_{KZ} \Omega/z + O(z^{-2})$. Does the non-trivial R -matrix change the E_3 -algebra structure on the derived chiral centre? On cohomology, no: the P_3 bracket coincides with the classical answer (Proposition A.12.26). On cochains, yes: the quantum corrections encode the braided monoidal structure of $\text{Rep}(Y_h(\mathfrak{sl}_2))$.

The underlying graded vector space. The EK quantum VOA is a flat formal deformation of $V_k(\mathfrak{sl}_2)$ over $C[[h_{KZ}]]$, with $h_{KZ} = 1/(k + 2)$. Since the chiral Hochschild cohomology is computed by a bounded complex of finite-dimensional $\mathfrak{sl}_2$ -modules, the deformation does not change the underlying graded vector space:

$$Z_{\text{ch}}^{\text{der}}(V_{\text{EK}}) = C[[h_{KZ}]] \oplus \mathfrak{sl}_2[[h_{KZ}]][-1] \oplus C[[h_{KZ}]][-2],$$

with total rank 5 over $C[[h_{KZ}]]$. The generators $\mathbf{1} \in HH^0$, $\{e, f, h\} \in HH^1$, and $\eta \in HH^2$ are defined as in Proposition A.12.26, now taken over the base ring $C[[h_{KZ}]]$.

Equivariance under the quantum R -matrix. The Yang R -matrix $R(u) = uI + \hbar P$ on $V \otimes V$ is $\mathfrak{sl}_2$ -equivariant: $[R(u), \rho(X) \otimes I + I \otimes \rho(X)] = 0$ for all $X \in \mathfrak{sl}_2$. The full vertex R -matrix $S(z)$ on $V_{\text{EK}}^{\otimes 2}$ (equation (??)) is likewise $\mathfrak{sl}_2$ -equivariant, since it is constructed from $\mathcal{R}(z)$, the spectral universal R -matrix of the Yangian $Y_h(\mathfrak{sl}_2)$, which commutes with the $\mathfrak{sl}_2$ -action by the defining property of the Drinfeld coproduct.

This equivariance is the key structural constraint: all three levels of the E_3 operations on $Z_{\text{ch}}^{\text{der}}(V_{\text{EK}})$ are $\mathfrak{sl}_2$ -equivariant maps between representations. The equivariance arguments of Proposition A.12.26 therefore apply verbatim to the quantum case.

PROPOSITION A.12.28 (E_3 operations on $Z_{\text{ch}}^{\text{der}}(V_{\text{EK}})$). Let V_{EK} be the Etingof–Kazhdan quantum vertex algebra for $\mathfrak{sl}_2$ at KZ coupling $h_{KZ} = 1/(k + 2) \neq 0$ (discussed in this subsection). The E_3 -algebra structure on the derived chiral centre $Z_{\text{ch}}^{\text{der}}(V_{\text{EK}})$ coincides with the classical E_3 structure of Proposition A.12.26: the cup product and Gerstenhaber bracket vanish, and the P_3 bracket is

$$\{X, Y\}_q = h_{KZ} \cdot (X, Y) \quad \text{for } X, Y \in HH^1 = \mathfrak{sl}_2,$$

with all other brackets zero. In particular, the vertex R -matrix $S(z)$ does not renormalise the P_3 bracket on cohomology.

Proof. The argument has four ingredients: equivariance, one-dimensionality of the obstruction space, exactness of the rational classical r -matrix, and a GRT_1 consistency check.

Step 1: cup product and BV operator. The cup product $\mu: HH^p \otimes HH^q \rightarrow HH^{p+q}$ is a graded-commutative product on $\mathfrak{sl}_2$ -modules over $C[[h_{KZ}]]$. For $X, Y \in HH^1 = \mathfrak{sl}_2[[h_{KZ}]]$, the product $\mu(X, Y) \in HH^2 = C[[h_{KZ}]]$ is an $\mathfrak{sl}_2$ -equivariant antisymmetric bilinear form on the adjoint representation: $\Lambda^2(\text{ad})^{\mathfrak{sl}_2} = 0$, so $\mu(X, Y) = 0$ over $C[[h_{KZ}]]$.

The BV operator $\Delta: HH^n \rightarrow HH^{n-1}$ is $\mathfrak{sl}_2$ -equivariant. The components $\Delta|_{HH^1}: \text{ad} \rightarrow C$ and $\Delta|_{HH^2}: C \rightarrow \text{ad}$ vanish by Schur's lemma. Hence $\Delta = 0$ on the derived centre, and the BV relation gives $[X, Y] = 0$ for all $X, Y \in HH^1$, just as in the classical case.

Step 2: the P_3 bracket is proportional to the Killing form. For $X, Y \in HH^1$, the bracket $\{X, Y\}_q \in HH^0 = C[[h_{KZ}]]$ is an $\mathfrak{sl}_2$ -equivariant symmetric bilinear form on the adjoint representation: $\text{Sym}^2(\text{ad})^{\mathfrak{sl}_2} \cong C$. (the notation κ here denotes the Koszul invariant, not the Killing form). At critical level $k = -h^\vee$ (i.e. $k + h^\vee = 0$), the curvature vanishes and $\text{CE}^{\text{ch}}(\mathfrak{g}_{-h^\vee}) = (\text{Sym}^c(\mathfrak{g}^*[-1]) \otimes \omega_X, d_{\text{CE}})$ is an uncurved commutative (E_∞) factorisation coalgebra on X .

Definition A.12.29 (The chiral Chevalley–Eilenberg complex). Let $\mathfrak{g}$ be a simple Lie algebra with Killing form $(\cdot, \cdot)$ and dual Coxeter number $h^\vee$. The *chiral Chevalley–Eilenberg complex* is the curved chiral coalgebra

$$\text{CE}^{\text{ch}}(\mathfrak{g}_k) := (\text{Sym}^c(\mathfrak{g}^*[-1]) \otimes \omega_X, d_{\text{CE}}, m_0 = \frac{k+h^\vee}{2h^\vee} \kappa),$$

where ω_X denotes the dualising sheaf of X , d_{CE} is the chiral Chevalley–Eilenberg differential encoding the Lie bracket of $\mathfrak{g}$, and the curvature m_0 is the image of the level under the bar construction (the notation κ here denotes the Koszul invariant, not the Killing form). At critical level $k = -h^\vee$ (i.e. $k + h^\vee = 0$), the curvature vanishes and $\text{CE}^{\text{ch}}(\mathfrak{g}_{-h^\vee}) = (\text{Sym}^c(\mathfrak{g}^*[-1]) \otimes \omega_X, d_{\text{CE}})$ is an uncurved commutative (E_∞) factorisation coalgebra on X .

Construction A.12.30 (The chiral P_3 bracket). The PVA λ -bracket on $V_k(\mathfrak{g})$ is (see [521], §5.11):

$$\{J^a{}_\lambda J^b\} = f^{ab}{}_c J^c + k(a, b)\lambda,$$

where $f^{ab}{}_c$ are the structure constants of $\mathfrak{g}$ and (a, b) is the Killing form.

At the level of the chiral Chevalley–Eilenberg complex, the λ -bracket induces a degree- (-2) bracket

$$\{-, -\}^{\text{ch}}: \text{CE}^{\text{ch}}(\mathfrak{g}_k) \otimes \text{CE}^{\text{ch}}(\mathfrak{g}_k) \longrightarrow \text{CE}^{\text{ch}}(\mathfrak{g}_k),$$

defined on generators $\phi_a = (J^a)^* \in \mathfrak{g}^*[-1]$ by the two components of the PVA bracket:

- (i) (Lie bracket term.) The structure constant term $f^{ab}{}_c J^c$ contributes the Chevalley–Eilenberg differential d_{CE} at the algebra level. On the dual (coalgebra) side, it induces a coderivation. This is the classical P_3 bracket of the uncurved complex $\text{CE}^{\text{ch}}(\mathfrak{g}_0)$: the degree- (-2) Lie bracket

$$\{\phi_a, \phi_b\}_{\text{Lie}}^{\text{ch}} = f^{ab}{}_c \phi_c.$$

This bracket is the coinvariant shadow of the ordered bar R -matrix at the critical level.

- (ii) (Cocycle term.) The level-dependent term $k(a, b)\lambda$ contributes a degree- (-2) symmetric pairing valued in $\mathcal{O}_X$:

$$\{\phi_a, \phi_b\}_{\text{cocycle}}^{\text{ch}} = k(a, b) \cdot \partial,$$

where ∂ denotes the $\mathcal{D}$ -module action (the spectral parameter λ of the PVA bracket becomes the derivation ∂_z in the $\mathcal{D}$ -module structure). This term is the cocycle that controls the deformation away from the commutative (E_∞) factorisation structure.

The total chiral P_3 bracket is

$$\{\phi_a, \phi_b\}^{\text{ch}} = f^{ab}{}_c \phi_c + k(a, b) \partial. \quad (\text{A.28})$$

PROPOSITION A.12.31 (*The chiral P_3 structure*). The bracket (A.28) equips the chiral Chevalley–Eilenberg complex $\mathrm{CE}^{\mathrm{ch}}(\mathfrak{g}_k)$ with the structure of a P_3 -algebra object in $\mathcal{D}\text{-mod}(X)$. Concretely:

- (i) The bracket is a degree- (-2) Lie bracket satisfying graded antisymmetry and the Jacobi identity. The Jacobi identity follows from the Jacobi identity of the PVA λ -bracket, which in turn encodes the Jacobi identity of the Lie algebra $\mathfrak{g}$ together with the $\mathfrak{g}$ -invariance of the Killing form.
- (ii) The bracket is compatible with the commutative product on $\mathrm{Sym}^c(\mathfrak{g}^*[-1])$ via the Leibniz rule:

$$\{a, b \cdot c\}^{\mathrm{ch}} = \{a, b\}^{\mathrm{ch}} \cdot c + (-1)^{(|a|-2)|b|} b \cdot \{a, c\}^{\mathrm{ch}}.$$

- (iii) The bracket is $\mathcal{D}$ -linear in the sense that it respects the flat connection on $\mathrm{CE}^{\mathrm{ch}}(\mathfrak{g}_k)$ inherited from the $\mathcal{D}$ -module structure: the chiral P_3 bracket is a morphism of $\mathcal{D}$ -modules, not merely of $\mathcal{O}_X$ -modules.

Proof. The PVA λ -bracket on $V_k(\mathfrak{g})$ satisfies the PVA axioms (sesquilinearity, Leibniz, skew-symmetry, Jacobi); these are the λ -bracket translations of the classical master equation for the Poisson structure. The identification of the λ -bracket with a degree- (-2) Lie bracket on the shifted dual follows the general correspondence between PVA brackets and shifted Poisson structures (Beilinson–Drinfeld [40], §3.8): a PVA λ -bracket of conformal weight 1 (where λ has weight 1) corresponds to a P_3 bracket (degree $-2 = -\dim_{\mathbb{C}} X - 1$, where $\dim_{\mathbb{C}} X = 1$) on the $\mathcal{D}$ -module of chiral cochains.

The $\mathcal{D}$ -linearity follows because the PVA λ -bracket is a $\mathcal{D}$ -module morphism by construction: the derivation ∂ acts via $\lambda \mapsto \lambda$ in the λ -bracket formalism, and this action is compatible with the Leibniz rule by the sesquilinearity axiom of the PVA. $\square$

A.12.3 THE FILTERED E_3 -CHIRAL ALGEBRA

The chiral P_3 bracket and the chiral Chevalley–Eilenberg complex assemble into a single object: a filtered E_3 -chiral algebra $\mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g})$, a factorisation $\mathcal{D}$ -module on $\mathrm{Ran}(X)$ whose global sections on the formal disk recover the CFG E_3 -algebra.

Definition A.12.32 (*The filtered E_3 -chiral algebra*). The *chiral E_3 -algebra*

$$\mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g}) := (\mathrm{CE}^{\mathrm{ch}}(\mathfrak{g}_k), \{-, -\}^{\mathrm{ch}}, \mathcal{D}\text{-module structure})$$

is the chiral Chevalley–Eilenberg complex (Definition A.12.29) equipped with the chiral P_3 bracket (Construction A.12.30) and the $\mathcal{D}$ -module structure from the factorisation algebra on X . It carries a $(k + h^\vee)$ -adic filtration $F^\bullet \mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g})$ defined by:

$$F^p \mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g}) = (k + h^\vee)^p \cdot \mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g}).$$

THEOREM A.12.33 (*Structure of the chiral E_3 -algebra*). Let $\mathfrak{g}$ be a simple Lie algebra. The chiral E_3 -algebra $\mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g})$ satisfies:

- (i) (Associated graded.) The associated graded with respect to the $(k + h^\vee)$ -adic filtration is the uncurved chiral Chevalley–Eilenberg complex at the critical level:

$$\mathrm{gr}_F \mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g}) \simeq \mathrm{CE}^{\mathrm{ch}}(\mathfrak{g}_{-h^\vee}) = (\mathrm{Sym}^c(\mathfrak{g}^*[-1]) \otimes \omega_X, d_{\mathrm{CE}}),$$

which is an E_∞ -chiral algebra (commutative factorisation $\mathcal{D}$ -module on $\mathrm{Ran}(X)$).

- (ii) (The E_3 structure.) The chiral P_3 bracket (Proposition A.12.31) deforms the E_∞ structure to a filtered E_3 -chiral algebra: E_2 from the curve geometry +1 from the chiral P_3 bracket = E_3 .

- (iii) (Curvature and the deformation parameter.) The curvature $m_0 = \frac{k+h^\vee}{2h^\vee} \kappa$ of the chiral Chevalley–Eilenberg complex is the obstruction to the E_∞ structure: at $k = -h^\vee$, the curvature vanishes and the algebra is commutative; at $k \neq -h^\vee$, the P_3 bracket and the curvature together deform the commutative structure to a filtered E_3 -chiral algebra. The deformation parameter is $(k + h^\vee) \in (k + h^\vee) H^3(\mathfrak{g})[[k + h^\vee]]$, matching the deformation space of Theorem A.12.19(ii).
- (iv) (Factorisation property.) The E_3 -chiral algebra $CE_k^{\text{ch}}(\mathfrak{g})$ is a factorisation algebra on X in the sense that the restriction to disjoint opens $U_1 \sqcup U_2 \hookrightarrow X$ induces

$$CE_k^{\text{ch}}(\mathfrak{g})|_{U_1 \sqcup U_2} \simeq CE_k^{\text{ch}}(\mathfrak{g})|_{U_1} \otimes CE_k^{\text{ch}}(\mathfrak{g})|_{U_2},$$

where the tensor product is in the derived category of $\mathcal{D}$ -modules. The E_3 structure is compatible with the factorisation isomorphism.

The following lemma supplies the key compatibility between the BV operator Δ and the chiral P_3 bracket used in the proof of part (ii). The “independent geometric data” heuristic (genus-1 sewing vs. genus-0 collision) motivates the result, but the proof requires a precise argument.

LEMMA A.12.34 (*Commutativity of the BV operator and the chiral P_3 bracket*). Let $\mathfrak{g}$ be a simple Lie algebra and $k \neq -h^\vee$. The BV operator Δ on the derived chiral centre $Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g}))$ (from the framed E_2 structure, genus-1 sewing) and the chiral P_3 bracket $\{-, -\}^{\text{ch}}$ (Construction A.12.30, genus-0 collision residue) satisfy

$$[\Delta, \{a, -\}^{\text{ch}}] = 0 \quad \text{for all } a \in CE_k^{\text{ch}}(\mathfrak{g}). \quad (\text{A.29})$$

Proof. The abstract E_3 -algebra structure on the derived chiral centre $Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g}))$ is provided by Theorem A.12.19(ii) via the Higher Deligne Conjecture applied to the E_2 -coalgebra $\overline{B}^\Sigma(V_k(\mathfrak{g}))$. This abstract E_3 structure includes, in particular, an abstract BV operator Δ_{HDC} (from the framed E_2 structure) and an abstract P_3 bracket $\{-, -\}_{\text{HDC}}$ (the degree- (-2) Lie bracket from the S^2 fundamental class of $C_2(\mathbb{R}^3)/\mathbb{R}^+$). These satisfy all E_3 compatibility conditions, including $[\Delta_{\text{HDC}}, \{a, -\}_{\text{HDC}}] = 0$, by the operadic structure of E_3 .

It remains to identify the explicit chiral P_3 bracket $\{-, -\}^{\text{ch}}$ from Construction A.12.30 with the abstract bracket $\{-, -\}_{\text{HDC}}$. We argue in three steps.

Step 1: matching on the associated graded. At $k = -h^\vee$ (the associated graded of the $(k + h^\vee)$ -adic filtration), the chiral Chevalley–Eilenberg complex becomes the uncurved commutative coalgebra $CE^{\text{ch}}(\mathfrak{g}_0)$, which is an E_∞ -chiral algebra. Both $\{-, -\}^{\text{ch}}$ and $\{-, -\}_{\text{HDC}}$ reduce to the classical P_3 bracket on $\text{Sym}^c(\mathfrak{g}^*[-1]) \otimes \omega_X$ induced by the Lie bracket of $\mathfrak{g}$: the bracket $\{\phi_a, \phi_b\} = f^{ab}_c \phi_c$ on generators, extended as a biderivation. This classical bracket is uniquely determined by the $\mathfrak{g}$ -equivariance and degree constraints on $\text{Sym}^c(\mathfrak{g}^*[-1])$: the space of degree- (-2) Lie brackets on $\text{Sym}^c(\mathfrak{g}^*[-1])$ that are biderivations of the commutative product and $\mathfrak{g}$ -equivariant is one-dimensional (generated by the bracket induced by $\mathfrak{g}$ itself). Therefore $\{-, -\}^{\text{ch}}$ and $\{-, -\}_{\text{HDC}}$ agree on gr_F .

Step 2: matching order by order. The $(k + h^\vee)$ -adic filtration on $CE^{\text{ch}}(\mathfrak{g}_k)$ induces a filtration on the space of degree- (-2) Lie biderivations. At each order $p \geq 1$ in $(k + h^\vee)$, the bracket is determined by its value on generators $\phi_a \otimes \phi_b \in \mathfrak{g}^*[-1] \otimes \mathfrak{g}^*[-1]$ (since both brackets are biderivations of μ). On generators, the space of $\mathfrak{g}$ -equivariant $\mathcal{D}$ -linear pairings $\mathfrak{g}^*[-1] \otimes \mathfrak{g}^*[-1] \rightarrow CE^{\text{ch}}(\mathfrak{g}_k)$ of degree -2 is spanned by $f^{ab}_c \phi_c$ and $k(a, b) \partial$ (the structure constants and the Killing form, the only $\mathfrak{g}$ -invariant tensors of the appropriate type for simple $\mathfrak{g}$). Step 1 fixes the structure-constant coefficient $f^{ab}_c \phi_c$ at order 0. At each subsequent order $p \geq 1$, the *correction* to the bracket on generators lies in the subspace spanned by the Killing-form term $k(a, b) \partial$ alone (since the structure-constant component is already

determined by the lower orders and the biderivation property). For simple $\mathfrak{g}$, this correction space is one-dimensional: $\text{Hom}_{\mathfrak{g}}(\text{Sym}^2 \mathfrak{g}, C) \cong C$ (the Killing form is the unique $\mathfrak{g}$ -invariant symmetric bilinear form). Both $\{-, -\}^{\text{ch}}$ and $\{-, -\}_{\text{HDC}}$ are $\mathfrak{g}$ -equivariant $\mathcal{D}$ -linear biderivations with the same order-0 value (Step 1), so their corrections at each order p coincide by the one-dimensionality of the Killing-form component. Therefore the two brackets agree at each order.

Step 3: conclusion. Since $\{-, -\}^{\text{ch}} = \{-, -\}_{\text{HDC}}$ as formal power series in $(k + h^\vee)$, and $[\Delta_{\text{HDC}}, \{a, -\}_{\text{HDC}}] = 0$ holds by the E_3 operadic structure, the commutativity (A.29) follows. $\square$

Remark A.12.35 (Chain-level status of Lemma A.12.34). The proof reduces the commutativity to the identification of the explicit chiral P_3 bracket with the abstract HDC bracket. This identification is proved order by order in $(k + h^\vee)$ using the one-dimensionality of the deformation space, which holds for simple $\mathfrak{g}$. For non-simple $\mathfrak{g}$, the deformation space $H^3(\mathfrak{g})[[k + h^\vee]]$ may be higher-dimensional, and the order-by-order uniqueness argument requires a more refined comparison.

The “independent geometric data” intuition (that Δ comes from genus-1 sewing strata of $\overline{\mathcal{M}}_{1,n}$ while $\{-, -\}^{\text{ch}}$ comes from genus-0 collision strata of $\overline{\mathcal{M}}_{0,n}$) captures the operadic reason: in the modular envelope of the E_3 operad, genus-1 and genus-0 operations compose without interference because they correspond to disjoint cells in the modular operad. Making this precise at the chain level in the chiral (as opposed to topological) setting is what the identification argument above accomplishes for simple $\mathfrak{g}$.

Proof of Theorem A.12.33. Part (i) is immediate from the filtration: the $(k + h^\vee)$ -adic filtration is exhaustive, and at $k = -h^\vee$ the curvature and the cocycle term of the P_3 bracket both vanish, leaving the uncurved commutative chiral coalgebra $\text{CE}^{\text{ch}}(\mathfrak{g}_{-h^\vee})$.

Part (ii) requires three things: that the chiral P_3 bracket is a degree- (-2) Lie bracket (Jacobi), that it satisfies the Leibniz rule with respect to the commutative product (Poisson compatibility), and that it is compatible with the E_2 structure from the curve geometry, so that the combined data assembles into an E_3 -algebra. We prove each in turn.

Step 1: the P_3 Jacobi identity from the PVA Jacobi. The PVA λ -bracket on $V_k(\mathfrak{g})$ satisfies the (-1) -shifted Jacobi identity (see [522], Appendix A, Proposition A.5):

$$\{a \lambda \{b \mu c\}\} - (-1)^{(|a|+1)(|b|+1)} \{b \mu \{a \lambda c\}\} = \{\{a \lambda b\} \lambda + \mu c\}. \quad (\text{A.30})$$

The chiral P_3 bracket $\{-, -\}^{\text{ch}}$ on $\text{CE}^{\text{ch}}(\mathfrak{g}_k)$ is obtained from the λ -bracket by specialising $\lambda \mapsto \partial$ (the $\mathcal{D}$ -module derivation) and passing to the chiral Chevalley–Eilenberg complex. On generators $\phi_a, \phi_b, \phi_c \in \mathfrak{g}^*[-1]$ (cohomological degree 1, shifted bracket-degree $|\phi_a| - 2 = -1$), the degree- (-2) Jacobi identity is:

$$\{\phi_a, \{\phi_b, \phi_c\}^{\text{ch}}\}^{\text{ch}} + \text{graded cyclic} = 0. \quad (\text{A.31})$$

To derive this from (A.30), set $\lambda = \mu = 0$ (the constant-coefficient specialisation that extracts the P_3 bracket from the λ -bracket). The left side of (A.30) becomes $\{\phi_a, \{\phi_b, \phi_c\}^{\text{ch}}\}^{\text{ch}} - (-1)^{(|\phi_a|+1)(|\phi_b|+1)} \{\phi_b, \{\phi_a, \phi_c\}^{\text{ch}}\}^{\text{ch}}$, and the right side becomes $\{\{\phi_a, \phi_b\}^{\text{ch}}, \phi_c\}^{\text{ch}}$ (at $\lambda + \mu = 0$). The PVA λ -bracket has degree -1 (it is (-1) -shifted); the chiral P_3 bracket has degree -2 , accounting for the additional degree shift from the $\mathcal{D}$ -module derivation ∂ (conformal weight 1). The Koszul sign $(-1)^{(|\phi_a|+1)(|\phi_b|+1)}$ in the PVA identity translates to $(-1)^{(|\phi_a|-2)(|\phi_b|-2)}$ in the P_3 identity after incorporating the degree shift $|-| \mapsto |-| - 2$ appropriate to a degree- (-2) bracket. On $\mathfrak{g}^*[-1]$ where $|\phi_a| = 1$, both signs evaluate to $(-1)^{(-1)(-1)} = -1$. Rearranging gives (A.31).

For general elements of $\text{Sym}^c(\mathfrak{g}^*[-1])$ (not just generators), the Jacobi identity extends by the Leibniz rule (Step 2 below): the bracket is a biderivation of the free commutative algebra, so a trilinear identity that holds on generators holds on all elements.

Step 2: the Leibniz rule from PVA sesquilinearity. The PVA right Leibniz rule (see [522], Appendix A, Proposition A.6) states:

$$\{a \cdot_\lambda (b \cdot c)\} = \{a \cdot_\lambda b\} \cdot c + (-1)^{(|a|+1)|b|} b \cdot \{a \cdot_\lambda c\} + \int_0^\lambda \{\{a \cdot_\mu b\} \cdot_\lambda c\} d\mu.$$

At $\lambda = 0$, the integral term vanishes (the integration range collapses to a point), leaving:

$$\{a, b \cdot c\}^{\text{ch}} = \{a, b\}^{\text{ch}} \cdot c + (-1)^{(|a|+1)|b|} b \cdot \{a, c\}^{\text{ch}}.$$

Adjusting the Koszul sign from the (-1) -shifted convention to the degree- (-2) convention: $(|a| + 1)|b|$ becomes $(|a| - 2)|b|$ after the degree shift, recovering the P_3 Leibniz rule

$$\{a, b \cdot c\}^{\text{ch}} = \{a, b\}^{\text{ch}} \cdot c + (-1)^{(|a|-2)|b|} b \cdot \{a, c\}^{\text{ch}},$$

as stated in Proposition A.12.31(ii). This identifies the chiral P_3 bracket as a derivation of the commutative product μ on $\text{Sym}^c(\mathfrak{g}^*[-1]) \otimes \omega_X$: a commutative algebra equipped with a compatible degree- (-2) Lie bracket is a P_3 -algebra.

Step 3: compatibility with E_2 and the E_3 assembly. The E_2 -coalgebra structure on $\overline{B}^\Sigma$ and its framed variant (from genus-1 sewing) equip the derived centre with a BV operator Δ satisfying $[f, g] = \Delta(f \cdot g) - (\Delta f) \cdot g - (-1)^{|f|} f \cdot (\Delta g)$ (the BV relation (A.25)). The P_3 bracket of degree -2 supplements this E_2 structure with one additional degree of operadic freedom: the P_3 bracket (degree $-2 = -(3-1)$) corresponds to the fundamental class of $S^2 = C_2(\mathbb{R}^3)/\mathbb{R}^+$, the extra generator needed for E_3 beyond E_2 .

The compatibility condition is that the P_3 bracket must be a derivation of the Gerstenhaber bracket $[-, -]$ of degree -1 from the E_2 structure. Since the Gerstenhaber bracket is determined by Δ and μ via the BV relation, it suffices to show that $\{-, -\}^{\text{ch}}$ commutes with Δ and is a derivation of μ (already proved in Step 2). The commutativity $[\Delta, \{a, -\}^{\text{ch}}] = 0$ follows from Lemma A.12.34. Given this, for any $a, b, c \in \text{CE}^{\text{ch}}(\mathfrak{g}_k)$:

$$\begin{aligned} \{a, [b, c]\}^{\text{ch}} &= \{a, \Delta(b \cdot c) - (\Delta b) \cdot c - (-1)^{|b|} b \cdot (\Delta c)\}^{\text{ch}} \\ &= \Delta\{a, b \cdot c\}^{\text{ch}} - \{a, (\Delta b) \cdot c\}^{\text{ch}} - (-1)^{|b|} \{a, b \cdot (\Delta c)\}^{\text{ch}}, \end{aligned}$$

where the first term uses $[\Delta, \{a, -\}^{\text{ch}}] = 0$. Expanding each term by the Leibniz rule of Step 2 and collecting via the BV relation yields

$$\{a, [b, c]\}^{\text{ch}} = [\{a, b\}^{\text{ch}}, c] + (-1)^{(|a|-2)|b|} [b, \{a, c\}^{\text{ch}}] :$$

the P_3 bracket is a derivation of the Gerstenhaber bracket.

This is the mixed Leibniz rule that characterises $E_3 = E_2 + P_3$: the P_3 bracket acts as a derivation of the E_2 Gerstenhaber bracket. By the recognition principle for E_n -algebras (Lurie [303], Theorem 5.1.2.2; Francis [168], Theorem 4.1): a commutative algebra with a compatible E_2 structure and a degree- (-2) Lie bracket satisfying the mutual Leibniz rules (Jacobi, Poisson compatibility with the product, and derivation of the Gerstenhaber bracket) is an E_3 -algebra. The three verifications above establish all the required relations.

Part (iii) combines two observations. The curvature $m_0 = \frac{k+h^\vee}{2h^\vee} \kappa$ is the bar-complex encoding of the level departure (the identification $\text{CE}^{\text{ch}}(\mathfrak{g}_k) \simeq B^{\text{ch}}(V_k(\mathfrak{g}))$). The cocycle term $k(a, b) \partial$ of the P_3 bracket is linear in k and hence linear in $(k + h^\vee)$. Both vanish at $k = -h^\vee$, so the deformation is controlled by $(k + h^\vee)$. The identification of the deformation space as $(k + h^\vee)H^3(\mathfrak{g})[[k + h^\vee]]$ then follows from

the computation of Theorem A.12.19(ii): $H^3(\mathfrak{g})$ is one-dimensional for simple $\mathfrak{g}$, and the Cartan 3-form $\omega_3(X, Y, Z) = (X, [Y, Z])$ is the generator.

Part (iv) is the factorisation property of the chiral bar complex. The chiral Chevalley–Eilenberg complex, being a chiral coalgebra, satisfies the factorisation axiom by construction (Beilinson–Drinfeld [40], Chapter 3). The P_3 bracket, being a $\mathcal{D}$ -module morphism (Proposition A.12.31(iii)), is compatible with the factorisation isomorphisms. $\square$

A.12.4 THE $\mathcal{D}$ -MODULE STRUCTURE AND THE KZ CONNECTION

The chiral E_3 -algebra $CE_k^{\text{ch}}(\mathfrak{g})$ is not an abstract E_3 -algebra: it is an E_3 -algebra object in the category of $\mathcal{D}$ -modules on X , or equivalently on $\text{Ran}(X)$. This $\mathcal{D}$ -module structure is the content that distinguishes the chiral construction from the topological CFG construction.

PROPOSITION A.12.36 (*The $\mathcal{D}$ -module structure*). The chiral E_3 -algebra $CE_k^{\text{ch}}(\mathfrak{g})$ carries a flat connection

$$\nabla^{\text{ch}} = d + \sum_{i < j} \frac{k \Omega_{ij}}{z_i - z_j} dz_{ij}$$

on $C_n(X)$, where Ω_{ij} is the Casimir element acting on the i -th and j -th tensor factors. This is the Knizhnik–Zamolodchikov connection.

- (i) The flatness $(\nabla^{\text{ch}})^2 = 0$ follows from the classical Yang–Baxter equation for the r -matrix $r(z) = k \Omega/z$ (trace-form convention; at $k = 0$, $r = 0$): the curvature of ∇^{ch} is proportional to the LHS of the CYBE, which vanishes.
- (ii) The E_3 -algebra operations are horizontal with respect to ∇^{ch} : the cup product, the Gerstenhaber bracket, and the P_3 bracket are all flat sections of the corresponding Hom-bundles. This is the $\mathcal{D}$ -linearity of Proposition A.12.31(iii) in the multi-point form.
- (iii) The monodromy representation of ∇^{ch} on $\pi_1(C_n(X))$ gives the braid group action. For $X = C$, the monodromy of the KZ connection is computed by the Drinfeld associator Φ_{KZ} and recovers the braided monoidal structure on $\text{Rep}(U_h(\mathfrak{g}))$.

Proof. The KZ connection on the n -point conformal blocks of $V_k(\mathfrak{g})$ is classical (Knizhnik–Zamolodchikov, 1984). The presentation here identifies this connection as the $\mathcal{D}$ -module structure on the chiral Chevalley–Eilenberg complex, viewed as a factorisation algebra on $\text{Ran}(X)$.

For (i): the curvature of ∇^{ch} on $C_n(X)$ is $[\nabla_i, \nabla_j] = k^2 [\Omega_{ij}/(z_i - z_j), \Omega_{ik}/(z_i - z_k) + \Omega_{jk}/(z_j - z_k)] dz_{ij} \wedge dz_{ik}$ plus cyclic permutations. The vanishing of this expression is equivalent to the classical Yang–Baxter equation $[r_{12}, r_{13}] + [r_{12}, r_{23}] + [r_{13}, r_{23}] = 0$ for $r_{ij} = k \Omega_{ij}/(z_i - z_j)$.

For (ii): the E_3 operations are defined in terms of the PVA λ -bracket, which is itself a $\mathcal{D}$ -module morphism. The cup product is a $\mathcal{D}$ -module map by the commutative algebra structure on the factorisation algebra. The P_3 bracket involves the derivation ∂ (from the λ in the PVA bracket), which is the $\mathcal{D}$ -module action; its compatibility with the connection follows from the PVA sesquilinearity axiom.

For (iii): this is the Drinfeld–Kohno theorem (Drinfeld [147], Kohno, Kassel): the monodromy of the KZ connection on $C_n(C)$ factors through the pure braid group P_n and gives, via the Drinfeld associator $\Phi_{\text{KZ}} \in \exp(\hat{\mathfrak{t}}_3)$, a braided monoidal structure on $\text{Rep}(U_h(\mathfrak{g}))$. $\square$

A.12.5 COMPARISON WITH CFG: FORMAL DISK GLOBAL SECTIONS

The chiral E_3 -algebra $CE_k^{\text{ch}}(\mathfrak{g})$ lives on $\text{Ran}(X)$ and carries the KZ connection; the CFG algebra $\mathcal{A}^\lambda$ lives on $\mathbb{R}^3$ and is purely topological. The formal disk $D = \text{Spec } C[[z]]$ is the bridge: restricting to D trivializes the $\mathcal{D}$ -module structure and recovers the CFG algebra as the fiber.

THEOREM A.12.37 (*Formal disk restriction recovers CFG*). Let $D = \text{Spec } C[[z]]$ be the formal disk in X . There is a natural map of filtered E_3 -algebras

$$\Gamma(D, CE_k^{\text{ch}}(\mathfrak{g})) \longrightarrow \mathcal{A}^\lambda \quad (\text{A.32})$$

from the global sections of the chiral E_3 -algebra on the formal disk to the CFG E_3 -algebra of Theorem A.12.20, where the CFG coupling λ equals the departure from critical level $k + h^\vee$.

- (i) (Associated graded.) At the level of associated graded algebras,

$$\text{gr } \Gamma(D, CE_k^{\text{ch}}(\mathfrak{g})) \simeq C^*(\mathfrak{g}) = \text{Sym}(\mathfrak{g}^\vee[-1]),$$

the Chevalley–Eilenberg cochains of $\mathfrak{g}$: both the chiral construction restricted to the formal disk and the CFG construction have the same classical limit.

- (ii) (Matching of P_3 brackets.) The restriction of the chiral P_3 bracket (A.28) to the formal disk recovers the CFG P_3 bracket. On the formal disk, the derivation $\partial = \partial_z$ acts on $C[[z]]$; the global sections $\Gamma(D, \mathfrak{g}^*[-1] \otimes \omega_D) \cong \mathfrak{g}^*[-1][[z]] dz$ produce, after extracting the residue at $z = 0$, the finite-dimensional P_3 bracket

$$\{\phi_a, \phi_b\}_{\text{CFG}} = f^{ab}{}_c \phi_c + k(a, b) \cdot \delta_0,$$

where δ_0 is the delta-function at the origin, the formal-disk avatar of ∂ . Under the identification $\Gamma(D, \omega_D) \cong C dz$ (taking the constant mode), this recovers the CFG bracket on $C^*(\mathfrak{g})$.

- (iii) (Matching of deformation spaces.) Both $CE_k^{\text{ch}}(\mathfrak{g})|_D$ and $\mathcal{A}^\lambda$ are deformations of $C^*(\mathfrak{g})$ over the base $(k + h^\vee) H^3(\mathfrak{g})[[k + h^\vee]]$, with the same one-dimensional fibre at each order in $(k + h^\vee)$ for simple $\mathfrak{g}$. The map (A.32) intertwines the $(k + h^\vee)$ -adic filtrations.

Proof. The argument has two steps: construct the E_3 -algebra structure on $\Gamma(D, CE_k^{\text{ch}}(\mathfrak{g}))$ by symmetric monoidal transport, then identify it with the CFG algebra $\mathcal{A}^\lambda$.

Step 1: symmetric monoidal trivialization on D . The formal disk $D = \text{Spec } C[[z]]$ is contractible: every $\mathcal{D}$ -module on D (that is, a $C[[z]]$ -module with flat connection) is isomorphic to its fibre at the origin, since every flat connection on D is trivializable ($\pi_1(D^n) = 0$ for all n , so there is no monodromy obstruction). The global sections functor

$$\Gamma(D, -): \mathcal{D}\text{-mod}(D) \xrightarrow{\sim} \text{Vect} \quad (\text{A.33})$$

is an equivalence of categories. This equivalence is symmetric monoidal: the tensor product of $\mathcal{D}$ -modules on D (the $!$ -tensor product, which on the contractible formal disk coincides with the $*$ -tensor product and with the ordinary tensor product of the underlying vector spaces) corresponds under (A.33) to the tensor product in Vect .

An equivalence of symmetric monoidal categories preserves all algebraic structures definable in terms of the monoidal structure. In particular, it preserves E_3 -algebra structures: if $\mathcal{B}$ is an E_3 -algebra in $\mathcal{D}\text{-mod}(D)$, then $\Gamma(D, \mathcal{B})$ is an E_3 -algebra in Vect , with structure maps obtained by applying $\Gamma(D, -)$ to those of $\mathcal{B}$.

Applying this to $\mathcal{B} = \mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g})|_D$: the restriction of the chiral E_3 -algebra to D is an E_3 -algebra in $\mathcal{D}\text{-mod}(D)$ (by restriction of the E_3 -structure on X), and the equivalence (A.33) endows $\Gamma(D, \mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g}))$ with an E_3 -algebra structure in Vect . This E_3 -structure is functorial and carries the $(k + h^\vee)$ -adic filtration inherited from the chiral side.

Step 2: identification with $\mathcal{A}^\lambda$. It remains to identify $\Gamma(D, \mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g}))$ with the CFG algebra $\mathcal{A}^\lambda$ as filtered E_3 -algebras, where $\lambda = k + h^\vee$. Both are filtered E_3 -algebras deforming the same classical limit over the same base, and the identification proceeds through three structural invariants.

Part (i): on D , the $\mathcal{D}$ -module structure trivializes, so the chiral Chevalley–Eilenberg complex reduces to the ordinary one. The associated graded of the chiral E_3 -algebra on D is

$$\mathrm{gr} \Gamma(D, \mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g})) = \Gamma(D, \mathrm{gr} \mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g})) = \Gamma(D, \mathrm{Sym}^c(\mathfrak{g}^*[-1]) \otimes \omega_D).$$

On the formal disk, $\omega_D \cong \mathcal{O}_D dz$; the equivalence (A.33) extracts the constant mode in the z -expansion, giving $\mathrm{Sym}(\mathfrak{g}^\vee[-1]) = C^*(\mathfrak{g})$, the Chevalley–Eilenberg cochains of $\mathfrak{g}$ as a commutative algebra. This is the associated graded of $\mathcal{A}^\lambda$ (Theorem A.12.20(i)).

Part (ii): the chiral P_3 bracket on X (equation (A.28)) is defined via the PVA λ -bracket. On the formal disk, the spectral parameter λ becomes the formal variable of the completed enveloping algebra: the translation generator ∂_z acts on $C[[z]]$, and taking global sections via (A.33) extracts the residue at $z = 0$. The resulting bracket on $\Gamma(D, \mathfrak{g}^*[-1] \otimes \omega_D) \cong \mathfrak{g}^*[-1][[z]] dz$ is

$$\{\phi_a, \phi_b\}_{\mathrm{CFG}} = f^{ab}{}_c \phi_c + k(a, b) \cdot \delta_0,$$

where $f^{ab}{}_c$ are the structure constants of $\mathfrak{g}$, (a, b) is the Killing form, and δ_0 is the delta-function at the origin (the formal-disk avatar of the derivation ∂). Under the identification $\Gamma(D, \omega_D) \cong C dz$, this is the CFG P_3 bracket on $C^*(\mathfrak{g})$ (Theorem A.12.20(ii)).

Part (iii): the deformation theory of E_3 -algebras with fixed associated graded $C^*(\mathfrak{g})$ is controlled by the E_3 -Hochschild cohomology, which for $C^*(\mathfrak{g})$ with $\mathfrak{g}$ simple is $(k + h^\vee) H^3(\mathfrak{g})[[k + h^\vee]]$, one-dimensional at each order in $(k + h^\vee)$. Both $\Gamma(D, \mathrm{CE}_k^{\mathrm{ch}}(\mathfrak{g}))$ and $\mathcal{A}^\lambda$ are deformations of $C^*(\mathfrak{g})$ over this base (Theorem A.12.19(ii) and Theorem A.12.20(iv) respectively). Since the deformation space is one-dimensional at each order, and both deformations have matching associated graded (Part (i)) and matching P_3 bracket (Part (ii)), they are isomorphic as filtered E_3 -algebras. The $(k + h^\vee)$ -adic filtration on the chiral side maps to the λ -adic filtration on the CFG side under $\lambda = k + h^\vee$. $\square$

Remark A.12.38 (The chain of spaces). The restriction passes through $\mathrm{pt} \leftarrow D \rightarrow \mathbb{A}^1 \rightarrow \mathbb{P}^1 \rightarrow X$, with each step adding geometric content: the formal disk provides the derivation ∂ (cocycle term $k(a, b)\partial$); $\mathbb{A}^1$ adds Arnold relations and braid monodromy; $\mathbb{P}^1$ and higher-genus X add compactness and modular curvature. None of these restrictions is an identity; each step loses geometric information.

A.12.6 THE KHAN–ZENG TOPOLOGICAL ENHANCEMENT

The chiral E_3 -algebra is holomorphic: it depends on the complex structure of X through the KZ connection. At non-critical level $k \neq -h^\vee$, the Sugawara Virasoro element kills holomorphic translation on BRST cohomology, which upgrades the resulting cohomology algebra from holomorphic to topological. The same cohomology complex then provides a chain-level E_3^{top} model on a quasi-isomorphic complex. A lift to the original complex requires the coherence equation of Remark A.12.9. At the critical level, the Sugawara element is undefined and the enhancement fails.

PROPOSITION A.12.39 (*Topological enhancement via Sugawara*). At non-critical level $k \neq -h^\vee$, the affine Kac–Moody vertex algebra $V_k(\mathfrak{g})$ possesses a Sugawara Virasoro element

$$T_{\text{Sug}} = \frac{1}{2(k + h^\vee)} \sum_{a=1}^{\dim \mathfrak{g}} :J^a J_a:, \quad (\text{A.34})$$

which generates an inner action of the Virasoro algebra at central charge $c = k \dim(\mathfrak{g})/(k + h^\vee)$.

By Theorem A.12.2, the Virasoro element controls three distinct statements at the level of the derived chiral centre:

- (i) (Holomorphic-topological.) The chiral E_3 -algebra $CE_k^{\text{ch}}(\mathfrak{g})$ lives on $X \times \mathbb{R}$, where X carries holomorphic structure and $\mathbb{R}$ carries topological structure. The E_2 from the curve geometry is holomorphic; the $+1$ from the P_3 bracket is topological (from the $\mathbb{R}$ factor).
- (ii) (Cohomological topologization and transferred model.) BRST cohomology $H_Q^\bullet(Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g})))$ carries an E_3^{top} -structure, and the zero-differential cohomology complex is therefore a chain-level E_3^{top} model on a quasi-isomorphic complex (Theorem A.12.2(i), (ii)).
- (iii) (Original-complex lift.) The original complex $Z_{\text{ch}}^{\text{der}}(V_k(\mathfrak{g}))$ itself carries a chain-level E_3^{top} -structure precisely when the A_∞ -coherence equation $[m, G] = \partial_z$ holds in the brace deformation complex (Theorem A.12.2(iii); Remark A.12.9).
- (iv) (Failure at critical level.) At $k = -h^\vee$, the Sugawara element (A.34) is undefined (the denominator $2(k + h^\vee)$ vanishes). The critical-level chiral E_3 -algebra $CE_{-h^\vee}^{\text{ch}}(\mathfrak{g})$ is genuinely holomorphic, not topological: the E_2 -coalgebra on $\overline{B}^\Sigma(\mathcal{A})$ is topological, but $\mathcal{A}$ itself retains essential dependence on the complex structure of X . Without the Sugawara element, there is no homotopy between the holomorphic and topological directions, so the full structure is not topological E_3 . Perturbatively, in the formal neighbourhood of critical level, the topological enhancement holds order-by-order in $(k + h^\vee)$ (since T_{Sug} exists at any nonzero departure from critical level).

Proof. Part (i) is the HT structure of the 3d gauge theory whose boundary chiral algebra is $V_k(\mathfrak{g})$ (Costello–Gwilliam [92]). The factorisation algebra of the HT theory lives on $\Sigma \times \mathbb{R}$ with holomorphic dependence on Σ and topological dependence on $\mathbb{R}$; the chiral E_3 -algebra is the algebraic encoding of this factorisation structure.

Part (ii) is exactly Theorem A.12.2(i), (ii). The Sugawara construction (Frenkel–Ben-Zvi [171], Chapter 15) produces the element (A.34), and the topological enhancement on BRST cohomology together with the chain-level model on the zero-differential cohomology complex are proved there.

Part (iii) is the conditional clause Theorem A.12.2(iii): the original-complex lift exists exactly when the A_∞ -coherent null-homotopy of holomorphic translation holds in the brace deformation complex.

Part (iv): at $k = -h^\vee$, the Feigin–Frenkel centre $Z(V_{-h^\vee}(\mathfrak{g})) = \text{Fun}(\text{Op}_{\mathfrak{g}^\vee}(D))$ (Feigin–Frenkel) is a commutative algebra with non-trivial dependence on the complex structure of the formal disk (through the notion of $\mathfrak{g}^\vee$ -oper). The absence of the Sugawara element means no homotopy between holomorphic and topological directions exists, and the chiral E_3 -algebra is genuinely holomorphic. The perturbative statement follows because the Sugawara element exists as a formal power series in $(k + h^\vee)$ for $k \neq -h^\vee$. $\square$

A.12.7 EXAMPLE: $\mathfrak{sl}_2$ CHIRAL E_3 -ALGEBRA

The general construction specialises cleanly to $\mathfrak{g} = \mathfrak{sl}_2$: the chiral P_3 bracket is determined by six pairings on the generators ϕ_e, ϕ_f, ϕ_h , each consisting of a Lie bracket term (from the structure constants) and a

cocycle term (proportional to the level k , vanishing at $k = 0$). Restricting to the formal disk and extracting the zero mode recovers the CFG bracket of Proposition A.12.26.

Example A.12.40 (Explicit chiral P_3 bracket for $\mathfrak{sl}_2$). For $\mathfrak{g} = \mathfrak{sl}_2$ with basis $\{e, f, h\}$, Killing form $(e, f) = (f, e) = 1$, $(h, h) = 2$, structure constants $[e, f] = h$, $[h, e] = 2e$, $[h, f] = -2f$, and $h^\vee = 2$, the chiral P_3 bracket (Construction A.12.30) on the generators $\phi_e, \phi_f, \phi_h \in \mathfrak{sl}_2^*[-1]$ is:

$$\{\phi_e, \phi_f\}^{\text{ch}} = \phi_h + k \partial, \quad (\text{A.35})$$

$$\{\phi_h, \phi_e\}^{\text{ch}} = 2\phi_e, \quad (\text{A.36})$$

$$\{\phi_h, \phi_f\}^{\text{ch}} = -2\phi_f, \quad (\text{A.37})$$

$$\{\phi_h, \phi_h\}^{\text{ch}} = 2k \partial, \quad (\text{A.38})$$

$$\{\phi_e, \phi_e\}^{\text{ch}} = 0,$$

$$\{\phi_f, \phi_f\}^{\text{ch}} = 0.$$

The Lie bracket terms (ϕ_h in (A.35), $2\phi_e$ in (A.36), $-2\phi_f$ in (A.37)) persist at $k = 0$; the cocycle terms ($k \partial$ in (A.35) and (A.38)) vanish at $k = 0$ (AP126 check: at $k = 0$, the level-dependent terms vanish, and the bracket reduces to the Chevalley–Eilenberg coderivation).

At the critical level $k = -2$ (i.e. $k + h^\vee = 0$), the cocycle terms become -2∂ , and the chiral E_3 -algebra degenerates: the curvature $m_0 = 0$ (uncurved), and the commutative factorisation structure is undeformed.

Taking formal disk global sections and extracting the zero mode recovers the CFG P_3 bracket of Proposition A.12.26: $\{\phi_a, \phi_b\}_{\text{CFG}} = f^{ab}_c \phi_c + k(a, b) \delta_0$, which at the cohomological level gives $\{X, Y\} = h_{\text{KZ}}(X, Y)$ for $X, Y \in \text{HH}^1 = \mathfrak{sl}_2$ (equation (A.24)), with $h_{\text{KZ}} = 1/(k + 2)$.

A.13 EXAMPLES

The preceding sections establish the operadic and homological constructions. The remaining examples record how those constructions reappear on the concrete surfaces used later in the monograph: the dimensional ladder of Section A.14, the E_n shadow tower of Section A.15, and the symmetric-bar obstruction package of Section A.16. This section is therefore not a new theory lane; it is the point where the abstract E_n framework is read back into explicit bar-complex calculations and obstruction statements.

A.14 THE DIMENSIONAL LADDER

The chapter establishes eight results. The Totaro presentation of $H^*(C_k(\mathbb{R}^n))$ generalizes Arnold's presentation from $n = 2$ to all n (Theorem A.1.3). The E_2 bar complex satisfies $d^2 = 0$ via the Totaro relations (Theorem A.3.2). The chiral bar-cobar duality of Main Theorem A is recovered as the $n = 2$ case of E_n Koszul duality (Corollary A.4.4), and our construction is the chain-level refinement of Ayala–Francis Poincaré–Koszul duality at $n = 2$ (Proposition A.5.2). The abstract E_n Koszul duality, E_n formality, and higher enveloping algebras are established in the literature for all n (Theorem A.4.2, Theorem A.6.7, Proposition A.6.10; see also Remark K.7.1). The *ordered* bar complex $\overline{B}^{\text{ord}}(\mathcal{A}) = T^c(s^{-1}\overline{\mathcal{A}})$ is a single-coloured E_1 -chiral dg coalgebra: the differential comes from holomorphic collision residues on $\text{FM}_k(\mathbb{C})$ and the deconcatenation coproduct comes from ordered interval splitting on $C_k(\mathbb{R})$ (Theorem A.9.4). The actual $\text{SC}^{\text{ch}, \text{top}}$ datum appears only on the derived center pair $(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \mathcal{A})$; the symmetric bar $\overline{B}^\Sigma(\mathcal{A})$ of

Theorem A is recovered by R -twisted Σ_n -coinvariants and uses the coshuffle coproduct instead. At higher genus the fibrewise differential d_{fib} is curved with $d_{\text{fib}}^2 = \kappa(\mathcal{A}) \cdot \omega_g$ but is *not* a coderivation; flatness and the coderivation property are restored only by the period-corrected differential D_g of Theorem 13.16.13 (Remark A.9.8). The topologization theorem (Theorem A.12.2) upgrades the BRST cohomology of the E_2 center of $V_k(\mathfrak{g})$ to E_3 via the Sugawara conformal vector, with an explicit antighost contraction $G(z)$ (Construction A.12.11) that makes the proof constructive. For class M algebras, where the chain-level E_3 encounters obstructions from step (iv) of Remark A.12.9, a coderived refinement (Conjecture A.12.14) provides the conjectural alternative.

Three concrete calculations remain beyond the proved theorems. First, explicit closed-form formulas for the E_n bar differential in terms of Totaro generators at each $n \geq 3$ have not been tabulated (the propagator and FM compactification exist and $d^2 = 0$ is proved). Second, the $n = 3$ Chern–Simons identification (Conjecture A.8.1) connecting the E_3 bar complex to perturbative CS invariants at the chain level is open. Third, higher-genus E_n theory for $n \geq 3$ would require a notion of higher-dimensional moduli replacing $\overline{\mathcal{M}}_g$; the correct framework may be cobordism categories or extended TQFTs.

The dimensional ladder makes precise the sense in which this monograph’s results (chiral bar-cobar duality, quantum complementarity, genus expansions) are the $n = 2$ chapter of a general story that extends through all dimensions.

Remark A.14.1 (The E_1 – E_2 obstruction). The Yangian is E_1 -chiral (Theorem O.1.9): binary fusion with braiding (R -matrix level). Upgrading to E_2 requires coherent many-point transport: an associator $\Phi \in \exp(\widehat{\text{Lie}}(t_{12}, t_{23}))$ satisfying pentagon and hexagon. The Drinfeld–Kohno theorem (Theorem O.13.5) is the E_1 -level comparison package on the affine Drinfeld–Kohno surface (KZ monodromy compared with the quantum-group R -matrix); full E_2 coherence requires associator input, governed by the Grothendieck–Teichmüller group.

Remark A.14.2 (The Grothendieck–Teichmüller group). E_2 formality (Tamarkin [385]) is not canonical: it depends on a Drinfeld associator Φ , and the non-uniqueness is governed by GRT. For the Yangian, the R -matrix is E_1 -level data (braid); the associator Φ provides E_2 -level coherence. DK is naturally an E_1 -factorization theorem; full E_2 coherence is a separate, GT-dependent upgrade.

Remark A.14.3 (Research remark: associator independence). There are four different independence questions here, and they should not be merged.

- (i) *Tamarkin’s route is not associator-free.* Tamarkin’s proof of E_2 -formality starts from a Drinfeld associator, so “via little disks formality” does not remove the choice: it packages it (Tamarkin [503]). Dolgushev–Paljug prove that Tamarkin’s construction is GRT_1 -equivariant, and Theorem A.7.2 identifies the controlling Lie algebra with $H^0(\text{GC}_2) \cong \mathfrak{grt}_1$ (Dolgushev–Paljug [133], Willwacher [444]). Changing the associator therefore changes the cochain-level E_2 and brace package by the corresponding graph-complex derivation. Any chain-level chiral quantum-group equivalence produced through Tamarkin’s route inherits that dependence.
- (ii) *What is proved on cohomology.* For $\mathfrak{sl}_2$, Proposition A.12.28 shows that the induced operations on $H^*(Z_{\text{ch}}^{\text{der}}(\text{VEK}))$ agree with the classical answer: the cup product and Gerstenhaber bracket vanish, and the only surviving binary operation is the P_3 bracket proportional to the Killing form. On this proved surface, changing the associator can only change the chosen cochain representative of that P_3 bracket; the cohomology class is fixed. For a general simple $\mathfrak{g}$, the missing step is not the classification of invariant bilinear forms, but a chiral exactness theorem: every $\mathfrak{grt}_1$ -generator must act on $C_{\text{ch}}^\bullet(V_k(\mathfrak{g}), V_k(\mathfrak{g}))$ by an inner, equivalently Hochschild-exact, derivation. This cannot be inferred from equivariance alone:

outside the local affine-disk setting, graph-complex classes can act nontrivially on cohomology (Dolgushev–Rogers–Willwacher [134]). The present proved surface is therefore: cohomological independence for $\mathfrak{sl}_2$; general $\mathfrak{g}$ remains a research problem.

- (iii) *What the bar side can see.* The scalar invariants used in the modular theorem are associator-free. The ordered lift retains the full GRT_1 -torsor of Drinfeld associators (Proposition 21.1.9), but Theorem 21.1.7 gives $\text{av}(\Theta_{\mathcal{A}}^{E_1}) = \Theta_{\mathcal{A}}$. Hence $\kappa(\mathcal{A})$ and every scalar shadow coefficient extracted from $\Theta_{\mathcal{A}}$ depend only on the averaged Maurer–Cartan class, not on the chosen ordered lift. Proposition A.7.3 is a refinement after choosing a formality morphism: its GC_2 -valued lift can move under GRT_1 , but the scalar coefficient S_r cannot. In this precise sense the bar-side scalar package is associator-free, while the ordered quantum-group datum is not.
- (iv) *Two research routes.* Route A keeps Tamarkin’s E_2 formality and seeks the missing exactness theorem for the induced grt_1 action on chiral Hochschild cochains. Route B bypasses the E_2 choice: when Theorem A.12.2 applies, the bulk on BRST cohomology is an E_3^{top} -algebra, and for $n \geq 3$ the little-disks operad is intrinsically formal (Fresse–Willwacher [459]). If one can identify the boundary restriction of this associator-free E_3^{top} package with the Drinfeld–Kohno operations on cohomology, then the cohomological chiral quantum-group equivalence becomes associator-free. This second route is unavailable at the chain level and remains a research programme even in the affine case.

A.15 THE E_n SHADOW OBSTRUCTION TOWER

The shadow obstruction tower of a chiral algebra $\mathcal{A}$ is built from the Maurer–Cartan element $\Theta_{\mathcal{A}}$ in the modular convolution algebra. This section extends the construction to E_n algebras for all n , computing the n -dependence of the modular characteristic κ , the shadow depth, and the higher shadow invariants. The key structural result is that the binary invariant κ is *independent* of n : it depends only on the degree-2 part of the bar complex, which involves $C_2(\mathbb{R}^n) \simeq S^{n-1}$ and produces the same pairing for all n . Higher-degree shadows *do* depend on n through the topology of $C_k(\mathbb{R}^n)$ for $k \geq 3$, but for formal E_n algebras this dependence vanishes entirely: formality of the E_n operad (Kontsevich, Tamarkin, Lambrechts–Volić) forces all shadow invariants to agree with their E_{∞} values.

Definition A.15.1 (E_n shadow obstruction tower). Let A be an E_n algebra with binary self-pairing of level k . The E_n bar complex $B_{E_n}(A)$ is the bar construction built from the Fulton–MacPherson compactification $\overline{C}_k(\mathbb{R}^n)$ with propagator the fundamental class of S^{n-1} (the codimension- n linking sphere). At degree m , the bar complex has underlying graded vector space

$$B_{E_n}(A)_m = H_*(C_m(\mathbb{R}^n); \mathbb{Q}) \otimes A^{\otimes m}.$$

The E_n shadow invariants $S_r^{E_n}(A)$ are defined as the degree- r projections of the Maurer–Cartan element in the E_n modular convolution algebra, exactly as in Definition 13.22.49 with the chiral bar complex replaced by the E_n bar complex.

THEOREM A.15.2 (*E_n shadow obstruction tower: universality of κ and formality collapse*;). Let A be an E_n algebra for $n \geq 1$.

- (i) (Binary universality.) The modular characteristic $\kappa_{E_n}(A)$ is *independent* of n :

$$\kappa_{E_n}(A) = \kappa(A) \quad \text{for all } n \geq 1.$$

In particular, $\kappa_{E_n}(\mathfrak{H}_k) = k$ (Heisenberg at level k), $\kappa_{E_n}(\widehat{\mathfrak{g}}_k) = \dim(\mathfrak{g})(k + h^{\vee})/(2h^{\vee})$ (affine Kac–Moody), and $\kappa_{E_n}(\text{Vir}_c) = c/2$ (Virasoro).

- (ii) (Formality collapse.) If A is *formal* as an E_n algebra (i.e., the transferred E_n structure on the bar cohomology $H^*(B_{E_n}(A))$ has trivial higher operations), then the full shadow obstruction tower collapses:

$$S_r^{E_n}(A) = S_r^{E_\infty}(A) \quad \text{for all } r \geq 2.$$

Since the E_∞ homology operad is commutative, the corresponding commutative shadow tower terminates at degree 2 for free algebras, a formal E_n algebra with vanishing structure constants beyond the self-pairing has shadow depth $r_{\max} = 2$ (class G).

- (iii) (Shadow depth classification.) The four-class partition (Definition 13.22.121)

$$G(r_{\max} = 2), \quad L(r_{\max} = 3), \quad C(r_{\max} = 4), \quad M(r_{\max} = \infty)$$

is stable under the operadic level n for formal E_n algebras: the shadow class of A does not depend on n .

- (iv) (Stabilization.) As $n \rightarrow \infty$, E_n approaches E_∞ , and the shadow obstruction tower stabilizes: $S_r^{E_n}(A) \rightarrow S_r^{E_\infty}(A)$. The stabilization is *finite*: for each fixed degree r , there exists $N(r)$ such that $S_r^{E_n}(A) = S_r^{E_\infty}(A)$ for all $n \geq N(r)$. Explicitly, $N(r) \leq r$, because all positive-degree classes in $H^*(C_r(\mathbb{R}^n))$ have degree $\geq n - 1$, which exceeds the bar-complex degree at degree r once $n > r$.

Proof. **Part (i).** The modular characteristic κ is determined by the degree-2 component of the bar complex. At degree 2:

$$B_{E_n}(A)_2 = H_*(C_2(\mathbb{R}^n)) \otimes A^{\otimes 2}.$$

The space $C_2(\mathbb{R}^n) = \mathbb{R}^n \setminus \{0\}$ deformation-retracts onto S^{n-1} , so $H_*(C_2(\mathbb{R}^n))$ has total rank 2: one generator in degree 0 and one in degree $n - 1$. The degree-2 self-pairing that defines κ is the evaluation of the binary propagator (the fundamental class of S^{n-1}) on the quadratic input $a \otimes a$. Since the fundamental class of S^{n-1} pairs with $a \otimes a$ via the level k of the algebra (the coefficient of the leading OPE singularity), this pairing is independent of n : it sees only the level. For each family the formula follows from the explicit computation in Theorem 13.21.44.

Part (ii). Formality of A as an E_n algebra means that the transferred E_n structure on $H^*(B_{E_n}(A))$ has $m_r^{\text{tr}} = 0$ for $r \geq 3$. The shadow invariant $S_r^{E_n}(A)$ for $r \geq 3$ is determined by the transferred operations m_j^{tr} for $j \leq r$ (Proposition 13.22.107). If all these vanish, then $S_r^{E_n}(A) = 0$ for $r \geq 3$, which equals the E_∞ value computed by the commutative shadow (which has no higher obstructions beyond the binary pairing for free algebras). For non-free formal algebras, the structure constants that contribute to S_r are the same as in the E_∞ computation because the higher-degree corrections from the topology of $C_r(\mathbb{R}^n)$ are killed by formality.

Part (iii). The shadow class is determined by the vanishing pattern of $\{S_r\}_{r \geq 2}$ (Definition 13.22.121). By (ii), for formal E_n algebras the vanishing pattern is independent of n , so the class label is stable.

Part (iv). For fixed degree r , the correction terms from $H^*(C_r(\mathbb{R}^n))$ to the shadow invariant $S_r^{E_n}$ involve classes of degree $\geq n - 1$ (the minimum degree of a positive-dimensional class in the Totaro algebra on r points, Theorem A.1.3). The bar-complex degree at degree r is bounded by $r - 2$ (the MC equation constrains the total propagator degree budget to $r - 2$ units). Once $n - 1 > r - 2$, i.e., $n \geq r$, all topological correction terms lie in degrees exceeding the MC degree budget, hence contribute zero. Therefore $S_r^{E_n}(A) = S_r^{E_\infty}(A)$ for $n \geq r$, giving $N(r) \leq r$ (Proposition A.6.4). For the binary invariant ($r = 2$), this gives $N(2) \leq 2$; in fact, $N(2) = 1$ by (i). $\square$

Remark A.15.3 (Configuration space Poincaré polynomials). The Poincaré polynomial of $C_k(\mathbb{R}^n)$ for $n \geq 2$ is

$$P_k^{(n)}(t) = \prod_{j=0}^{k-1} (1 + j t^{n-1}),$$

giving total Betti number $P_k^{(n)}(1) = k!$ for all $n \geq 2$ and Euler characteristic $\chi(C_k(\mathbb{R}^n)) = \prod_{j=0}^{k-1} (1 + j(-1)^{n-1})$, which vanishes for $k \geq 2$ when n is even and equals $k!$ when n is odd. For $n = 1$: $C_k(\mathbb{R})$ has $k!$ contractible components, so $P_k^{(1)}(t) = k!$. These formulas enter the bar complex dimensions via $\dim B_{E_n}(A)_k = P_k^{(n)}(1) \cdot \dim(A^{\otimes k})$ at the level of total Betti numbers.

A.16 E_2 STRUCTURE ON THE SYMMETRIC BAR AND THE E_3 OBSTRUCTION

The symmetric chiral bar complex $\overline{B}^\Sigma(\mathcal{A})$ of a chiral algebra on a curve carries a natural E_2 structure from the local configuration spaces $C_k(\mathbb{C})$. It is obtained from the ordered primitive $\overline{B}^{\text{ord}}(\mathcal{A})$ by the lossy R -twisted Σ_n -coinvariant passage. It does *not* carry an E_3 structure: a curve provides only $\mathbb{R}^2$, and the passage to E_3 requires $\mathbb{R}^3$ geometry. The correct statement is that, for E_∞ -chiral algebras (where $\overline{B}^\Sigma(\mathcal{A})$ exists), the *derived center* $Z_{\text{ch}}^{\text{der}}(\mathcal{A}) = \text{HH}^*(\mathcal{A}, \mathcal{A})$, computed using the symmetric bar resolution $\overline{B}^\Sigma(\mathcal{A})$, carries E_3 structure by the Higher Deligne Conjecture, a distinct object from $\overline{B}^\Sigma(\mathcal{A})$ itself. For genuinely E_1 -chiral algebras, $\overline{B}^\Sigma$ does not exist without an R -matrix, and the E_3 claim requires a 3d holomorphic-topological theory as independent input.

PROPOSITION A.16.1 (*E_2 structure on the bar complex and the E_3 obstruction*;). Let $\mathcal{A}$ be a chiral algebra on a smooth algebraic curve X .

- (i) (E_2 on $\overline{B}^\Sigma(\mathcal{A})$.) The symmetric bar $\overline{B}^\Sigma(\mathcal{A})$ carries a natural E_2 -coalgebra structure from the operad $\text{FM}_2 \simeq E_2$ acting on $C_k(\mathbb{C}) \cong C_k(\mathbb{R}^2)$. The corresponding cohomological structure on $H^*(\overline{B}^\Sigma(\mathcal{A}))$ is a *Gerstenhaber algebra*: an associative product of degree 0 and a Lie bracket of degree 1 satisfying the Leibniz rule.
- (ii) (E_3 obstruction.) The symmetric bar $\overline{B}^\Sigma(\mathcal{A})$ does *not* carry a natural E_3 structure. The obstruction is topological: E_3 requires configurations in $\mathbb{R}^3$, but the curve X provides only $\mathbb{R}^2$. The Swiss-cheese operad $\text{SC}^{\text{ch}, \text{top}}$, which governs the joint open–closed structure, is a *colored* operad with E_2 on the closed holomorphic color and E_1 on the open topological color; it is not the tensor product $E_2 \otimes E_1$. Dunn additivity ($E_m \otimes E_n \simeq E_{m+n}$) does not apply to colored operads, so $\text{SC}^{\text{ch}, \text{top}} \neq E_3$.
- (iii) (Framed $E_2 \neq E_3$.) The BV operator Δ from genus-1 sewing equips $\overline{B}^\Sigma(\mathcal{A})$ with a *framed* E_2 (equivalently, BV) structure. This is strictly weaker than E_3 : the BV operator has degree 1 (same as the Gerstenhaber bracket), while an E_3 bracket would require degree 2. The identity $\Delta^2 = 0$ does not produce a degree-2 bracket.
- (iv) (E_3 on the derived center.) By the Higher Deligne Conjecture (Lurie [303], §5.3; Francis [168]), if $\overline{B}^\Sigma(\mathcal{A})$ is an E_2 -algebra, then the resulting Hochschild cochain object carries a natural E_3 structure. In the present chiral setting, this structure lives on the derived center $Z_{\text{ch}}^{\text{der}}(\mathcal{A}) = \text{HH}^*(\mathcal{A}, \mathcal{A})$, computed by the symmetric bar resolution. This is the correct E_3 object: the derived center, not the symmetric bar.

- (v) (Obstruction dimension.) The obstruction to extending E_2 to E_3 on $\overline{B}^\Sigma(\mathcal{A})$ lives in $\mathrm{HH}_{E_2}^3(\overline{B}^\Sigma(\mathcal{A}), \overline{B}^\Sigma(\mathcal{A}))$. For the Heisenberg $\mathfrak{H}_k$: $\dim \mathrm{HH}_{E_2}^3 = 0$ ($\Lambda^3(\mathbb{C}^1) = 0$), so the obstruction vanishes vacuously; this is consistent with $H^*(\overline{B}^\Sigma(\mathfrak{H}_k)) = \mathrm{Sym}(V^*[1])$ being E_∞ . For affine $\widehat{\mathfrak{sl}}_2$: $\dim \mathrm{HH}_{E_2}^3 = 1$ ($\Lambda^3(\mathbb{C}^3) = \mathbb{C}$, a genuine obstruction).

Proof. Part (i). The E_2 -coalgebra structure on $\overline{B}^\Sigma(\mathcal{A})$ comes directly from the $\mathrm{FM}_2 \simeq E_2$ operad acting on local configurations in $C_k(\mathbb{C}) \cong C_k(\mathbb{R}^2)$. Concretely, one starts from the ordered E_1 primitive $\overline{B}^{\mathrm{ord}}(\mathcal{A})$ and passes to the R -twisted Σ_n -coinvariant shadow $\overline{B}^\Sigma(\mathcal{A})$. This passage is lossy, but the resulting local object retains the E_2 operations detected by FM_2 . At the cohomological level, the product is the cup product on Hochschild cochains and the bracket is the Gerstenhaber bracket $[-, -]$ of degree 1; the Leibniz rule $[a, bc] = [a, b]c + (-1)^{(|a|-1)|b|}b[a, c]$ is the defining relation of a Gerstenhaber algebra (Getzler–Jones [202]). For the explicit computation of this bracket on $CH^1(V_k(\mathfrak{sl}_2)) \cong \mathfrak{sl}_2$, see Proposition A.11.27.

Part (ii). An E_3 structure on a chain complex C requires an action of $C_k(\mathbb{R}^3)$ on $C^{\otimes k}$ for all k , compatible with the FM_3 operad structure. The bar complex $\overline{B}^\Sigma(\mathcal{A})$ is built from $C_k(\mathbb{C}) = C_k(\mathbb{R}^2)$; no embedding $\mathbb{R}^3 \hookrightarrow \mathbb{C}$ exists that would provide the additional topological data. The Swiss-cheese operad $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$ has E_2 acting on the closed holomorphic sector (points in $\mathbb{C}$) and E_1 acting on the open topological sector (points in $\mathbb{R}$); these are *different colors* of a colored operad. Dunn additivity ($E_m \otimes E_n \simeq E_{m+n}$, [473]) applies to the tensor product of operads acting on the *same* underlying object, not to different colors of a colored operad.

Part (iii). The BV operator Δ has $|\Delta| = 1$ and $\Delta^2 = 0$. The BV relation (Getzler [476]) is $[a, b] = \Delta(ab) - (\Delta a)b - (-1)^{|a|}a(\Delta b)$, which defines the degree-1 bracket from Δ ; it does not produce a degree-2 bracket. A genuine E_3 bracket would require a map $A \otimes A \rightarrow A[2]$, corresponding to the fundamental class of $S^2 = C_2(\mathbb{R}^3)/\mathbb{R}^+$, which has degree 2. The degree-1 BV structure is the framed E_2 structure, not E_3 .

Part (iv). The Higher Deligne Conjecture states that for an E_n -algebra A , the Hochschild cohomology $\mathrm{HH}^*(A, A)$ carries a natural E_{n+1} structure. At $n = 2$: if $\overline{B}^\Sigma(\mathcal{A})$ is E_2 , then the Hochschild cohomology of this E_2 bar model is E_3 . Applied to the symmetric bar resolution of $\mathcal{A}$, this yields the E_3 structure on the derived center $Z_{\mathrm{ch}}^{\mathrm{der}}(\mathcal{A}) = \mathrm{HH}^*(\mathcal{A}, \mathcal{A})$. This is proved by Lurie ([303], Theorem 5.3.1.30) and Francis ([168]).

Part (v). The obstruction to lifting E_2 to E_3 on an E_2 -algebra A lives in the E_2 -Hochschild cohomology $\mathrm{HH}_{E_2}^3(A, A)$, which at the level of the Gerstenhaber algebra computes degree-3 deformations of the E_2 structure. For $A = H^*(\overline{B}^\Sigma(\mathfrak{H}_k)) = \mathrm{Sym}(V^*[1])$ with $V = \mathbb{C}$ (one-dimensional): the relevant obstruction space contains $\Lambda^3(V)$ as a subquotient, which vanishes for $\dim V = 1$. For $V = \mathbb{C}^3$ (affine $\widehat{\mathfrak{sl}}_2$): $\Lambda^3(\mathbb{C}^3) = \mathbb{C}$, contributing a one-dimensional obstruction space. $\square$

Remark A.16.2 (The Heisenberg symmetric-bar cohomology is E_∞). The symmetric bar cohomology $H^*(\overline{B}^\Sigma(\mathfrak{H}_k)) = \mathrm{Sym}(V^*[1])$ is a free graded-commutative algebra, hence carries the local E_∞ structure on cohomology. This locality statement concerns symmetric-group invariance of operations, not the absence of OPE poles. It is therefore E_n for *all* n . However, the quasi-isomorphism $\overline{B}^\Sigma(\mathfrak{H}_k) \xrightarrow{\sim} H^*(\overline{B}^\Sigma(\mathfrak{H}_k))$ used in this section is an E_2 quasi-isomorphism. The ordered bar $\overline{B}^{\mathrm{ord}}(\mathfrak{H}_k)$ remains the underlying E_1 primitive, and the passage to $\overline{B}^\Sigma(\mathfrak{H}_k)$ forgets ordered braid data.

Remark A.16.3 (The factorization envelope perspective). The E_n shadow obstruction tower of the factorization envelope $U_M(L)$ of a Lie conformal algebra L on an n -manifold M is determined by the λ -bracket

data of L (Proposition 14.11.1). By Theorem A.15.2(i), the modular characteristic $\kappa_{E_n}(U_M(L))$ agrees with the chiral value $\kappa(U_X(L))$ for all n . The shadow depth class is likewise independent of n for the standard families. This reflects the structural principle that the binary-level data (OPE self-pairing, Killing form, central charge) is universal across the E_n hierarchy, while higher-degree corrections from configuration-space topology are governed by formality.

Conjecture A.16.4 (Chromatic bar-cobar duality;). The rational, trigonometric, and elliptic hierarchy of Yangian-type chiral algebras is the chromatic tower of one-dimensional formal groups. The bar propagator on $\mathbb{P}^1$ is the additive formal group $\mathbb{G}_a$ (height ∞ , rational Yangian); the bar propagator on $\mathbb{C}^\times$ is the multiplicative formal group $\mathbb{G}_m$ (height 1, trigonometric Yangian, K -theory orientation); and the bar propagator on an elliptic curve E_τ is the formal group $\hat{E}_\tau$ of the elliptic curve (height ≤ 2 , elliptic Yangian, TMF orientation). The symmetric chiral bar-cobar construction on the universal family $\mathcal{E} \rightarrow \mathcal{M}_{1,1}$ then defines an E_2 -algebra sheaf whose associated formal group is the universal elliptic formal group, producing a TMF-module structure on the resulting factorization coalgebras. The conjecture has three levels of status:

- (a) (PROVED.) At each fixed elliptic curve E_τ the elliptic bar differential satisfies $d^2 = 0$ by the Fay trisecant identity (Fay [159]), as established for the period-corrected differential D_g in Remark A.9.8 and in the higher-genus foundations chapter. This gives a well-defined bar coalgebra in each fibre of $\mathcal{E} \rightarrow \mathcal{M}_{1,1}$.
- (b) (PARTIAL.) The symmetric bar cohomology $H^*(\bar{B}^\Sigma(\mathcal{A}_E))$ of an elliptic chiral algebra $\mathcal{A}_E$ decomposes into a rational part (pulled back along the degeneration $E_\tau \rightsquigarrow \mathbb{P}^1 \cup \mathbb{P}^1$ via the additive formal group) and a genuinely elliptic part (supported on the interior of $\mathcal{M}_{1,1}$ and controlled by $\hat{E}_\tau$). The rational piece is controlled by the additive specialization of Section A.16 and is known; the elliptic piece is conjecturally computed by the period-integral corrections of Theorem 13.16.13, but a complete identification with an elliptic cohomology class remains open.
- (c) (OPEN.) The full TMF-module structure on the factorization coalgebra of $\mathcal{A}_E$ as a sheaf over $\mathcal{M}_{1,1}$ is conjectural. Establishing it requires constructing a E_2 -oriented spectrum map from the bar complex of $\mathcal{A}_E$ to the topological modular forms spectrum, in the sense of Ando–Hopkins–Strickland [488], and verifying that the chiral Koszul dual $\mathcal{A}_E^1$ implements the TMF-dualizing structure. A proof of (c) would imply the elliptic Yangian of $\mathcal{A}_E$ is TMF-oriented.

Remark A.16.5 (Chromatic tower and the Yangian hierarchy). The chromatic filtration of stable homotopy theory (Ravenel [487]) stratifies spectra by the height of the associated formal group: height 0 is rational, height 1 is K -theory, height 2 is TMF, and so on. The representation-theoretic tower rational $\rightarrow$ trigonometric $\rightarrow$ elliptic of Yangian-type quantum groups stratifies chiral algebras by the formal group of the underlying curve: $\mathbb{G}_a$ on $\mathbb{P}^1$, $\mathbb{G}_m$ on $\mathbb{C}^\times$, and $\hat{E}_\tau$ on E_τ . Conjecture A.16.4 asserts that these two towers are dual under bar-cobar: the bar propagator on a curve with formal group $\hat{F}$ produces a factorization coalgebra whose cobar recovers a quantum group whose R -matrix is the classical r -matrix attached to $\hat{F}$. This is a version of the Ginzburg–Kapranov [203] operadic Koszul duality, and of Baranovsky’s [489] universal enveloping construction, adapted from the general E_n -operad setting to the one-parameter family of Yangians. The novelty is that the chromatic filtration on the topological side implies a stratification of $r(z)$ by formal-group height on the chiral side, and conversely the one-parameter deformation on the chiral side implies the height filtration on the factorization coalgebra: the correspondence is strictly one-directional at the current status, and a complete equivalence awaits resolution of part (c).

Remark A.16.6 (Feynman transform and genus-1 Koszul duality). The Feynman transform $\mathrm{FT}_{\mathrm{Mod}}(\mathcal{A})$ of Getzler–Kapranov [199, §4–5] (Definition 15.12.25) admits a natural filtration by genus:

$$\mathrm{FT}_{\mathrm{Mod}}^{(\leq g)}(\mathcal{A}) = \bigoplus_{h=0}^g \bigoplus_{\substack{n \\ 2h-2+n>0}} \bigoplus_{\Gamma \in \mathcal{G}_{h,n}} \bigotimes_{v \in V(\Gamma)} \mathcal{A}(\mathrm{val}(v)) \otimes \bigotimes_{e \in E(\Gamma)} \det(e),$$

where $\mathcal{G}_{h,n}$ denotes stable graphs of type (h, n) and $\mathrm{FT}^{(\leq g)}$ retains only graphs Γ with $\sum_v g_v + b_1(\Gamma) \leq g$. The full Feynman transform is the colimit $\mathrm{FT}_{\mathrm{Mod}}(\mathcal{A}) = \varinjlim_g \mathrm{FT}_{\mathrm{Mod}}^{(\leq g)}(\mathcal{A})$. By Theorem 15.12.26(ii), the genus- g piece $\bar{B}^{(g)}(\mathcal{A})$ of the full bar complex $\bar{B}^{\mathrm{full}}(\mathcal{A}) = T^c(s^{-1}\bar{\mathcal{A}})$ is the genus- g summand of this Feynman transform.

At genus 0, $\mathrm{FT}^{(\leq 0)}$ recovers the classical (cyclic) bar-cobar adjunction: the only stable graphs are trees, and edge contraction reproduces the operadic bar differential. The genus-1 truncation $\mathrm{FT}^{(\leq 1)}$ is the first extension beyond classical Koszul duality. It includes stable graphs Γ with first Betti number $b_1(\Gamma) = 1$ (one-loop graphs) as well as trees with a single genus-1 vertex. The genus-1 bar complex $\bar{B}^{(1)}(\mathcal{A})$ captures exactly these contributions; its differential encodes the non-separating self-gluing $\xi_{\mathrm{ns}}: \bar{\mathcal{M}}_{0,n+2} \rightarrow \bar{\mathcal{M}}_{1,n}$ together with the separating gluings that produce genus-1 curves from two genus-0 components.

The modular characteristic $\kappa(\mathcal{A})$ first appears as a genuine obstruction at this genus level: the genus-1 free energy satisfies $\mathrm{obs}_1(\mathcal{A}) = \kappa(\mathcal{A}) \cdot \lambda_1$ (UNIFORM-WEIGHT; unconditional at $g = 1$; Theorem 13.13.16). Thus the passage from $\mathrm{FT}^{(\leq 0)}$ to $\mathrm{FT}^{(\leq 1)}$ is precisely the passage from classical Koszul duality (which sees only the binary self-pairing) to the first modular correction controlled by κ . The Feynman transform involution $\mathrm{FT} \circ \mathrm{FT} \simeq \mathrm{Id}$ (Corollary 15.12.34) guarantees that the information in $\bar{B}^{(1)}(\mathcal{A})$, combined with the genus-0 data, determines the algebra $\mathcal{A}$ up to the genus-2 and higher obstructions: each genus level of the Feynman transform refines the reconstruction by one modular correction.

Conjecture A.16.7 (Spectrum-level lift of the bar complex;). Let A be an augmented dg algebra on the genus-0 Koszul locus, and suppose it admits a spectrum-level refinement, again denoted A . Then the classical bar coalgebra

$$B(A) = T^c(s^{-1}\bar{A}), \quad \bar{A} = \ker(\epsilon), \quad |s^{-1}v| = |v| - 1$$

admits a spectrum-level lift $B^{\mathrm{Sp}}(A)$ with the following properties:

- (i) (Coalgebra spectrum.) $B^{\mathrm{Sp}}(A)$ is a coalgebra object in spectra, and its rationalization recovers the Eilenberg–Mac Lane realization of the dg coalgebra $B(A)$. Under this comparison, the deconcatenation coproduct on $B(A)$ is the rational shadow of a map of spectra

$$\Delta^{\mathrm{Sp}}: B^{\mathrm{Sp}}(A) \longrightarrow B^{\mathrm{Sp}}(A) \wedge B^{\mathrm{Sp}}(A).$$

- (ii) (THH comparison.) The cyclic bar construction on the same spectrum-level object computes $\mathrm{THH}(A)$, and the passage from the classical bar complex to Hochschild chains is the rational shadow of the passage from $B^{\mathrm{Sp}}(A)$ to $\mathrm{THH}(A)$. In this sense the chiral bar-cobar adjunction $\bar{B}^{\mathrm{ch}} \dashv \Omega^{\mathrm{ch}}$ admits a spectrum-level shadow in which the bar coalgebra spectrum controls the open sector and $\mathrm{THH}(A)$ is the first closed trace.
- (iii) (Chromatic lift.) If one replaces the classical rational bar complex by its Eilenberg–Mac Lane spectrum $H(B(A))$, then $L_{K(n)}H(B(A)) \simeq 0$ for every $n \geq 1$. By contrast the genuine spectrum-level lift can satisfy $L_{K(n)}B^{\mathrm{Sp}}(A) \neq 0$, and the resulting chromatic tower of $B^{\mathrm{Sp}}(A)$ records higher-categorical shadow data invisible to the rational dg coalgebra $B(A)$.

Remark A.16.8 (Evidence). Three pieces of evidence support Conjecture A.16.7. First, Theorem A.5.1 and Proposition A.5.2 already place the E_2 bar construction inside factorization homology, whose native target is spectral. The dg coalgebra $B(A)$ therefore sits in a context where a coalgebra spectrum is the natural refinement.

Second, Theorem A.17.16 identifies the annulus trace with Hochschild homology and writes it by a cyclic bar model. For an associative ring spectrum, factorization homology over S^1 is THH, so the dg passage from the bar complex to Hochschild chains has the same formal shape as a spectrum-level comparison from $B^{\text{Sp}}(A)$ to $\text{THH}(A)$. This is the closest theorem-level shadow of the conjectured lift.

Third, Conjecture A.16.4 already predicts a height-sensitive TMF package for the elliptic bar construction. That prediction cannot be detected by the rational chain model alone: if the spectrum-level object were only $H(B(A))$, every positive chromatic localization would vanish. Any nontrivial $K(n)$ -local layer of $B^{\text{Sp}}(A)$ must therefore come from genuinely spectral data, and this is exactly the data forgotten by the classical bar complex.

A.17 THE OPEN/CLOSED REALIZATION: CHIRAL DERIVED CENTER AS UNIVERSAL BULK

Remark A.17.1 (Dependency spine). Everything in this section depends only on:

- (i) the chiral Hochschild complex $C_{\text{chiral}}^\bullet(\mathcal{A})$ (Definition 17.6.5),
- (ii) the bordered FM compactification $\overline{C}_{k,\vec{m}}^{\text{oc}}(X, D, \tau)$ (§5.3),
- (iii) the open-closed convolution algebra $\mathfrak{g}_{\mathcal{A},\vec{M}}^{\text{oc}}$ (Definition 5.4.1), and
- (iv) the bar-intrinsic MC element $\Theta_{\mathcal{A}}$ (Theorem 13.21.69).

No additional geometric or physical hypotheses are needed beyond the gravitational input (Definition K.7.1).

A.17.1 THE CHIRAL ENDOMORPHISM OPERAD AND THE ALGEBRAIC DERIVED CENTER

The geometric chiral Hochschild complex of Definition 17.6.5 lives on FM compactifications with log forms. Its algebraic counterpart, constructed below, makes the operadic braces and the universal open/closed structure explicit.

Definition A.17.2 (Chiral endomorphism operad). Let A be a graded vector space equipped with a translation operator $\partial: A \rightarrow A$ of degree 0. The *chiral endomorphism operad* End_A^{ch} is the nonsymmetric operad with:

- (a) *Components.* $\text{End}_A^{\text{ch}}(n) := \text{Hom}(A^{\otimes n}, A((\lambda_1)) \cdots ((\lambda_{n-1})))$ for $n \geq 1$, where $\lambda_1, \dots, \lambda_{n-1}$ are formal spectral variables of degree 0.
- (b) *Operadic composition.* For $f \in \text{End}_A^{\text{ch}}(n)$ and $g \in \text{End}_A^{\text{ch}}(m)$, the i -th partial composition $f \circ_i g \in \text{End}_A^{\text{ch}}(n+m-1)$ is defined by

$$(f \circ_i g)(a_1, \dots, a_{n+m-1}) := f(a_1, \dots, a_{i-1}, g(a_i, \dots, a_{i+m-1}), a_{i+m}, \dots, a_{n+m-1}) \quad (\text{A.39})$$

with the *block-substitution rule* for spectral variables: the variable λ_i in f is replaced by the block sum $\Lambda_i := \lambda_i + \lambda_{i+1} + \cdots + \lambda_{i+m-2}$, and the variables $\lambda_i, \dots, \lambda_{i+m-2}$ in g are inserted consecutively.

Associativity of the operadic composition follows from associativity of consecutive block-substitution: if a block B_1 is inserted into a block B_2 which is itself inserted into an ambient expression, the result is a single contiguous block $B_1 \subset B_2$ whose variables partition correctly.

Remark A.17.3 (Relation to the OPE). For a vertex algebra V with OPE $a(z)b(w) \sim \sum_{n \geq 0} (a_{(n)}b)(w) (z-w)^{-n-1}$, the element $\mu \in \text{End}_V^{\text{ch}}(2)$ encoding the OPE is

$$\mu(a, b; \lambda) = \sum_{n \geq 0} (a_{(n)}b) \lambda^n / n! = a_{(\lambda)}b,$$

which is exactly the λ -bracket of the corresponding Lie conformal algebra. The higher operations $\mu_n \in \text{End}_V^{\text{ch}}(n)$ for $n \geq 3$ encode iterated OPE with the spectral variables tracking the collision parameters.

Definition A.17.4 (Chiral Hochschild cochain complex, algebraic model). Let $\mathcal{A}$ be a chiral algebra with underlying graded vector space A and A_∞ -chiral structure $m = \sum_{n \geq 1} m_n \in \prod_{n \geq 1} \text{End}_A^{\text{ch}}(n)$. The *algebraic chiral Hochschild cochain complex* is

$$C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}) := \prod_{n \geq 0} \text{End}_A^{\text{ch}}(n+1)[-n], \quad (\text{A.40})$$

so a degree- p element f is a sequence $(f_0, f_1, f_2, \dots)$ with $f_n \in \text{End}_A^{\text{ch}}(n+1)$ of internal degree $p+n$.

Definition A.17.5 (Operadic braces). For $f \in \text{End}_A^{\text{ch}}(n+1)$ and $g_1 \in \text{End}_A^{\text{ch}}(k_1+1), \dots, g_r \in \text{End}_A^{\text{ch}}(k_r+1)$, define the *brace operation*

$$f\{g_1, \dots, g_r\} := \sum_{1 \leq i_1 < \dots < i_r \leq n} (-1)^\varepsilon f \circ_{i_1} g_1 \circ_{i_2+k_1} g_2 \circ_{i_3+k_1+k_2} g_3 \cdots \circ_{i_r+k_1+\dots+k_{r-1}} g_r, \quad (\text{A.41})$$

where $\varepsilon = \sum_{s=1}^r (|g_s| - 1)(i_s + k_1 + \dots + k_{s-1} - s)$ is the Koszul sign from permuting g_s past the preceding inputs. The one-fold brace defines the *Gerstenhaber bracket*:

$$[f, g] := f\{g\} - (-1)^{(|f|-1)(|g|-1)} g\{f\}. \quad (\text{A.42})$$

The differential on $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ is $\delta f := [m, f]$, where $m = \sum_{n \geq 1} m_n$ is the A_∞ -chiral structure.

THEOREM A.17.6 (*Brace dg algebra structure on chiral Hochschild cochains;*). Let $\mathcal{A}$ be a chiral algebra. The complex $(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \delta)$ with braces (A.41) is a brace dg algebra. Equivalently:

- (i) $\delta^2 = 0$ (using the A_∞ -chiral relation $m\{m\} = 0$).
- (ii) The *higher pre-Lie identity*: for all $f, g_1, \dots, g_r, h$,

$$f\{g_1, \dots, g_r\}\{h\} = \sum_{s=0}^r (-1)^{(|h|-1)\sum_{t>s}(|g_t|-1)} f\{g_1, \dots, g_s, h, g_{s+1}, \dots, g_r\} + \text{insertion terms}.$$

- (iii) The *Leibniz rule*: $\delta(f\{g_1, \dots, g_r\}) = (\delta f)\{g_1, \dots, g_r\} + \sum_s (-1)^{\varepsilon_s} f\{g_1, \dots, \delta g_s, \dots, g_r\} + \text{boundary terms}$.
- (iv) The *Gerstenhaber algebra on cohomology*: $H^*(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \delta)$ carries a Gerstenhaber algebra structure, with cup product from braces and Lie bracket from (A.42).

Proof. Step 1: $\delta^2 = 0$. By direct computation, $\delta^2(f) = [m, [m, f]]$. In the shifted complex (A.40), each $m_n \in \text{End}_A^{\text{ch}}(n)$ has internal degree $2-n$, hence cochain degree 1 in $\text{End}_A^{\text{ch}}(n)[1-n]$. The suspended degree entering the Gerstenhaber sign is therefore $|m| - 1 = 0$. Thus the graded-Jacobi shortcut $[m, [m, f]] = \frac{1}{2}[[m, m], f]$ is not available here: at even suspended degree the Jacobi identity only gives the tautology $[[m, m], f] = 0$.

Instead one uses the brace form of the A_∞ relations. Since $|m| - 1 = 0$, the bracket is $[m, g] = m\{g\} - g\{m\}$, so

$$\begin{aligned}\delta^2(f) &= m\{m\{f\} - f\{m\}\} - (m\{f\} - f\{m\})\{m\} \\ &= m\{m\{f\}\} - m\{f\{m\}\} - m\{f\}\{m\} + f\{m\}\{m\}.\end{aligned}$$

Expanding these four terms by direct insertions, every summand is either a term containing $m\{m\}$ or a pair of nested/external insertions with opposite signs. The A_∞ -chiral relations are precisely

$$(m\{m\})_n = \sum_{\substack{r+s+t=n \\ s \geq 1}} (-1)^{rs+t} m_{r+1+t}(\text{id}^{\otimes r} \otimes m_s \otimes \text{id}^{\otimes t}) = 0,$$

so all contributions vanish. In the chiral setting, the operadic compositions still carry block-substitution of spectral variables (Definition A.17.2(b)), and associativity of block-substitution gives the same cancellation pattern as in the classical brace algebra.

Step 2: Pre-Lie identity. The single-brace product $f \bullet g := f\{g\}$ satisfies the *right pre-Lie identity*: $(f \bullet g) \bullet h - f \bullet (g \bullet h) = (-1)^{\|g\| \|h\|} [(f \bullet h) \bullet g - f \bullet (h \bullet g)]$. This is proved by expanding both sides using the partial compositions (A.39): the left side involves summing over pairs of insertion positions (i, j) in f , and the right side involves the same sum with g and h interchanged. The difference telescopes because block-substitution is *sequential*: inserting g then h into non-overlapping slots of f produces the same spectral variable assignment regardless of order, while inserting into overlapping slots is governed by nested associativity (Lemma A.11.2(b) of §A.11.1). The pre-Lie identity implies the Jacobi identity for the Gerstenhaber bracket $[f, g] = f\{g\} - (-1)^{\|f\| \|g\|} g\{f\}$.

Step 3: Higher brace identities and Leibniz rule. The multi-fold brace operations satisfy the higher pre-Lie (brace) identities by the same sequential/nested argument. The Leibniz rule $\delta(f\{g_1, \dots, g_r\}) = (\delta f)\{g_1, \dots, g_r\} + \sum_s \pm f\{g_1, \dots, \delta g_s, \dots, g_r\} + \text{boundary terms}$ follows because $\delta = [m, -]$ and m has cochain degree 1, so $[m, -]$ acts as a graded derivation of the brace operations. The boundary terms are the braces involving m insertions, which cancel pairwise by the brace form $m\{m\} = 0$ of the A_∞ identities.

Step 4: Gerstenhaber on cohomology. The cup product $f \smile g$ (concatenation composition) and the Gerstenhaber bracket $[f, g]$ both descend to cohomology because δ is a derivation of both. The resulting structure $(H^*, \smile, [-, -])$ satisfies the Gerstenhaber axioms (graded commutativity of $\smile$, graded Jacobi for $[-, -]$, Leibniz compatibility) because these are identities in the brace dg algebra. The full proof with explicit signs in the chiral setting is given in §A.11.4 (Theorem A.11.11, Definition A.11.3). $\square$

Definition A.17.7 (Chiral derived center). The *chiral derived center* of $\mathcal{A}$ is the cohomology

$$\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A}) := H^*(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \delta).$$

By Theorem A.17.6(iv), this is a Gerstenhaber algebra. On the Koszul locus, Theorem H (Theorem 14.4.12) gives $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})^n = 0$ for $n \notin \{0, 1, 2\}$, so the derived center is a three-term Gerstenhaber algebra:

$$\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A}) = \mathcal{Z}^0 \oplus \mathcal{Z}^1 \oplus \mathcal{Z}^2, \quad (\text{A.43})$$

with the Lie bracket of degree -1 giving $[\cdot, \cdot]: \mathcal{Z}^1 \otimes \mathcal{Z}^1 \rightarrow \mathcal{Z}^1$ (a Lie algebra on bulk derivations) and $[\cdot, \cdot]: \mathcal{Z}^1 \otimes \mathcal{Z}^2 \rightarrow \mathcal{Z}^2$ (the action of derivations on obstructions).

Definition A.17.8 (Genus- g chiral derived center). For a curved A_∞ -chiral algebra $(\mathcal{A}, \{m_k\})$ with modular characteristic $\kappa(\mathcal{A})$ (Definition 13.21.39), the *genus- g chiral derived center* ($g \geq 1$) is

$$\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})^{(g)} := H^*(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}) \otimes_{\mathcal{O}_{\overline{\mathcal{M}}_g}} \Omega_{\overline{\mathcal{M}}_g}^\bullet(\log D), D_g),$$

where $D \subset \overline{\mathcal{M}}_g$ is the boundary divisor and the total corrected differential

$$D_g = d_{\text{fib}} + \nabla^{\text{GM}}$$

has two components: the fiberwise differential d_{fib} with $d_{\text{fib}}^2 = \kappa(\mathcal{A}) \cdot \omega_g \cdot \text{id}$ (Convention 13.0.2), and the Gauss–Manin connection ∇^{GM} on the family of bar complexes over $\overline{\mathcal{M}}_g$. The total differential satisfies $D_g^2 = 0$: the Gauss–Manin connection absorbs the fiberwise curvature $\kappa(\mathcal{A}) \cdot \omega_g$.

At genus 0, $\overline{\mathcal{M}}_{0,n}$ carries no Hodge class ($\omega_0 = 0$), the fiberwise differential is strict ($d_{\text{fib}}^2 = 0$), and $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})^{(0)}$ reduces to the local chiral derived center of Definition A.17.7.

A.17.2 THE UNIVERSAL OPEN/CLOSED PAIR

Definition A.17.9 (Local chiral open/closed pair). A *local chiral open/closed pair* with open color $\mathcal{A}$ is a triple $(\mathcal{B}, \mathcal{A}, \iota)$ where:

- (a) $\mathcal{B}$ is a dg vertex algebra (the “bulk”);
- (b) $\mathcal{A}$ is a chiral algebra (the “boundary”);
- (c) $\iota: \mathcal{B} \rightarrow C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ is a dg algebra map (the “bulk-to-boundary coupling”).

A *morphism* of local chiral open/closed pairs $(\mathcal{B}, \mathcal{A}, \iota) \rightarrow (\mathcal{B}', \mathcal{A}, \iota')$ (with fixed open color) is a dg algebra map $\phi: \mathcal{B} \rightarrow \mathcal{B}'$ such that $\iota' \circ \phi = \iota$.

THEOREM A.17.10 (*Universal open/closed pair (chiral Swiss-cheese theorem)*). Let $(A, \{m_k\})$ be a curved A_∞ -chiral algebra. The pair

$$\mathcal{U}(\mathcal{A}) := (C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \mathcal{A}, \{\mu_{p;q}^{\text{univ}}\})$$

is the *terminal* (final) local chiral Swiss-cheese pair over $\mathcal{A}$ (Definition A.17.9): for every local chiral open/closed pair $(\mathcal{B}, \mathcal{A}, \{\mu_{p;q}\})$ over $\mathcal{A}$, there exists a *unique* morphism

$$\Phi: (\mathcal{B}, \mathcal{A}, \{\mu_{p;q}\}) \longrightarrow \mathcal{U}(\mathcal{A})$$

of local chiral Swiss-cheese pairs. Here the universal mixed operations $\mu_{p;q}^{\text{univ}}: (C_{\text{ch}}^\bullet)^{\otimes p} \otimes A^{\otimes q} \rightarrow A((\lambda_1)) \cdots ((\lambda_{p+q-1}))$ are defined by iterated brace evaluation of chiral Hochschild cochains on algebra elements.

Proof. The morphism $\Phi: \mathcal{B} \rightarrow C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ is constructed by evaluating closed observables on the open sector: for $b \in \mathcal{B}$, define

$$\Phi(b)_n(a_1, \dots, a_n) := \mu_{1;n}(b; a_1, \dots, a_n),$$

where $\mu_{1;n}$ is the mixed operation of the Swiss-cheese pair. This gives a well-defined element $\Phi(b) \in C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ because $\mu_{1;n}$ is $\mathbb{C}$ -multilinear in the a_i with values in $A((\lambda_1)) \cdots ((\lambda_{n-1}))$ by the sesquilinearity axiom.

The Swiss-cheese codimension-1 identities for the pair $(\mathcal{B}, \mathcal{A}, \mu)$ imply:

- (i) *Chain map*: $\Phi \circ \delta_{\mathcal{B}} = \delta \circ \Phi$ (from the $(p, q) = (1, n)$ identity);
- (ii) *Brace compatibility*: $\Phi(b\{b_1, \dots, b_r\}) = \Phi(b)\{\Phi(b_1), \dots, \Phi(b_r)\}$ (from the $(p, q) = (1 + r, N)$ identity).

Uniqueness: any Swiss-cheese morphism $\Psi: \mathcal{B} \rightarrow C_{\text{ch}}^\bullet$ must intertwine the mixed operations, forcing $\Psi(b)_n = \mu_{1;n}(b; -)$ by evaluation, so $\Psi = \Phi$. The full proof with explicit signs and spectral-variable bookkeeping is given in Theorem A.11.16 (§A.11.5). $\square$

Remark A.17.11 (Physical interpretation). In the holomorphic-topological framework of Costello–Dimofte–Gaiotto, the boundary of a 3d HT theory is an A_∞ -chiral algebra $\mathcal{A}$, and the bulk local operators map to the derived center of $\mathcal{A}$. Theorem A.17.10 makes this precise: the universal bulk attached to a boundary algebra $\mathcal{A}$ is exactly $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$. The distinction from bar/cobar is sharp: bar/cobar classifies *twisting morphisms* (universal couplings between $\mathcal{A}$ and $\mathcal{A}^!$), while the derived center classifies *bulk operators acting on the boundary*.

PROPOSITION A.17.12 (*Mixed sector encodes bulk-to-boundary module structure;*). The mixed sector of the Koszul dual cooperad $\text{SC}^{\text{ch}, \text{top}, !}$ at bi-degree (k, m) , $k \geq 1$, with $\dim = (k-1)! \binom{k+m}{m}$ (Proposition A.10.2), encodes the bulk-to-boundary module structure: the iterated brace evaluation $\mu_{k;m}: (Z_{\text{ch}}^{\text{der}}(\mathcal{A}))^{\otimes k} \otimes \mathcal{A}^{\otimes m} \rightarrow \mathcal{A}$ by which the chiral derived center acts on the boundary algebra. At $(k=1, m=n)$, this recovers the n -fold brace evaluation with $\dim = n+1$ counting the insertion positions for one bulk operator among n ordered boundary points. Computational verification: `sc_mixed_sector_engine.py` (47 tests).

Proof. The mixed operations $\text{SC}^{\text{ch}, \text{top}}(c^k, o^m; o) = \text{FM}_k(\mathbb{C}) \times E_1(m)$ parametrize k closed (bulk) inputs and m open (boundary) inputs producing one open output. By Theorem A.17.10, the terminal open/closed pair $(Z_{\text{ch}}^{\text{der}}(\mathcal{A}), \mathcal{A})$ realizes these operations as iterated brace evaluations. The Künneth factorization $\text{Lie}^c(k) \otimes \text{Sh}(k, m)$ (where $\text{Sh}(k, m) = \binom{k+m}{m}$ counts (k, m) -shuffles) gives the dimension. $\square$

Remark A.17.13 (Mixed sector is genus-independent). The product decomposition $C_*(\text{FM}_{k|m}(\Sigma_g, \partial)) \simeq C_*(\text{FM}_k(\Sigma_g)) \times C_*(E_1(m))$ (Volume II, Proposition ?? in the modular Swiss-cheese chapter) holds at all genera. The open colour $E_1(m)$ is genus-independent: the interval $\mathbb{R}$ has no genus. All genus dependence lives in the closed factor. The curvature $\kappa(\mathcal{A}) \cdot \omega_g$ is purely closed-sector. Genus-raising operations act only on closed inputs; open inputs are passive. Beware: the “mixed channels” of the multi-weight correction $\delta F_g^{\text{cross}}$ are *mixed-weight* (closed-sector endomorphism decorations), not *mixed-sector* (bulk-to-boundary SC operations).

A.17.3 RESTRICTION FROM GLOBAL TO LOCAL: THE BORDERED FM BRIDGE

The bordered FM compactification $\overline{C}_{k, \vec{m}}^{\text{oc}}(X, D, \tau)$ of Construction 5.3.7 provides the global geometric stage. The algebraic derived center is identified with the local restriction of the global open-closed convolution.

THEOREM A.17.14 (*Local-global bridge;*). Let (X, D, τ) be a tangential log curve with a single puncture $D = \{p\}$, and let $\mathcal{A}$ be a chiral algebra on X with module $\mathcal{M}$ at p . Assume $\mathcal{M}$ admits a compact generator b (this holds whenever $\mathcal{M}$ is a proper dg-category, e.g. when $\mathcal{A}$ is chirally Koszul and the module category is the category of bounded $\mathcal{A}$ -modules). Then:

- (i) *Algebraic chart.* The boundary algebra $A_b := \text{RHom}_{\mathcal{M}}(b, b)$ is an A_∞ -algebra, with operations $\mu_n^{A_b}$ encoding the ordered boundary collisions of $\text{Conf}_n^{\text{ord}}(I_p)$ (Definition 5.3.5).

- (ii) *Derived center identification.* The genus-0, pure-interior component of the open-closed convolution algebra $\mathfrak{g}_{\mathcal{A}, \mathcal{M}}^{\text{oc}}$ (Definition 5.4.1), restricted to the formal disk at p , is canonically quasi-isomorphic to the algebraic chiral Hochschild cochain complex:

$$\mathfrak{g}_{\mathcal{A}, \mathcal{M}}^{\text{oc}}|_{g=0, \text{int-only}, \widehat{D}_p} \simeq C_{\text{ch}}^{\bullet}(\mathcal{A}, \mathcal{A}). \quad (\text{A.44})$$

- (iii) *Morita invariance.* The quasi-isomorphism type of the right side of (A.44) depends only on the Morita equivalence class of the boundary category $\mathcal{M}$, not on the choice of compact generator b .

Proof. (i) The ordered boundary configuration space $\text{Conf}_n^{\text{ord}}(I_p)$ is the interior of the simplex Δ^{n-1} (Remark 5.3.6). Its compactification is the associahedron K_n , whose codimension-one faces parametrize consecutive-block compositions. The boundary corrections give the A_{∞} operations $\mu_n^{A_b}$ by the standard Stasheff construction on $C_*(\overline{K}_n) \otimes \text{End}(b)$.

(ii) The interior configuration space $C_k(X \setminus D)$, restricted to the formal disk $\widehat{D}_p$, is the configuration space of k points in a formal punctured disk. After choosing a local coordinate, this identifies with the space of k spectral variables $\lambda_1, \dots, \lambda_{k-1}$ (the relative positions). The FM compactification on this formal disk gives exactly the operadic compositions of End_A^{ch} (Definition A.17.2): codimension-one faces correspond to operadic insertions with block-substitution. The identification $C_*(\overline{C}_k(\widehat{D}_p)) \otimes \text{Hom}(A^{\otimes k}, A) \cong \text{End}_A^{\text{ch}}(k)$ at each degree gives (A.44).

(iii) Standard Morita theory: if $b' \in \mathcal{M}$ is another compact generator with $\mathcal{M} \simeq \text{Perf}(A_b) \simeq \text{Perf}(A_{b'})$, then the derived centers of A_b and $A_{b'}$ are canonically quasi-isomorphic via the bimodule implementing the Morita equivalence. $\square$

COROLLARY A.17.15 (*The intrinsic bulk*). The *intrinsic bulk* of the open sector is the Morita-invariant object

$$\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{M}) := \text{RHom}_{\text{Fun}(\mathcal{M}, \mathcal{M})}(\text{Id}, \text{Id}),$$

which in a chart $\mathcal{M} \simeq \text{Perf}(A_b)$ is computed by $C_{\text{ch}}^{\bullet}(A_b, A_b)$. On the Koszul locus, this is the three-term Gerstenhaber algebra of (A.43).

A.17.4 THE ANNULUS TRACE: FIRST MODULAR SHADOW OF THE OPEN SECTOR

THEOREM A.17.16 (*Annulus trace theorem*;). Let (X, D, τ) be a tangential log curve with a single puncture p , and let $\mathcal{M}$ be the boundary category (an E_1 -category, i.e. a monoidal dg-category whose monoidal structure is locally constant along the boundary interval I_p). There is a canonical quasi-isomorphism

$$\int_{S_p^1} \mathcal{M} \simeq HH_*(\mathcal{M}).$$

In a chart $\mathcal{M} \simeq \text{Perf}(A_b)$ (Theorem A.17.14(i)), the right side is the categorical Hochschild homology of the A_{∞} -algebra A_b :

$$HH_*(A_b) = H_*(B^{\text{cyc}}(A_b), d_{\text{cyc}}),$$

where $B^{\text{cyc}}(A_b) = \bigoplus_{n \geq 0} (sA_b)^{\otimes n} \otimes_{(\mathbb{Z}/n\mathbb{Z})} A_b$ is the cyclic bar complex.

Proof. The argument applies the Ayala–Francis excision framework for factorization homology [30] to the boundary circle S_p^1 viewed as a 1-manifold on which $\mathcal{M}$ is a locally constant factorization category (by axiom (iv) of Definition ??). The same excision strategy appears for locally constant factorization algebras

in Theorem 17.8.3 (§17.8); the present proof adapts it to the boundary-circle setting of the open/closed factorization category, retaining full detail for self-containment.

The proof proceeds in five steps: an excision decomposition of S_p^1 , identification of the resulting bar-type complex, verification of the differential, the passage to cyclic invariants, and Morita functoriality.

Step 1: Excision decomposition of S_p^1 . Choose two distinct points $\star_+, \star_- \in S_p^1$ with $\star_+ \neq \star_-$, and let

$$U_+ := S_p^1 \setminus \{\star_-\}, \quad U_- := S_p^1 \setminus \{\star_+\}.$$

Each $U_\pm$ is diffeomorphic to $\mathbb{R}$ and the intersection $U_+ \cap U_- = S_p^1 \setminus \{\star_+, \star_-\}$ has two connected components, each diffeomorphic to an open interval. The pair $\{U_+, U_-\}$ forms a Weiss cover of S_p^1 in the sense of [30]: every finite subset of S_p^1 is contained in some U_α . The excision theorem for factorization homology [30, Theorem 3.24] gives a canonical equivalence

$$\int_{S_p^1} \mathcal{M} \simeq \int_{U_+} \mathcal{M} \underset{\int_{U_+ \cap U_-} \mathcal{M}}{\overset{\mathbf{L}}{\otimes}} \int_{U_-} \mathcal{M}. \quad (\text{A.45})$$

This is a derived tensor product over the factorization homology of the intersection, with the two maps given by the restriction functors $U_\pm \hookrightarrow U_+ \cap U_-$.

Step 2: Evaluation on intervals. Since $\mathcal{M}$ is an E_1 -category (locally constant factorization category on the 1-manifold S_p^1 , axiom (iv) of Definition ??), factorization homology over any interval $J \cong \mathbb{R}$ recovers the underlying category:

$$\int_J \mathcal{M} \simeq \mathcal{M}. \quad (\text{A.46})$$

This is because $\mathbb{R}$ is contractible, so the factorization homology collapses: the constant cosheaf on $\text{Ran}(\mathbb{R})$ is computed by global sections [303, Proposition 5.4.5.15], [30, Theorem 3.19].

In a chart $\mathcal{M} \simeq \text{Perf}(A_b)$ with compact generator b , the evaluation (A.46) is witnessed by the A_∞ -algebra $A_b = \text{RHom}_{\mathcal{M}}(b, b)$: one has $\int_{\mathbb{R}} A_b \simeq A_b$ as an A_b -bimodule (the “diagonal” bimodule).

Step 3: Identification of the derived tensor product. Applying Step 2 to the three terms in (A.45):

$$\int_{U_+} \mathcal{M} \simeq A_b \quad (\text{right } A_b^e\text{-module via restriction to } U_+ \cap U_-), \quad (\text{A.47})$$

$$\int_{U_-} \mathcal{M} \simeq A_b \quad (\text{left } A_b^e\text{-module}),$$

$$\int_{U_+ \cap U_-} \mathcal{M} \simeq A_b \otimes A_b^{\text{op}} =: A_b^e \quad (\text{the enveloping algebra}). \quad (\text{A.48})$$

For (A.48): the intersection $U_+ \cap U_-$ has two connected components, say V_L and V_R , each diffeomorphic to $\mathbb{R}$. Factorization homology is symmetric monoidal with respect to disjoint union [30, Theorem 3.19], so $\int_{V_L \sqcup V_R} \mathcal{M} \simeq (\int_{V_L} \mathcal{M}) \otimes (\int_{V_R} \mathcal{M}) \simeq A_b \otimes A_b$. The two inclusions $V_L, V_R \hookrightarrow U_+$ (resp. U_-) compose to give A_b the structure of an (A_b, A_b) -bimodule, equivalently a right (resp. left) A_b^e -module via $a \cdot (x \otimes y^{\text{op}}) = x \cdot a \cdot y$ (resp. $(x \otimes y^{\text{op}}) \cdot a = y \cdot a \cdot x$ with A_∞ corrections). The bimodule structure on the right side in (A.47) has the left action coming from the inclusion $V_L \hookrightarrow U_+$ and the right action from $V_R \hookrightarrow U_+$; concretely, both act by the A_∞ -multiplication of A_b .

Substituting into (A.45):

$$\int_{S_p^1} \mathcal{M} \simeq A_b \underset{A_b^e}{\overset{\mathbf{L}}{\otimes}} A_b. \quad (\text{A.49})$$

This is a derived tensor product of bimodules: A_b is a right A_b^e -module (from the right interval decomposition) and A_b is a left A_b^e -module (from the left interval decomposition).

Step 4: The two-sided bar complex resolves the derived tensor product. The derived tensor product (A.49) is computed by the *two-sided bar complex* $B(A_b, A_b^e, A_b)$:

$$B(A_b, A_b^e, A_b)_n = A_b \otimes (sA_b)^{\otimes n} \otimes A_b, \quad n \geq 0. \quad (\text{A.50})$$

The differential d_{bar} on $B(A_b, A_b^e, A_b)$ is the sum of the internal A_∞ -differential b' and the simplicial face maps b'' : for a typical element $a_0[a_1] \cdots [a_n]a_{n+1}$,

$$\begin{aligned} b''(a_0[a_1] \cdots [a_n]a_{n+1}) &= \sum_{i=0}^{n-1} (-1)^{\epsilon_i} a_0[a_1] \cdots [m_2(a_i, a_{i+1})] \cdots [a_n]a_{n+1} \\ &\quad + (-1)^{\epsilon_n} m_2(a_0, a_1)[a_2] \cdots [a_n]a_{n+1} \\ &\quad + (-1)^{\epsilon_{n+1}} a_0[a_1] \cdots [a_{n-1}]m_2(a_n, a_{n+1}), \end{aligned} \quad (\text{A.51})$$

where ϵ_i are the standard Koszul signs for desuspended elements (Appendix G). The higher A_∞ -operations m_k for $k \geq 3$ contribute the b' terms (the internal differential of the bimodule resolution).

The two-sided bar complex (A.50) is naturally identified with the *cyclic bar complex* $B^{\text{cyc}}(A_b)$: an element $a_0[a_1] \cdots [a_n]a_{n+1}$ in (A.50) with a_0 and a_{n+1} not suspended is the same datum as a cyclic word $a_0 \otimes a_1 \otimes \cdots \otimes a_n \otimes a_{n+1}$ with the identification $(a_0, a_1, \dots, a_n, a_{n+1}) \sim (a_{n+1}, a_0, a_1, \dots, a_n)$ (cyclic permutation of the unsuspended slots). The differential (A.51) becomes the standard topological Hochschild boundary operator under this identification, because the last face map wraps a_n past a_{n+1} to compose with a_0 ; this is the cyclic trace term that distinguishes the topological Hochschild differential from the bar differential.

Therefore:

$$A_b \overset{\mathbf{L}}{\otimes}_{A_b^e} A_b \simeq H_*(B^{\text{cyc}}(A_b), d_{\text{cyc}}) = HH_*(A_b).$$

The first equivalence is that the two-sided bar complex computes the derived tensor product (it is a free A_b^e -resolution of A_b ; see [297, §5.3], [299, §2.2]). The second is the definition of topological Hochschild homology.

Step 5: Morita invariance. The quasi-isomorphism type of $\int_{S^1_p} \mathcal{M}$ depends only on the Morita equivalence class of $\mathcal{M}$, not on the choice of compact generator b . This holds because factorization homology is a functor of the E_1 -category [30, Theorem 3.19], and Morita equivalent E_1 -categories (those with equivalent module categories) produce canonically quasi-isomorphic factorization homology: if $b' \in \mathcal{M}$ is another compact generator with $A_{b'} = \text{RHom}(b', b')$, the Morita bimodule $M = \text{RHom}(b, b')$ induces a quasi-isomorphism $HH_*(A_b) \simeq HH_*(A_{b'})$ via the derived trace $\text{Tr}_M: A_b \otimes_{A_b^e}^{\mathbf{L}} A_b \xrightarrow{\sim} A_{b'} \otimes_{A_{b'}^e}^{\mathbf{L}} A_{b'}$ ([260, Theorem 1.2]).

Combining Steps 1–5: $\int_{S^1_p} \mathcal{M} \simeq A_b \otimes_{A_b^e}^{\mathbf{L}} A_b \simeq HH_*(A_b) = HH_*(\mathcal{M})$. $\square$

Remark A.17.17 (Relation to the Ayala–Francis excision axiom). The excision decomposition in Step 1 is the instance of the Ayala–Francis [30] “ $\otimes$ -excision” axiom for factorization homology applied to the standard Weiss cover of S^1 . The key geometric input is that S^1 admits a cover by two contractible open sets whose intersection is the disjoint union of two contractible open sets, a feature specific to the circle among closed 1-manifolds (the unique non-simply-connected case). This is why factorization homology of an E_1 -algebra

over S^1 produces a two-sided bar construction (two external modules tensored over an enveloping algebra from two intersection components), hence topological Hochschild homology, rather than something more exotic.

For higher-dimensional manifolds M , the excision axiom still holds but the resulting complex involves higher-degree factorization data from the topology of M . The present theorem uses only the 1-dimensional case, where the open sector is an E_1 -category and the computation is purely algebraic.

Remark A.17.18 (The annulus as first modular shadow). The annulus $S_p^1 \times [0, 1]$ is the simplest bordered surface with two boundary components. Its partition function in the open-closed theory is the *trace* of the open sector: $Z_{\text{ann}} = \text{Tr}_{\mathcal{M}}(\text{Id})$. By the annulus trace theorem, this is the topological Hochschild homology class $[1] \in HH_0(A_b)$. This is the *first modular shadow of the open sector*: a trace of the open world that precedes the genus-1 curvature $\kappa(\mathcal{A})\lambda_1$ in the modular hierarchy. The Calabi–Yau/cyclic structure on $\mathcal{M}$ (when it exists) upgrades $HH_*(A_b) \simeq HH^{2-*}(A_b)$ by Poincaré duality, connecting the annulus trace to the derived center.

PROPOSITION A.17.19 (Annulus degeneration and the genus-1 curvature;). Let $\mathcal{A}$ be a modular Koszul chiral algebra with boundary category $\mathcal{M}$ and annulus trace class $\text{Tr}_{\mathcal{A}} = [1] \in HH_0(\mathcal{M})$. The non-separating nodal degeneration of the annulus $S_p^1 \times [0, 1]$ to a once-punctured torus $\Sigma_{1,1}$ sends the annulus trace to the genus-1 curvature:

$$\Delta_{\text{ns}}(\text{Tr}_{\mathcal{A}}) = \kappa(\mathcal{A}) \cdot \lambda_1,$$

where $\Delta_{\text{ns}}: HH_*(\mathcal{M}) \rightarrow H^*(\overline{\mathcal{M}}_{1,1})$ is the clutching map associated to the non-separating degeneration, and $\lambda_1 \in H^2(\overline{\mathcal{M}}_{1,1})$ is the first Chern class of the Hodge bundle.

Proof. The non-separating degeneration identifies the two boundary components of the annulus $S^1 \times [0, 1]$ to create a genus-1 surface. In the open/closed MC framework (Theorem A.17.21(d)), the clutching operator Δ_{clutch} acts on the annulus amplitude $\text{Tr}_{\mathcal{A}} \in HH_0(\mathcal{M})$ by contracting the two boundary insertions using the cyclic pairing of the Calabi–Yau structure. At the bar-complex level, this is precisely the genus-1 component $\Theta_{\mathcal{A}}^{(1,0)}$ of the bar-intrinsic MC element $\Theta_{\mathcal{A}} = D_{\mathcal{A}} - d_0$ (Theorem 13.21.69). By Theorem D (Theorem 13.21.44), $\Theta_{\mathcal{A}}^{(1,0)} = \kappa(\mathcal{A}) \cdot \lambda_1$ on the Koszul locus. Therefore $\Delta_{\text{ns}}(\text{Tr}_{\mathcal{A}}) = \kappa(\mathcal{A}) \cdot \lambda_1$, as claimed. $\square$

A.17.5 THE OPEN/CLOSED MC ELEMENT

Construction A.17.20 (Open/closed MC element). Let $(\mathcal{A}, X, \langle \cdot, \cdot \rangle, k)$ be a gravitational input and let (X, D, τ) be a tangential log curve with $\mathcal{A}$ -modules $\mathcal{M}_1, \dots, \mathcal{M}_r$ at the punctures. The open-closed convolution algebra $\mathfrak{g}_{\mathcal{A}, \vec{\mathcal{M}}}^{\text{oc}}$ (Definition 5.4.1) carries a dg Lie structure with seven-component differential (5.5). Define the *open/closed MC element*

$$\Theta_{\mathcal{A}}^{\text{oc}} := \Theta_{\mathcal{A}} + \sum_{j=1}^r \mu^{\mathcal{M}_j},$$

where $\Theta_{\mathcal{A}} = D_{\mathcal{A}} - d_0 \in \mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ is the bar-intrinsic MC element (Theorem 13.21.69), with d_0 the genus-0 free differential and $D_{\mathcal{A}}$ the full bar differential, viewed in $\mathfrak{g}^{\text{oc}}$ via the closed-sector inclusion (5.5), and $\mu^{\mathcal{M}_j} = \sum_{n \geq 1} \mu_n^{\mathcal{M}_j}$ is the A_{∞} -module structure on $\mathcal{M}_j$.

THEOREM A.17.21 (Open/closed MC equation;). The element $\Theta_{\mathcal{A}}^{\text{oc}}$ satisfies the Maurer–Cartan equation in $\mathfrak{g}_{\mathcal{A}, \vec{\mathcal{M}}}^{\text{oc}}$:

$$D^{\text{oc}} \Theta_{\mathcal{A}}^{\text{oc}} + \frac{1}{2} [\Theta_{\mathcal{A}}^{\text{oc}}, \Theta_{\mathcal{A}}^{\text{oc}}] + \hbar \Delta_{\text{clutch}}(\Theta_{\mathcal{A}}^{\text{oc}}) = 0. \quad (\text{A.52})$$

This equation decomposes by sector:

- (a) *Pure closed sector.* The restriction to $\vec{m} = 0$ recovers the closed MC equation $D_{\mathcal{A}}\Theta_{\mathcal{A}} + \frac{1}{2}[\Theta_{\mathcal{A}}, \Theta_{\mathcal{A}}] + \hbar\Delta(\Theta_{\mathcal{A}}) = 0$.
- (b) *Pure open sector.* The restriction to $k = 0$ recovers the A_{∞} -module equations $\sum_{i+j=n} \mu_i \circ \mu_j = 0$ at each boundary component.
- (c) *Mixed sector.* The terms with $k \geq 1$ and $|\vec{m}| \geq 1$ encode the bulk-to-boundary couplings: how closed-sector operators (elements of $C_{\text{ch}}^{\bullet}(\mathcal{A}, \mathcal{A})$) act on the boundary modules $\mathcal{M}_j$.
- (d) *Clutching sector.* The $\hbar\Delta_{\text{clutch}}$ term encodes the genuinely modular data: sewing boundary circles together to create higher-genus surfaces.

Proof. The equation (A.52) is the Stokes theorem on the bordered FM compactification $\overline{C}_{k,\vec{m}}^{\text{oc}}(X, D, \tau)$ (Construction 5.3.7). The total boundary of $\overline{C}_{k,\vec{m}}^{\text{oc}}$ decomposes into four types (interior collision, consecutive boundary collision, mixed bubbling, nodal clutching), and the vanishing of the total codimension-one boundary contribution gives precisely the four-sector decomposition above.

The pure closed sector (a) is the restriction to the interior FM compactification $\text{FM}_k(X | D)$, which is the known MC equation for $\Theta_{\mathcal{A}}$. The pure open sector (b) is the restriction to the associahedral factor $\prod_j K_{m_j}$, giving the A_{∞} relations. The mixed sector (c) comes from the mixed boundary strata (Type III faces), and the clutching sector (d) from the nodal boundary strata (Type IV faces). $\square$

A.17.6 THE OPEN/CLOSED PROJECTION PRINCIPLE

THEOREM A.17.22 (*Open/closed projection principle*;). The holographic modular Koszul datum $\mathcal{H}(\mathcal{A}) = (\mathcal{A}, \mathcal{A}^!, C, r(z), \Theta_{\mathcal{A}}, \nabla^{\text{hol}})$ (Definition K.7.1) is recovered from the open/closed MC element $\Theta_{\mathcal{A}}^{\text{oc}}$ by projection:

- (i) The *closed projection* $\pi_{\text{cl}}: \mathfrak{g}^{\text{oc}} \rightarrow \mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ sends $\Theta_{\mathcal{A}}^{\text{oc}} \mapsto \Theta_{\mathcal{A}}$.
- (ii) The *open projection* $\pi_{\text{op}}: \mathfrak{g}^{\text{oc}} \rightarrow \prod_j \text{End}(\mathcal{M}_j)$ sends $\Theta_{\mathcal{A}}^{\text{oc}} \mapsto \sum_j \mu^{\mathcal{M}_j}$.
- (iii) The *mixed projection* at genus 0, one interior point, and n boundary points on one component gives the *bulk-to-boundary map* $\iota_{0,1,n}: C_{\text{ch}}^{\bullet}(\mathcal{A}, \mathcal{A}) \rightarrow \text{Hom}(\mathcal{M}_j^{\otimes n}, \mathcal{M}_j)$, which is the universal open/closed coupling (Theorem A.17.10) realized geometrically.
- (iv) The *shadow obstruction tower projections* $\Theta_{\mathcal{A}}^{\text{oc}}|_{\leq r}$ at each degree r recover the nonlinear shadows $(\kappa(\mathcal{A}), \mathfrak{C}, \mathfrak{Q}, \dots)$ in the closed sector, and the *open boundary corrections* $(\mu_2^{\mathcal{M}}, \mu_3^{\mathcal{M}}, \dots)$ in the open sector.

Proof. Each statement follows from the additive decomposition $\Theta_{\mathcal{A}}^{\text{oc}} = \Theta_{\mathcal{A}} + \sum_j \mu^{\mathcal{M}_j}$ and the seven-component structure (5.5) of the differential D^{oc} . The closed projection (i) drops the boundary terms (d_{bdy} and d_{mix}), recovering the five-component closed differential. The open projection (ii) drops the interior terms. The mixed projection (iii) extracts the cross terms, which live in $\text{Hom}(C_*(\overline{C}_{1,(n)}^{\text{oc}}), \text{Hom}(\mathcal{A} \otimes \mathcal{M}_j^{\otimes n}, \mathcal{A} \otimes \mathcal{M}_j))$. At genus 0 on a formal disk, this identifies with the chiral chiral Hochschild cochain complex by Theorem A.17.14(ii). The shadow obstruction tower projections (iv) follow from the degree filtration on $\mathfrak{g}^{\text{oc}}$. $\square$

THEOREM A.17.23 (*MC-forced open-closed consistency*;). Let $\mathcal{A}$ be a modular Koszul chiral algebra with boundary category $\mathcal{M}$, and let $\Theta_{\mathcal{A}}^{\text{oc}} = \Theta_{\mathcal{A}} + \sum_j \mu^{\mathcal{M}_j}$ be the open/closed MC element

(Construction A.17.20). The modular MC equation (Theorem A.17.21) simultaneously determines, at every genus $g \geq 0$:

- (a) *Closed-sector genus tower.* The closed projection $\pi_{\text{cl}}(\Theta_{\mathcal{A}}^{\text{oc}})|_g = \Theta_{\mathcal{A}}|_g$ recovers the genus- g component of the bar-intrinsic MC element. On the uniform-weight lane, this is the genus tower $F_g = \kappa(\mathcal{A}) \cdot \lambda_g$ (UNIFORM-WEIGHT) (Theorem 13.21.69(ii), Theorem D).
- (b) *Open-sector module structure.* The open projection $\pi_{\text{op}}(\Theta_{\mathcal{A}}^{\text{oc}})|_g$ recovers the genus- g component of the A_{∞} -module operations $\mu_n^{\mathcal{M}_j}$, twisted by the genus- g curvature $\kappa(\mathcal{A}) \cdot \omega_g$.
- (c) *Clutching sector.* The $\hbar\Delta_{\text{clutch}}$ term encodes the genus-raising sewing: non-separating clutching $\xi_{\text{ns}}^*(\Theta^{(g+1)}) = \Delta_{\text{ns}}(\Theta^{(g)})$ and separating clutching $\xi_{\text{sep}}^*(\Theta^{(g)}) = \sum_{g_1+g_2=g} \Theta^{(g_1)} \star \Theta^{(g_2)}$ (Theorem 13.21.69(iii)).

Since all three sectors are projections of the *same* MC element $\Theta_{\mathcal{A}}^{\text{oc}}$, the genus- g component of the MC equation is a single identity whose restriction to each sector yields a compatible system. In particular:

- (d) *Open-closed consistency at every genus.* The closed-sector genus- g amplitude and the open-sector genus- g amplitude are not independent: both are determined by $\Theta_{\mathcal{A}}^{\text{oc}}|_g$, and the MC equation constrains their joint values. No additional consistency check is required beyond the MC equation itself.

Proof. The MC equation $D^{\text{oc}}\Theta^{\text{oc}} + \frac{1}{2}[\Theta^{\text{oc}}, \Theta^{\text{oc}}] + \hbar\Delta_{\text{clutch}}(\Theta^{\text{oc}}) = 0$ holds at all genera by Theorem A.17.21. Each genus- g component of this equation lives in $\mathfrak{g}_{\mathcal{A}, \overline{\mathcal{M}}}^{\text{oc}, (g)}$, which decomposes into the four sectors of Theorem A.17.21(a)–(d). The projections (a)–(c) follow from Theorem A.17.22: the closed projection recovers $\Theta_{\mathcal{A}}|_g$ with the scalar trace $\kappa(\mathcal{A})\lambda_g$ on the uniform-weight lane; the open projection recovers the module operations; the clutching projection recovers the separating and non-separating degenerations.

Part (d) is the key structural consequence. The genus- g MC equation is a *single* vanishing condition in $\mathfrak{g}^{\text{oc}, (g)}$. Its restriction to any sector is a consequence of the same equation. Therefore any identity obtained by projecting to the closed sector is automatically compatible with the identity obtained by projecting to the open sector. The compatibilities are not additional axioms: they are projections of the Stokes theorem on the bordered FM compactification $\overline{C}_{k, \vec{m}}^{\text{oc}}$. $\square$

Remark A.17.24 (Scope and residual questions). Theorem A.17.23 proves that open and closed data are consistent at every genus, but it does not by itself determine the closed-sector amplitudes. Two distinct questions remain:

- (i) *The scalar identification.* The specific formula $F_g = \kappa(\mathcal{A}) \cdot \lambda_g$ (UNIFORM-WEIGHT) is proved on the uniform-weight lane and at genus 1 for all families. For multi-weight algebras at genus $g \geq 2$, the scalar formula *fails*: the free energy receives a cross-channel correction $\delta F_g^{\text{cross}} \neq 0$ (**op:multi-generator-universality**, resolved negatively; Theorem 13.22.225). The MC equation does not resolve this because the question is about which tautological class on $\overline{\mathcal{M}}_g$ appears in the scalar trace of $\Theta_{\mathcal{A}}$, not about open-closed consistency.
- (ii) *The independent open-sector derivation.* Computing F_g from iterated clutching on C_{op} alone (without invoking the bar-intrinsic construction) and verifying agreement with the closed-sector tower is a separate programme. The MC-forced consistency guarantees that such a computation, if carried out, *must* agree; it does not construct the computation.

A.17.7 CT-2: THE MODULAR COOPERAD CONJECTURE FOR THE OPEN SECTOR

The open-sector factorization dg category C_{op} carries cocomposition maps read off from clutching on bordered Fulton–MacPherson compactifications, and at genus 1 the annulus trace recovers the open-closed identification proved in Theorem A.17.23. The structural question left open by that theorem is whether these partial data assemble into a *modular cooperad* in the sense of Getzler–Kapranov [435], and whether the assembled structure is determined by the open-closed MC element $\Theta_{\mathcal{A}}^{\text{oc}}$. We record the expected answer as a conjecture and give a five-phase road map whose first three phases are already proved.

Conjecture A.17.25 (CT-2: modular cooperad on the open sector). Let $\mathcal{A}$ be a gravitational input (Definition K.7.1) and let C_{op} denote the open-sector factorization dg category of §???. There exists a modular cooperad structure

$$\Delta_{\text{mod}}^{\text{op}} : C_{\text{op}} \longrightarrow C_{\text{op}} \widehat{\boxtimes} C_{\text{op}}$$

on C_{op} with the following three properties.

- (a) *Clutching compatibility.* The cocomposition $\Delta_{\text{mod}}^{\text{op}}$ is compatible with the clutching maps on the bordered Fulton–MacPherson compactification $\overline{C}_{k,\vec{m}}^{\text{oc}}$ of §5.3.
- (b) *Annulus trace at genus 1.* The trace of $\Delta_{\text{mod}}^{\text{op}}$ at genus 1 recovers the annulus identification of Theorem A.17.16.
- (c) *MC determination.* The full structure is determined by the open-closed MC element $\Theta_{\mathcal{A}}^{\text{oc}}$ of Definition A.17.20: two modular cooperad structures on C_{op} that agree on $\Theta_{\mathcal{A}}^{\text{oc}}$ are equivalent as $(\infty, 2)$ -functors.

Remark A.17.26 (Three-layer decomposition). The content of Conjecture A.17.25 decomposes into three layers whose statuses are different.

Layer 1 (existence; categorical lift). The cooperad structure on C_{op} lifts the known modular operad structure on the closed sector C_{cl} through the bar-cobar adjunction of Theorem A. The lift exists because C_{op} is homotopy Koszul: this is proved in Vol II via the PVA descent (see the chapter on the open-sector PVA). Layer 1 is the content of Phase 4 below.

Layer 2 (compatibility; automatic from Getzler–Kapranov). The Getzler–Kapranov modular operad framework [435] guarantees that any cooperad structure compatible with clutching on the bordered Fulton–MacPherson compactification is automatically compatible with the factorization structure: no additional axioms are needed. Layer 2 is therefore subsumed by Layer 1 once clutching compatibility is established.

Layer 3 (uniqueness; $(\infty, 2)$ -categorical integration). Uniqueness of the cooperad structure requires integrating the strict clutching data to an $(\infty, 2)$ -category. This is where the categorical gap sits. The blueprint is the Brochier–Woike strategy for factorization homology and topological field theory [72], which produces an $(\infty, 2)$ -functor from clutching data under additional coherence hypotheses. Layer 3 is the content of Phase 5 below.

Remark A.17.27 (Five-phase road map). The Conjecture A.17.25 proof strategy decomposes into five phases. The first three are proved; the last two are the genuinely conjectural content.

- (i) *Phase 1: Bordered FM construction.* PROVED. The bordered Fulton–MacPherson compactification $\overline{C}_{k,\vec{m}}^{\text{oc}}(X, D, \tau)$ with its clutching and gluing strata is constructed in the Vol II chapter on bordered FM geometry, building on [278]. Cross-reference: §5.3 of the present volume.
- (ii) *Phase 2: Chain-level $D_{\text{oc}}^2 = 0$.* PROVED. The open-closed differential squares to zero on the chain complex, with the convolution-level identity proved via Mok’s log-FM framework and the ambient differential

identity recorded in Theorem A.17.21(a). This fixes the ambient cochain model on which any cooperad structure must act.

- (iii) *Phase 3: Annulus trace at genus 1. PROVED.* The genus-1 trace of $\Theta_{\mathcal{A}}^{\text{oc}}$ recovers the annulus identification by a Zhu-type argument, producing the open-closed pairing on $\text{HH}_*(\mathcal{A})$ at $g = 1$ (Theorem A.17.16). This pins down Conjecture A.17.25(b).
- (iv) *Phase 4: Categorical lift existence. CONJECTURE.* Lift the modular cooperad structure along the bar-cobar adjunction from C_{cl} to C_{op} , using homotopy Koszulness of C_{op} (Vol II PVA descent) to promote the strict clutching data to a cooperad up to coherent homotopy. This is the main CT-2 existence claim; it implies Conjecture A.17.25(a).
- (v) *Phase 5: $(\infty, 2)$ -uniqueness. CONJECTURE.* Integrate the homotopy-coherent clutching data to an $(\infty, 2)$ -category and prove that two such integrations agreeing on $\Theta_{\mathcal{A}}^{\text{oc}}$ are equivalent as $(\infty, 2)$ -functors. This is the main CT-2 uniqueness claim; it implies Conjecture A.17.25(c). The strategy follows Brochier–Woike [72].

The statement of Conjecture A.17.25 asserts Phase 4 and Phase 5 together: the modular cooperad structure on C_{op} exists and is unique up to $(\infty, 2)$ -equivalence.

Remark A.17.28 (The Brochier–Woike strategy and the uniqueness gap). The obstruction separating Phases 1–3 from Phases 4–5 is *categorical, not geometric*. The bordered FM geometry, the chain-level differential, and the genus-1 annulus trace are all constructed at the level of dg categories and their homologies; clutching compatibility is a concrete chain-level identity. What is missing is the passage from these strict chain-level data to a homotopy-coherent $(\infty, 2)$ -category of open-sector factorization algebras in which cooperad structures are classified up to equivalence.

The Brochier–Woike strategy [72] provides the blueprint: one first builds a $(2, 2)$ -category of bordered factorization data with strict clutching, and then localizes at the homotopy equivalences using the universal property of $(\infty, 2)$ -localization. The step that does *not* transfer automatically is the verification that the localization preserves the clutching compatibility recorded in Conjecture A.17.25(a); this is the categorical obstruction. Once the localization is shown to preserve clutching, the uniqueness statement of Conjecture A.17.25(c) follows by the Brochier–Woike rigidity argument applied to $\Theta_{\mathcal{A}}^{\text{oc}}$ as the classifying datum. The gap is therefore isolated to a single categorical step, and CT-2 is not obstructed by any geometric or chain-level computation.

A.17.8 THE FIRST NONLINEAR OPEN/CLOSED INVARIANT

Construction A.17.29 (Open/closed quartic resonance class). Let $\mathcal{A}$ be a gravitational input of shadow archetype $\mathbf{M}$ (Definition K.7.1, mixed class with $r_{\text{max}} = \infty$). The quartic contact invariant $\mathfrak{Q}^{\text{ct}}(\mathcal{A}) \in C_{\text{ch}}^2(\mathcal{A}, \mathcal{A})$ is a degree-2 chiral Hochschild cochain measuring the quartic nonlinearity of the OPE. Define the *open/closed quartic resonance class*

$$\mathfrak{R}_4^{\text{oc}}(\mathcal{A}) := [\mathfrak{Q}^{\text{ct}}(\mathcal{A})] + [\mathfrak{C}(\mathcal{A}) \star_{P_{\mathcal{A}}} \mathfrak{C}(\mathcal{A})] \in H^2(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \delta) = \mathcal{Z}^2,$$

where $\mathfrak{C}(\mathcal{A})$ is the cubic shadow (eq. (18.2)), $H_{\mathcal{A}}$ is the Hessian (the quadratic shadow, i.e. the modular characteristic $\kappa(\mathcal{A})$ on the one-dimensional primary slice), $P_{\mathcal{A}} = H_{\mathcal{A}}^{-1}$ is the propagator, and $(\mathfrak{C} \star_{P_{\mathcal{A}}} \mathfrak{C})(x_1, x_2, x_3, x_4) := \sum_{\alpha} \mathfrak{C}(x_1, x_2, e_{\alpha}) P_{\mathcal{A}}^{\alpha\beta} \mathfrak{C}(e_{\beta}, x_3, x_4)$ is the sewing product contracting one pair of indices with the propagator. The first term is the local quartic contact; the second is the tree correction from two cubic emissions joined by one propagator.

THEOREM A.17.30 (*Vanishing and nonvanishing of $\mathfrak{R}_4^{\text{oc}}(\mathfrak{j})$ Gaussian vanishing.* For $\mathcal{A}$ of shadow archetype G (Heisenberg, lattice, free fermion): $\mathfrak{R}_4^{\text{oc}}(\mathcal{A}) = 0$.

- (ii) *Lie/tree vanishing of contact.* For $\mathcal{A}$ of archetype L (affine $\widehat{\mathfrak{g}}$ at generic level): the contact term vanishes in the standard gauge, $[\mathfrak{Q}^{\text{ct}}(\mathcal{A})] = 0$, but the tree correction $[\mathfrak{C} \star_P \mathfrak{C}]$ is generically nonzero.
- (iii) *Contact termination.* For $\mathcal{A}$ of archetype C ($\beta\gamma$ on the weight-changing line): the tree correction vanishes ($\mathfrak{C}_{\beta\gamma} = 0$), and the contact term $[\mathfrak{Q}_{\beta\gamma}^{\text{ct}}]$ collapses by rank-one abelian rigidity (Corollary 18.5.16).
- (iv) *Mixed nonvanishing.* For $\mathcal{A}$ of archetype M (Virasoro, principal $\mathcal{W}_N$): both terms are generically nonzero, and

$$\mathfrak{R}_4^{\text{oc}}(\text{Vir}_c) = \left[\frac{10}{c(5c + 22)} \right] \cdot x^4 + [\mathfrak{C}_{\text{Vir}} \star_{P_{\text{Vir}}} \mathfrak{C}_{\text{Vir}}] \neq 0$$

for generic c . The contact term has poles at $c = 0$ and $c = -22/5$ (the null-state divisor), while the tree term is regular.

Proof. (i)–(iii) follow directly from the shadow archetype classification and the explicit computations in the nonlinear modular shadows appendix (Appendix 18): Heisenberg has $\mathfrak{C} = \mathfrak{Q} = 0$; affine has $\mathfrak{Q}^{\text{ct}} = 0$ (Jacobi identity kills the quartic obstruction) but $\mathfrak{C}(x, y, z) = \kappa(x, [y, z]) \neq 0$; $\beta\gamma$ has $\mathfrak{C} = 0$ and $\mu_{\beta\gamma} = 0$ on the weight-changing line.

(iv) For Virasoro: $\mathfrak{C}_{\text{Vir}} = 2x^3$ from the universal gravitational cubic tensor, and $\mathfrak{Q}_{\text{Vir}}^{\text{ct}} = 10/(c(5c + 22))$ from the quartic contact computation. Both are nonzero for generic c , and they contribute independently to $\mathfrak{R}_4^{\text{oc}}$ since contact lives in the quartic sector of $\mathcal{C}_{\text{ch}}^2$ while the tree term lives in the image of the sewing product $\mathcal{C}_{\text{ch}}^1 \star \mathcal{C}_{\text{ch}}^1 \rightarrow \mathcal{C}_{\text{ch}}^2$. $\square$

Remark A.17.31 (*The open/closed resonance class as gravitational observable*). The class $\mathfrak{R}_4^{\text{oc}}(\mathcal{A}) \in \mathcal{Z}^2$ is the first genuinely *nonlinear* gravitational observable in the holographic modular Koszul datum. The scalar modular characteristic $\kappa(\mathcal{A})$ and its duality constraint (Theorem D) are linear invariants of the boundary OPE. The cubic shadow $\mathfrak{C}(\mathcal{A})$ is the first nonlinear correction but lives in $\mathcal{Z}^1$ (derivations), not in $\mathcal{Z}^2$ (obstructions). The quartic class $\mathfrak{R}_4^{\text{oc}}$ is the first obstruction-level nonlinear invariant, and its nonvanishing for $\mathcal{W}$ -type theories signals that the boundary A_∞ structure is *irreducibly quartic*: the perturbative partition function cannot be captured by any quadratic or cubic truncation of the modular master equation.

The clutching law for $\mathfrak{R}_4^{\text{oc}}$ (Theorem 18.7.11) shows that this obstruction propagates across nodal degenerations, and the tree correction $\mathfrak{C} \star_P \mathfrak{C}$ is the trace of cubic graviton exchange across a boundary node. In the holographic interpretation: the bulk gravitational scattering at quartic order receives contributions from both local four-point contact (the $\mathfrak{Q}^{\text{ct}}$ term) and tree-level exchange of two three-graviton vertices (the $\mathfrak{C} \star_P \mathfrak{C}$ term).

Remark A.17.32 (*$\mathcal{W}_3$ and the first nonlinear composite*). The $\mathcal{W}_3$ algebra is the minimal example where $\mathfrak{R}_4^{\text{oc}}$ detects genuinely nonlinear composite structure. The W – W OPE produces the quadratic composite $\Lambda := :TT: - \frac{3}{10} \partial^2 T$, which lies outside the linear span of the strong generators. The quartic contact coefficient receives contributions from both T – T – T – T and T – T – W – W channels. The quartic resonance divisor for $\mathcal{W}_3$ contains the factor $c(2c - 1)(5c + 22)$ (cf. the discussion in Appendix 18), where $c = 1/2$ is the Ising model (minimal model $M(4, 3)$) and $c = -22/5$ is the Yang–Lee edge singularity (minimal model $M(2, 5)$). These are the first two points where the boundary shadow obstruction tower degenerates.

A.17.9 THE MODULAR KOSZUL DATUM, COMPLETED

Definition A.17.33 (*Completed modular Koszul datum*). Let $(\mathcal{A}, X, \langle \cdot, \cdot \rangle, k)$ be a gravitational input on a tangential log curve (X, D, τ) with boundary modules $\vec{\mathcal{M}}$. The *completed modular Koszul datum* is the

octuple

$$\Pi_X^{\text{oc}}(\mathcal{A}) := \left(\mathcal{A}, \mathcal{A}^!, \mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A}), \Theta_{\mathcal{A}}^{\text{oc}}, r(z), \nabla^{\text{hol}}, \text{Tr}_{\mathcal{A}}, \mathfrak{R}_{\bullet}^{\text{oc}}(\mathcal{A}) \right)$$

consisting of:

Component	Object	Source
$\mathcal{A}$	boundary chiral algebra	given
$\mathcal{A}^!$	Koszul dual (line-operator algebra)	bar + Verdier
$\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})$	derived center (universal bulk)	Def. A.17.7
$\Theta_{\mathcal{A}}^{\text{oc}}$	open/closed MC element	Constr. A.17.20
$r(z)$	collision residue (classical r -matrix)	Def. K.7.1(c)
∇^{hol}	modular shadow connection	Def. K.7.1(e)
$\text{Tr}_{\mathcal{A}}$	annulus trace (= HH_*)	Thm. A.17.16
$\mathfrak{R}_{\bullet}^{\text{oc}}(\mathcal{A})$	nonlinear resonance tower	Constr. A.17.29

The datum extends the holographic modular Koszul datum $\mathcal{H}(\mathcal{A})$ (Definition K.7.1) by adding the derived center (universal bulk), the annulus trace (open modular shadow), and the nonlinear resonance tower (quartic and higher obstructions in the derived center).

Remark A.17.34 (What the completed datum captures). The completed datum $\Pi_X^{\text{oc}}(\mathcal{A})$ packages the following physical content:

- (a) *Boundary.* $\mathcal{A}$ is the boundary chiral algebra (the “boundary CFT” of holography).
- (b) *Bulk.* $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})$ is the universal bulk, reconstructed from the boundary. Holography is the assertion that the boundary data $\mathcal{A}$ determines the bulk $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})$ and the perturbative gravitational partition function.
- (c) *Lines.* $\mathcal{A}^!$ generates the line-operator category $\mathcal{C} \simeq \mathcal{A}^! \text{-mod}$, which is the modular tensor category of the 3d theory.
- (d) *Scattering.* $r(z)$ is the tree-level bulk scattering matrix, satisfying the classical YBE.
- (e) *Modular completion.* $\Theta_{\mathcal{A}}^{\text{oc}}$ is the all-genera, all-boundary MC element whose projections give the shadow obstruction tower, boundary corrections, and clutching identities.
- (f) *Boundary-holographic nonlinearity.* $\mathfrak{R}_{\bullet}^{\text{oc}}(\mathcal{A})$ detects when the boundary A_{∞} structure becomes irreducibly nonlinear, and its vanishing/nonvanishing separates the shadow archetypes G/L/C/M. The bulk is topological; all perturbative gravitational content is determined by the boundary shadow obstruction tower.

Part III

The Standard Landscape

In Chapter 2, we computed the bar complex, Koszul dual, curvature tower, and $\hat{A}$ -genus for the Heisenberg algebra. Part III applies the same programme to every major family of chiral algebras. These chapters should be read as complete portraits rather than as subordinate examples: each family reveals a structural feature that is invisible in the Heisenberg frame alone. The constructions of Parts I–II (the bar complex, the genus tower, the Koszul pair structure, the shadow obstruction tower, and the ordered refinement) are defined for any augmented chiral algebra satisfying mild finiteness conditions. The question driving Part III is: what do these constructions *produce* when applied to the algebras that arise in practice?

The answer is unexpectedly structured. The bar cohomology dimensions of apparently unrelated algebras (the Kac–Moody algebra $\widehat{\mathfrak{sl}}_2$, the Virasoro algebra, the $\beta\gamma$ -system) share a common discriminant $\Delta(x) = (1 - 3x)(1 + x)$. The genus expansion of every Koszul algebra is controlled by a single obstruction invariant κ , and κ transforms predictably under Drinfeld–Sokolov reduction. The complementarity sums $c + c'$ are root-datum invariants. These are not coincidences; they are the fingerprints of the general theory made visible in specific examples. Each family of chiral algebras reveals a distinct face of the modular Koszul structure: the Feigin–Frenkel involution $k \mapsto -k - 2h^\vee$ is Koszul duality for Kac–Moody algebras; Drinfeld–Sokolov reduction is a Koszul functor; the $\hat{A}$ -genus in the Heisenberg genus expansion witnesses a family index theorem; the Yangian forces a departure from E_∞ -chiral to E_1 -chiral Koszul duality.

The examples are organized along the axis from the E_∞ -commutative atom (Heisenberg) to the E_1 -associative atom (Yangian). Kac–Moody algebras, Virasoro, and $\mathcal{W}$ -algebras are E_∞ -chiral with increasingly complex OPE pole structures. Lattice vertex algebras carry an E_1 sublattice structure visible through screening operators. The Yangian is purely E_1 -chiral: its bar complex uses ordered configuration spaces and Verdier duality acts by R -matrix inversion, not type exchange.

Appendix B

The lattice construction

Lattice vertex algebras are the first genuinely braided family. The Heisenberg algebra (Chapter 2) and affine Kac–Moody algebras (Chapter G) have degenerate braiding: trivial or controlled entirely by the Lie bracket. The lattice construction introduces charge geometry. An even lattice Λ and a 2-cocycle ε select charges, screening operators, and a braiding depending on charge inner products. The bar complex acquires a cocycle twist; the Koszul dual reflects the discriminant group $D(\Lambda)$; the genus tower detects the lattice theta function. Spectral R -matrices and line-operator tensor products of Volume II first appear here.

In the shadow obstruction tower of $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ (Definition 13.22.1), lattice VOAs occupy a distinctive position. The scalar level $\Theta^{\leq 2} = \kappa$ is nonzero with $\kappa(V_\Lambda) = \text{rank}(\Lambda)$, independent of the cocycle ε (Theorem B.14.2). The tower terminates at the scalar level, as for Heisenberg, but for a different reason: the cocycle twist ensures that $\text{Def}_\infty^{\text{mod}}(V_\Lambda)$ is *formal* (curvature and braiding decouple). The Heisenberg tower terminates because all higher brackets vanish identically; the lattice tower terminates because the cocycle twist is *orthogonal* to the curvature direction. This orthogonality is a nontrivial cancellation that sharpens in the more elaborate shadow archetypes of subsequent chapters.

Remark B.o.1 (Three-pillar interpretation: lattice VOAs). In the three-pillar architecture (§K.7.1): (i) the Čech complex of V_Λ carries a Ch_∞ -structure controlled by the cocycle twist; for even unimodular lattices, $F_3 \neq 0$ (unlike Heisenberg): the cocycle relations produce nontrivial homotopies at the chain level; (ii) despite $F_3 \neq 0$ at the Ch_∞ level, the convolution sL_∞ -algebra $\text{hom}_\alpha(C^!, V_\Lambda)$ is *formal* by cocycle-curvature orthogonality (Theorem B.14.2): the transferred L_∞ brackets ℓ_k^{tr} are all coboundaries, so the shadow algebra V_Λ^{sh} reduces to $\mathbb{Q}[\kappa]$ as for Heisenberg, but for a different reason (formality of the deformation algebra, not vanishing of higher operations); (iii) the log-FM geometry $\overline{\text{FM}}_n(C|D)$ is needed when twisted modules with insertions at lattice punctures are present; the braiding data from R -matrices live on $\overline{\text{FM}}_2(C|\{p_1, \dots, p_d\})$.

Every example in Part IV descends from a single algebraic seed. An even lattice Λ with a 2-cocycle ε determines V_Λ ; the choice of Λ selects OPE structure, Koszul dual, and genus tower. The Heisenberg algebra is V_Λ for $\Lambda = \mathbb{Z}$; affine Kac–Moody at level 1 is V_Q for the root lattice Q ; the free fermion is a subalgebra of a rank-1 lattice VOA; W-algebras arise by quantum Drinfeld–Sokolov reduction.

Remark B.o.2 (Four-level structure: lattice VOA). The lattice VOA illustrates the four levels of the modular engine: (i) the lattice vertex algebra V_Λ from an even lattice (geometric/physical); (ii) the bar complex with cocycle twist (strict model Conv_{str}); (iii) the L_∞ -algebra $\text{Def}_\infty^{\text{mod}}(V_\Lambda)$ is *formal*: curvature-braiding orthogonal by Theorem B.14.2; (iv) $\kappa(V_\Lambda) = \text{rank}(\Lambda)$, independent of cocycle.

Definition B.o.3 (Analytic theta-datum;). An *analytic theta-datum* on a positive-definite even lattice Λ of

rank r is $\Theta_\Lambda^{\text{an}} = (\kappa, \{L_\gamma\}_{\gamma \in D(\Lambda)}, c, \|\cdot\|)$, where $\kappa = r$ is the curvature, $D(\Lambda) = \Lambda^*/\Lambda$ is the discriminant group, each $L_\gamma = \widehat{\mathcal{F}}_\gamma$ is the Hilbert completion of the charge- γ Fock module with inner product inherited from the Bergman space $A^2(D)$, $c = r$ is the central charge, and $\|\cdot\|$ is the family of HS-sewing seminorms (Definition K.7.1). Realizability: Theorem B.o.4.

THEOREM B.o.4 (*Lattice sewing envelope*;). Let Λ be a positive-definite even lattice of rank r with discriminant group $D(\Lambda) = \Lambda^*/\Lambda$.

- (i) The lattice VOA V_Λ satisfies HS-sewing for every $0 < q < 1$.
- (ii) Every genus- g sewing amplitude factors as

$$Z_g(V_\Lambda; \Omega) = \underbrace{(\det \text{Im } \Omega)^{-r/2} \cdot (\det'_\zeta \Delta_{\Sigma_g})^{-r/2}}_{Z_g(\mathcal{H}_r; \Omega) \text{ (Theorem K.7.1)}} \cdot \underbrace{\sum_{\lambda \in \Lambda^g} e^{i\pi \lambda^T \Omega \lambda}}_{\Theta_\Lambda(\Omega)}, \quad (\text{B.1})$$

and each factor converges absolutely on the Siegel upper half-space $\mathfrak{H}_g$.

- (iii) The sewing envelope is the charge-refined Hilbert completion

$$V_\Lambda^{\text{sew}} = \widehat{\bigoplus_{\gamma \in D(\Lambda)} \text{Sym } A_\gamma^2(D)},$$

where $A_\gamma^2(D) \subset A^2(D)$ is the Bergman space with L_0 -shift $\frac{1}{2}\langle \gamma, \gamma \rangle$ and the completion is taken in the HS-sewing topology.

- (iv) The vertex operators $e^\gamma: \widehat{\mathcal{F}}_{\gamma'} \rightarrow \widehat{\mathcal{F}}_{\gamma'+\gamma}$ extend to bounded operators between completed sectors.
- (v) The analytic theta-datum (Definition B.o.3) is realized, with $\kappa = r$ (Theorem B.14.2).

Proof. (i). Sector growth satisfies $\dim(V_\Lambda)_n = |D(\Lambda)| \cdot p(n)^r$, which is subexponential: $\log \dim(V_\Lambda)_n = O(\sqrt{n})$. OPE structure constants satisfy $|C_{a,i;b,j}^{c,k}| \leq K(a+b+c+1)^r$ because all OPE singularities in V_Λ are at most r -th order poles (the lattice vertex operators are exponentials of the rank- r free boson). Theorem K.7.1 then gives HS-sewing for every $0 < q < 1$.

(ii). The Fock decomposition $V_\Lambda = \bigoplus_{\gamma \in D(\Lambda)} \mathcal{F}_\gamma$ is a direct sum of twisted Heisenberg modules. Within each sector, Wick's theorem reduces all correlation functions to propagator pairings on the underlying rank- r Heisenberg, contributing $Z_g(\mathcal{H}_r; \Omega)$. The lattice sum over winding modes contributes $\Theta_\Lambda(\Omega)$. The Heisenberg factor converges by Theorem K.7.1 (one-particle sewing: eigenvalues q^n , trace class). The theta factor converges absolutely on $\mathfrak{H}_g$ by $|\Theta_\Lambda(\Omega)| \leq \sum_\lambda e^{-\pi \lambda^T Y \lambda}$ with $Y = \text{Im}(\Omega) > 0$, and the exponent $\lambda^T Y \lambda \geq \lambda_{\min}(Y) \cdot \|\lambda\|^2$ grows as $\|\lambda\|^2 \rightarrow \infty$.

(iii)–(iv). The Bergman-space completion $\widehat{\mathcal{F}}_\gamma = \overline{\mathcal{F}_\gamma}^{\|\cdot\|_{A^2}}$ gives honest Hilbert sectors. The vertex operator e^γ acts on mode expansions via $e^\gamma \cdot a_{-n_1} \cdots a_{-n_k} |\gamma'\rangle = \varepsilon(\gamma, \gamma') \cdot a_{-n_1} \cdots a_{-n_k} |\gamma + \gamma'\rangle$, where ε is the cocycle (bounded by 1) and the mode operators are unchanged. The L_0 -shift $\Delta_\gamma = \frac{1}{2}\langle \gamma, \gamma \rangle$ is absorbed into the grading; the exponential weight damping q^{Δ_γ} in the HS topology gives $\|e^\gamma\|_{\text{op}} \leq q^{\langle \gamma, \gamma \rangle / 2}$.

(v). Collecting: $\kappa = r$ by Theorem B.14.2; $L_\gamma = \widehat{\mathcal{F}}_\gamma$ are the Hilbert sectors of (iii); multiplication boundedness is (iv); HS collar-sewing is (i). $\square$

Remark B.o.5 (*Convolution-algebraic interpretation*). The sewing envelope V_Λ^{sew} is the domain of convergence of the universal MC element. By Theorem I3.21.69, $\Theta_{V_\Lambda} = D_{V_\Lambda} - d_0 \in \text{MC}(\mathfrak{g}_{V_\Lambda}^{\text{mod}})$; the bar-intrinsic

construction gives an abstract element in the convolution algebra. The HS-sewing condition is the *analytic criterion* for the formal genus expansion

$$\Theta_{V_\Lambda} = \sum_{g \geq 0} \hbar^g \Theta_{V_\Lambda}^{(g)}$$

to converge in the HS topology on the completed Hilbert sectors $\widehat{\mathcal{F}}_\gamma$. The factorization (B.1) is the *computation* of this convergent element: the Heisenberg Fredholm determinant is the Gaussian (free-field) summand, and the Siegel theta function is the lattice winding correction. In the shadow obstruction tower language, V_Λ has depth $r_{\max} = 2$ (Gaussian archetype) and $\Theta_{V_\Lambda} = \kappa(V_\Lambda) \cdot \eta \otimes \Lambda$ for single-generator algebras of uniform conformal weight (Theorem D, Remark 13.13.21).

B.1 EVEN LATTICES AND ROOT SYSTEMS

Definition B.1.1 (Lattice). A *lattice* is a free abelian group Λ of finite rank equipped with a symmetric bilinear form $\langle \cdot, \cdot \rangle : \Lambda \times \Lambda \rightarrow \mathbb{Z}$. The lattice is:

- (i) *integral* if $\langle \alpha, \beta \rangle \in \mathbb{Z}$ for all $\alpha, \beta \in \Lambda$;
- (ii) *even* if $\langle \alpha, \alpha \rangle \in 2\mathbb{Z}$ for all $\alpha \in \Lambda$ (this implies integrality);
- (iii) *positive-definite* if $\langle \alpha, \alpha \rangle > 0$ for all $\alpha \neq 0$;
- (iv) *non-degenerate* if the map $\Lambda \rightarrow \Lambda^* := \text{Hom}(\Lambda, \mathbb{Z})$ given by $\alpha \mapsto \langle \alpha, \cdot \rangle$ is injective;
- (v) *unimodular* if this map is an isomorphism, i.e., $\Lambda = \Lambda^*$.

Definition B.1.2 (Discriminant group). For a non-degenerate lattice Λ , the *dual lattice* is $\Lambda^* = \{\lambda \in \Lambda \otimes_{\mathbb{Z}} \mathbb{Q} : \langle \lambda, \alpha \rangle \in \mathbb{Z} \forall \alpha \in \Lambda\}$. The *discriminant group* is the finite abelian group $D(\Lambda) = \Lambda^*/\Lambda$, whose order equals $|\det(\langle e_i, e_j \rangle)|$ for any basis $\{e_i\}$ of Λ . The bilinear form on Λ induces a $\mathbb{Q}/\mathbb{Z}$ -valued bilinear form on $D(\Lambda)$.

Example B.1.3 (Root lattices). The ADE root lattices provide the fundamental examples.

Lattice	Rank	det	$h^\vee$	Unimodular?
A_n	n	$n+1$	$n+1$	No
D_n	n	4	$2n-2$	No
E_6	6	3	12	No
E_7	7	2	18	No
E_8	8	1	30	Yes

For each simply-laced root system Φ , the root lattice $\Lambda_\Phi = \mathbb{Z}\Phi$ is even and positive-definite. The Cartan matrix $A_{ij} = \langle \alpha_i, \alpha_j \rangle$ encodes the bilinear form on simple roots.

Remark B.1.4 (Uniqueness of E_8). By Mordell's theorem (1938), E_8 is the unique even unimodular positive-definite lattice of rank 8. In rank 16, there are exactly two such lattices: $E_8 \oplus E_8$ and D_{16}^+ (the latter being the overlattice of D_{16} by its spinor class). This classification is the lattice-theoretic origin of the two heterotic string theories.

Definition B.1.5 (Lattice operations). The following operations become functorial on vertex algebras in Section B.7.

- (i) *Direct sum.* For lattices Λ_1, Λ_2 , the orthogonal direct sum $\Lambda_1 \oplus \Lambda_2$ has $\langle (\alpha_1, \alpha_2), (\beta_1, \beta_2) \rangle = \langle \alpha_1, \beta_1 \rangle + \langle \alpha_2, \beta_2 \rangle$.
- (ii) *Sublattice.* A sublattice $\Lambda' \hookrightarrow \Lambda$ of finite index gives rise to $D(\Lambda') \twoheadrightarrow D(\Lambda)$.
- (iii) *Overlattice (gluing).* For an isotropic subgroup $I \subset D(\Lambda)$ (meaning $\langle \gamma, \gamma' \rangle \equiv 0 \pmod{\mathbb{Z}}$ for all $\gamma, \gamma' \in I$), the preimage $\Lambda_I = \{\lambda \in \Lambda^* : [\lambda] \in I\}$ is a lattice with $\Lambda \subset \Lambda_I \subset \Lambda^*$.
- (iv) *Orbifold.* For $\sigma \in \text{Aut}(\Lambda)$, the fixed sublattice Λ^σ and the coinvariants $\Lambda/(1 - \sigma)\Lambda$ both carry induced bilinear forms.

B.2 COCYCLE THEORY

The vertex algebra structure on V_Λ requires a choice of 2-cocycle on Λ . Different cocycles produce genuinely different algebraic structures, ranging from honest vertex algebras (E_∞ -chiral) to nonlocal E_1 -chiral algebras. The cocycle theory controls this distinction.

Definition B.2.1 (2-cocycle on a lattice). A 2-cocycle on a lattice Λ is a function $\varepsilon : \Lambda \times \Lambda \rightarrow \mathbb{C}^\times$ satisfying:

$$\varepsilon(\alpha, \beta) \varepsilon(\alpha + \beta, \gamma) = \varepsilon(\alpha, \beta + \gamma) \varepsilon(\beta, \gamma) \quad (\text{B.2})$$

for all $\alpha, \beta, \gamma \in \Lambda$. The cocycle is:

- (i) *normalized* if $\varepsilon(\alpha, 0) = \varepsilon(0, \alpha) = 1$ for all α ;
- (ii) *bimultiplicative* if $\varepsilon(\alpha + \alpha', \beta) = \varepsilon(\alpha, \beta) \varepsilon(\alpha', \beta)$ and similarly in the second argument;
- (iii) *symmetric* (in the sense of Borchers) if

$$\varepsilon(\alpha, \beta) = (-1)^{\langle \alpha, \beta \rangle} \varepsilon(\beta, \alpha) \quad (\text{B.3})$$

for all $\alpha, \beta \in \Lambda$.

Remark B.2.2. The symmetry condition (B.3) is the *Borchers axiom*: it is precisely the condition needed for the vertex operator skew-symmetry $Y(a, z)b = e^{z\partial}Y(b, -z)a$ to hold. Note that for an even lattice, $(-1)^{\langle \alpha, \beta \rangle}$ is well-defined. For an odd lattice, one would need $(-1)^{\langle \alpha, \alpha \rangle \langle \beta, \beta \rangle / 4}$ corrections; we restrict to even lattices throughout.

Definition B.2.3 (Commutator map). The *commutator* of a cocycle ε is

$$c_\varepsilon(\alpha, \beta) := \frac{\varepsilon(\alpha, \beta)}{\varepsilon(\beta, \alpha)}.$$

LEMMA B.2.4 (*Cocycle classification*;). Let Λ be an even lattice. Then:

- (i) For any normalized bimultiplicative 2-cocycle ε , the commutator satisfies $c_\varepsilon(\alpha, \beta) = (-1)^{\langle \alpha, \beta \rangle}$ if and only if ε is symmetric.
- (ii) The set of symmetric cocycles on Λ is a torsor for $\text{Hom}(\Lambda \otimes \Lambda, \mathbb{C}^\times)^{\text{sym}}$, the group of symmetric bicharacters.
- (iii) The cohomology group $H^2(\Lambda, \mathbb{C}^\times)$ classifies cocycles up to coboundary equivalence. Two cocycles $\varepsilon, \varepsilon'$ are cohomologous if there exists $f : \Lambda \rightarrow \mathbb{C}^\times$ with $\varepsilon'(\alpha, \beta) = f(\alpha) f(\beta) f(\alpha + \beta)^{-1} \varepsilon(\alpha, \beta)$.

Proof. (i) Computing from the Borchers symmetry: $c_\varepsilon(\alpha, \beta) = \varepsilon(\alpha, \beta)/\varepsilon(\beta, \alpha) = (-1)^{\langle \alpha, \beta \rangle}$. Conversely, if $c_\varepsilon(\alpha, \beta) = (-1)^{\langle \alpha, \beta \rangle}$, then $\varepsilon(\alpha, \beta) = (-1)^{\langle \alpha, \beta \rangle} \varepsilon(\beta, \alpha)$ is the Borchers axiom.

(ii) If $\varepsilon, \varepsilon'$ are both symmetric, then ε'/ε is a symmetric bicharacter. Conversely, multiplying a symmetric cocycle by a symmetric bicharacter preserves the Borchers axiom.

(iii) Standard group cohomology: $\Lambda \cong \mathbb{Z}^d$ is free abelian, so $H^2(\Lambda, \mathbb{C}^\times) \cong (\mathbb{C}^\times)^{\binom{d}{2}}$, parametrized by the values $\varepsilon(e_i, e_j)$ for $i < j$ on a basis $\{e_1, \dots, e_d\}$. $\square$

Construction B.2.5 (Standard symmetric cocycle). For an even lattice Λ with ordered basis $\{e_1, \dots, e_d\}$, the *standard symmetric cocycle* is:

$$\varepsilon_0(\alpha, \beta) = (-1)^{\sum_{i < j} \alpha_i \beta_j G_{ij}}$$

where $\alpha = \sum_i \alpha_i e_i$, $\beta = \sum_j \beta_j e_j$, and $G_{ij} = \langle e_i, e_j \rangle$. One verifies:

$$\varepsilon_0(\alpha, \beta) \varepsilon_0(\beta, \alpha) = (-1)^{\sum_{i < j} G_{ij} (\alpha_i \beta_j + \beta_i \alpha_j)} = (-1)^{\sum_{i \neq j} \alpha_i \beta_j G_{ij}},$$

where the second equality uses $G_{ij} = G_{ji}$. Since $\langle \alpha, \beta \rangle = \sum_{i,j} \alpha_i G_{ij} \beta_j = \sum_{i \neq j} \alpha_i G_{ij} \beta_j + \sum_i \alpha_i \beta_i G_{ii}$ and $G_{ii} \in 2\mathbb{Z}$ for an even lattice, we have $\sum_{i \neq j} \alpha_i G_{ij} \beta_j \equiv \langle \alpha, \beta \rangle \pmod{2}$, giving $(-1)^{\langle \alpha, \beta \rangle}$ as required.

Example B.2.6 (Non-symmetric cocycle on $\mathbb{Z}^2$). On $\Lambda = \mathbb{Z}^2$ with standard bilinear form $\langle (a, b), (c, d) \rangle = ac + bd$, define:

$$\varepsilon((a, b), (c, d)) = e^{2\pi i \theta \cdot ad}$$

for $\theta \in \mathbb{R} \setminus \mathbb{Q}$. The cocycle condition holds since $\varepsilon((a, b), (c, d)) \varepsilon((a + c, b + d), (e, f)) = e^{2\pi i \theta (ad + (a+c)f)}$ equals $\varepsilon((a, b), (c + e, d + f)) \varepsilon((c, d), (e, f)) = e^{2\pi i \theta (a(d+f) + cf)}$.

For the symmetry check:

$$\frac{\varepsilon((a, b), (c, d))}{\varepsilon((c, d), (a, b))} = e^{2\pi i \theta (ad - cb)},$$

which is not $(-1)^{ac+bd}$ for irrational θ . Hence this cocycle is not symmetric, producing a strictly E_1 -chiral algebra (see Theorem B.3.2).

Remark B.2.7 (Non-symmetric deformations via roots of unity). More generally, given a symmetric cocycle ε_0 and an antisymmetric bilinear form $q: \Lambda \times \Lambda \rightarrow \mathbb{Z}/N\mathbb{Z}$, the product $\varepsilon(\alpha, \beta) = \varepsilon_0(\alpha, \beta) \cdot \zeta^{q(\alpha, \beta)}$ (where $\zeta = e^{2\pi i/N}$) is a non-symmetric cocycle whenever q is not identically zero. Such deformations interpolate between the commutative (E_∞) and noncommutative (E_1) worlds.

B.3 LATTICE VERTEX ALGEBRA CONSTRUCTION

Construction B.3.1 (Lattice vertex algebra). Let Λ be an even positive-definite lattice of rank d with bilinear form $\langle \cdot, \cdot \rangle$, and let $\varepsilon: \Lambda \times \Lambda \rightarrow \mathbb{C}^\times$ be a normalized 2-cocycle. The *lattice vertex algebra* V_Λ^ε is defined as follows.

State space. Let $\mathcal{H} = \mathbb{C}[\alpha_{-n}^i : 1 \leq i \leq d, n \geq 1]$ be the Heisenberg Fock space (bosonic oscillator algebra) for $\Lambda \otimes_{\mathbb{Z}} \mathbb{C}$, with vacuum $|0\rangle$ annihilated by all α_n^i for $n > 0$. Let $\mathbb{C}[\Lambda]$ denote the group algebra with basis $\{e^\alpha : \alpha \in \Lambda\}$ and multiplication $e^\alpha \cdot e^\beta = \varepsilon(\alpha, \beta) e^{\alpha+\beta}$. The state space is:

$$V_\Lambda^\varepsilon = \mathcal{H} \otimes_{\mathbb{C}} \mathbb{C}[\Lambda] = \bigoplus_{\alpha \in \Lambda} \mathcal{H} \otimes e^\alpha.$$

This is Λ -graded by declaring $\deg(\mathcal{H} \otimes e^\alpha) = \alpha$.

Vertex operators. For $\alpha \in \Lambda$, the vertex operator is:

$$Y(e^\alpha, z) = E^-(\alpha, z) E^+(\alpha, z) e^\alpha z^{\alpha_0}$$

where:

$$\begin{aligned} E^-(\alpha, z) &= \exp\left(-\sum_{n<0} \frac{\alpha_n}{n} z^{-n}\right) \quad (\text{creation part}), \\ E^+(\alpha, z) &= \exp\left(-\sum_{n>0} \frac{\alpha_n}{n} z^{-n}\right) \quad (\text{annihilation part}), \end{aligned}$$

the operator e^α acts on $\mathbb{C}[\Lambda]$ by $e^\alpha \cdot e^\beta = \varepsilon(\alpha, \beta) e^{\alpha+\beta}$, and z^{α_0} is the formal variable tracking the zero mode.

OPE.

$$Y(e^\alpha, z) Y(e^\beta, w) = \varepsilon(\alpha, \beta) (z-w)^{\langle \alpha, \beta \rangle} Y(e^{\alpha+\beta}, w) + \text{regular terms.} \quad (\text{B.4})$$

Conformal vector. Choose an orthonormal basis $\{h_i\}$ of $\Lambda \otimes \mathbb{C}$. The conformal vector is $\omega = \frac{1}{2} \sum_{i=1}^d h_{i,-1}^2 |0\rangle$, giving rise to the Virasoro algebra with central charge $c = d = \text{rank}(\Lambda)$. The conformal weight of e^α is:

$$h_{e^\alpha} = \frac{\langle \alpha, \alpha \rangle}{2}.$$

THEOREM B.3.2 (E_1 vs. E_∞ classification;). The lattice vertex algebra V_Λ^ε is:

- (i) an E_∞ -chiral algebra (a vertex algebra in the sense of Borchers) if and only if ε is symmetric;
- (ii) an E_1 -chiral algebra for any cocycle ε ;
- (iii) strictly E_1 (not E_∞) when ε is not symmetric.

Proof. (ii) The cocycle condition (B.2) on ε ensures associativity of the vertex operator products $Y(Y(e^\alpha, z-w) e^\beta, w) = Y(e^\alpha, z) Y(e^\beta, w)$. Hence V_Λ^ε is always at least E_1 -chiral.

(i) and (iii). The skew-symmetry axiom for vertex algebras requires $Y(e^\alpha, z) e^\beta = e^{z\partial} Y(e^\beta, -z) e^\alpha$. Computing both sides:

$$\begin{aligned} \text{LHS} &= \varepsilon(\alpha, \beta) z^{\langle \alpha, \beta \rangle} e^{\alpha+\beta} + \dots, \\ \text{RHS} &= \varepsilon(\beta, \alpha) (-z)^{\langle \beta, \alpha \rangle} e^{\alpha+\beta} + \dots = \varepsilon(\beta, \alpha) (-1)^{\langle \alpha, \beta \rangle} z^{\langle \alpha, \beta \rangle} e^{\alpha+\beta} + \dots. \end{aligned}$$

Equality of the leading terms requires $\varepsilon(\alpha, \beta) = (-1)^{\langle \alpha, \beta \rangle} \varepsilon(\beta, \alpha)$, which is the Borchers symmetry condition (B.3). Hence skew-symmetry holds if and only if ε is symmetric. When ε is not symmetric, the OPE exchange picks up a phase $c_\varepsilon(\alpha, \beta) / (-1)^{\langle \alpha, \beta \rangle} \neq 1$, so the algebra is strictly E_1 . $\square$

Example B.3.3 (Heisenberg as a lattice vertex algebra). The Heisenberg vertex algebra $\mathcal{H}_\kappa$ at level κ is the $\alpha = 0$ sector of V_Λ^ε for any lattice Λ :

$$\mathcal{H}_d := V_0 = \mathcal{H} \otimes e^0 \cong \mathbb{C}[\alpha_{-n}^i : i, n \geq 1],$$

with $d = \text{rank}(\Lambda)$ free bosons. The cocycle ε does not enter the $\alpha = 0$ sector. This is the simplest output of the lattice engine, and the base case for all bar complex computations.

Remark B.3.4 (Lattice specialization to the frame example). The case $\Lambda = \mathbb{Z}$ (with standard form $\langle 1, 1 \rangle = 2$, giving an even rank-1 lattice) recovers the Heisenberg algebra $\mathcal{H}_\kappa$ of Chapter 2; the bar complex computed there (§2.3) is the $\Lambda = \mathbb{Z}$ specialization of the lattice bar complex developed in §B.5.

B.4 THE FRENKEL–KAC–SEGAL THEOREM

THEOREM B.4.1 (*Frenkel–Kac–Segal*; [174, 372]). Let $\mathfrak{g}$ be a simply-laced simple Lie algebra with root lattice $\Lambda_{\mathfrak{g}}$. Let ε be a symmetric cocycle on $\Lambda_{\mathfrak{g}}$ satisfying $\varepsilon(\alpha, \beta) \varepsilon(\beta, \alpha) = (-1)^{\langle \alpha, \beta \rangle}$. Then there is an isomorphism of vertex algebras:

$$V_{\Lambda_{\mathfrak{g}}}^{\varepsilon} \cong L(\widehat{\mathfrak{g}}, 1)$$

where $L(\widehat{\mathfrak{g}}, 1)$ denotes the simple quotient of the level-1 vacuum module for the affine Kac–Moody algebra $\widehat{\mathfrak{g}}$.

Proof. The proof proceeds in three steps ([174]; [372]; see also [238] Ch. 5).

Step 1. The Heisenberg subalgebra $\mathcal{H} \subset V_{\Lambda_{\mathfrak{g}}}$ provides the Cartan subalgebra $\widehat{\mathfrak{h}} \hookrightarrow \widehat{\mathfrak{g}}$. For each root $\alpha \in \Phi$, define the root current:

$$E_{\alpha}(z) := Y(e^{\alpha}, z), \quad H_i(z) := Y(\alpha_{i,-1}|0\rangle, z)$$

for simple roots α_i . The cocycle ε ensures that the vertex operators E_{α_i} satisfy the Chevalley–Serre relations: $\varepsilon(\alpha, \beta) \varepsilon(\beta, \alpha) = (-1)^{\langle \alpha, \beta \rangle}$ produces the correct signs in the $[E_{\alpha}, E_{\beta}]$ commutation relations.

Step 2. The lattice OPE (B.4) gives, for roots α, β :

$$E_{\alpha}(z) E_{\beta}(w) = \varepsilon(\alpha, \beta) (z - w)^{\langle \alpha, \beta \rangle} E_{\alpha+\beta}(w) + \text{regular}.$$

When $\beta = -\alpha$ ($\langle \alpha, -\alpha \rangle = -2$):

$$E_{\alpha}(z) E_{-\alpha}(w) = \frac{\varepsilon(\alpha, -\alpha)}{(z - w)^2} + \frac{H_{\alpha}(w)}{z - w} + \text{regular},$$

reproducing the $\widehat{\mathfrak{g}}$ current algebra at level $k = \langle \alpha, \alpha \rangle / 2 = 1$ (simply-laced). When $\langle \alpha, \beta \rangle = -1$ (adjacent roots): $E_{\alpha}(z) E_{\beta}(w) = \varepsilon(\alpha, \beta) (z - w)^{-1} E_{\alpha+\beta}(w) + \dots$, reproducing $[E_{\alpha}, E_{\beta}] = \varepsilon(\alpha, \beta) E_{\alpha+\beta}$. When $\langle \alpha, \beta \rangle \geq 0$ and $\alpha + \beta \notin \Phi$: the OPE is regular, giving $[E_{\alpha}, E_{\beta}] = 0$.

Step 3. Steps 1–2 produce an injective vertex algebra homomorphism $L(\widehat{\mathfrak{g}}, 1) \hookrightarrow V_{\Lambda_{\mathfrak{g}}}$. Both sides have the same graded character: the level-1 Weyl–Kac character formula gives $\text{ch } L(\widehat{\mathfrak{g}}, 1) = \Theta_{\Lambda_{\mathfrak{g}}}(\tau) / \eta(\tau)^{\text{rank}(\mathfrak{g})}$, which equals the lattice vertex algebra character $\text{ch } V_{\Lambda_{\mathfrak{g}}}$. Since an injective map between graded vector spaces of the same graded dimension is an isomorphism, $L(\widehat{\mathfrak{g}}, 1) \cong V_{\Lambda_{\mathfrak{g}}}$. $\square$

Example B.4.2 (*Explicit verification for $\widehat{\mathfrak{sl}}_2$ at level 1*). The A_1 root lattice is $\Lambda = \mathbb{Z}\alpha$ with $\langle \alpha, \alpha \rangle = 2$. The lattice vertex algebra V_{Λ} has generators:

- $h(z) := Y(\alpha_{-1}|0\rangle, z)$, the Cartan current,
- $e(z) := Y(e^{\alpha}, z)$, the raising current,
- $f(z) := Y(e^{-\alpha}, z)$, the lowering current.

The OPE from (B.4):

$$\begin{aligned} h(z) h(w) &= \frac{2}{(z - w)^2} + \text{reg} && (\text{level } k = 1, \langle \alpha, \alpha \rangle = 2), \\ e(z) f(w) &= \frac{\varepsilon(\alpha, -\alpha)}{(z - w)^2} + \frac{h(w)}{z - w} + \text{reg} && (\text{simple pole gives } h), \\ h(z) e(w) &= \frac{2e(w)}{z - w} + \text{reg} && (\text{root } \alpha \text{ has } \langle \alpha, \alpha \rangle = 2). \end{aligned}$$

With the normalization $\varepsilon(\alpha, -\alpha) = 1$ (which is achievable by coboundary adjustment), this reproduces the $\widehat{\mathfrak{sl}}_2$ OPE at level $k = 1$. The Sugawara construction gives $T = \frac{1}{2(k+h^\vee)}(\frac{1}{2} : h h : + : e f : + : f e :)$ with $h^\vee = 2$, central charge $c = 3 \cdot 1/(1+2) = 1$, matching $\text{rank}(\Lambda) = 1$.

Remark B.4.3 (Non-simply-laced algebras). For non-simply-laced $\mathfrak{g}$ (types B_n, C_n, F_4, G_2), the Frenkel–Kac–Segal construction does not apply directly, because the root lattice contains roots of different lengths with $\langle \alpha, \alpha \rangle \neq 2$. Instead, one obtains non-simply-laced affine algebras via *orbifold* constructions: start with a simply-laced lattice Λ and quotient by a diagram automorphism σ . For instance:

- $\widehat{\mathfrak{so}}_{2n+1}$ (type B_n) at level 1 arises from D_{n+1} modulo its order-2 diagram automorphism (folding D_{n+1} gives the B_n root system, not C_n).
- $\widehat{G}_2$ at level 1 arises from D_4 modulo its order-3 triality automorphism.

See Section B.7 for the orbifold construction.

B.5 BAR COMPLEXES OF LATTICE VERTEX ALGEBRAS

The lattice grading decomposes the bar complex into orthogonal summands indexed by Λ , since the bar differential preserves the total lattice degree.

Construction B.5.1 (Bar complex of V_Λ^ε). The geometric bar complex $\bar{\mathbf{B}}(V_\Lambda^\varepsilon)$ has:

Generators. Elements of the form

$$[e^{\alpha_1} | e^{\alpha_2} | \cdots | e^{\alpha_p}] \otimes \omega$$

where $\alpha_i \in \Lambda \setminus \{0\}$ and ω is a logarithmic form on $\overline{C}_p(X)$. (We suppress Heisenberg descendants $\alpha_{-n}^i | 0\rangle$ for notational clarity; they contribute additional tensor factors.)

Grading. The total lattice degree is $\sum_{i=1}^p \alpha_i \in \Lambda$, and the bar degree is p .

Differential. The bar differential $d = d_{\text{res}}$ sums residues over collision divisors. For a degree-2 element $[e^\alpha | e^\beta] \otimes 1$:

$$d([e^\alpha | e^\beta] \otimes 1) = \varepsilon(\alpha, \beta) [e^{\alpha+\beta}] \otimes 1 \quad (\text{B.5})$$

when $\langle \alpha, \beta \rangle = -1$ (simple pole in the OPE), and $d = 0$ when $\langle \alpha, \beta \rangle \geq 0$ (no pole) or $\langle \alpha, \beta \rangle \leq -2$ (higher poles pair trivially with $d \log$).

THEOREM B.5.2 (Lattice bar complex structure;). The bar complex $\bar{\mathbf{B}}(V_\Lambda^\varepsilon)$ satisfies:

- Lattice grading.* The differential preserves the total lattice degree $\sum_i \alpha_i \in \Lambda$, decomposing the bar complex as $\bar{\mathbf{B}}(V_\Lambda^\varepsilon) = \bigoplus_{\gamma \in \Lambda} \bar{\mathbf{B}}(V_\Lambda^\varepsilon)_\gamma$.
- Residue criterion.* Simple poles occur only when $\langle \alpha_i, \alpha_j \rangle = -1$ for some pair, and these are the only contributions to the differential.
- Cocycle dependence.* The cocycle ε appears explicitly in the bar differential via (B.5). Different cocycles give non-isomorphic bar complexes.

Proof. (i) The OPE $Y(e^\alpha, z) Y(e^\beta, w)$ produces vertex operators of lattice degree $\alpha + \beta$. The residue operation preserves this degree, since $\text{Res}_{z=w}$ does not change the total lattice weight $\alpha + \beta$.

(ii) The OPE (B.4) has a pole of order $-\langle \alpha, \beta \rangle$ at $z = w$. Pairing with the logarithmic form $\eta_{ij} = d \log(z_i - z_j)$ extracts exactly the order-1 residue: $\text{Res}_{z=w} [(z-w)^{-m} d \log(z-w)] = \delta_{m,1}$. Hence the

differential is nonzero only for a simple pole (order 1, i.e., $\langle \alpha, \beta \rangle = -1$). For $\langle \alpha, \beta \rangle \geq 0$ there is no pole and the residue vanishes. For $\langle \alpha, \beta \rangle \leq -2$ the pole of order ≥ 2 pairs trivially with $d \log$.

(iii) To show that different cocycles give non-isomorphic bar complexes, note that the differential $d([e^\alpha | e^\beta] \otimes 1) = \varepsilon(\alpha, \beta)[e^{\alpha+\beta}] \otimes 1$ in (B.5) carries the sign $\varepsilon(\alpha, \beta) \in \{\pm 1\}$ explicitly. A change of cocycle $\varepsilon \mapsto \varepsilon'$ with $\varepsilon'(\alpha, \beta)/\varepsilon(\alpha, \beta) = c(\alpha)c(\beta)/c(\alpha + \beta)$ (a coboundary, $c : \Lambda \rightarrow \{\pm 1\}$) corresponds to rescaling each basis vector $e^\alpha \mapsto c(\alpha)e^\alpha$, hence to an isomorphism of bar complexes. However, if ε' and ε differ by a non-trivial class in $H^2(\Lambda; \{\pm 1\})$, no such coboundary exists: the two bar complexes have differentials that cannot be related by any diagonal change of basis, so they are non-isomorphic as chain complexes. $\square$

COMPUTATION B.5.3 (A_1 bar complex). For $\Lambda = A_1 = \mathbb{Z}\alpha$ with $\langle \alpha, \alpha \rangle = 2$, the relevant inner products are:

$$\langle n\alpha, m\alpha \rangle = 2nm.$$

Since $\langle n\alpha, m\alpha \rangle = -1$ has no integer solutions, *no simple poles occur*. The bar differential vanishes identically, and $H_*(\bar{\mathbf{B}}(V_{A_1})) \cong \bar{\mathbf{B}}(V_{A_1})$ as graded vector spaces.

The $\widehat{\mathfrak{sl}}_2$ current algebra at level 1 is “too small” to have nontrivial collisions in bar degree 2 within a single lattice sector. The nontrivial bar differential involves Heisenberg descendants (which carry additional oscillator modes that can produce simple poles via derivative OPEs).

COMPUTATION B.5.4 (A_2 bar complex). For $\Lambda = A_2$ with simple roots α_1, α_2 satisfying $\langle \alpha_1, \alpha_1 \rangle = \langle \alpha_2, \alpha_2 \rangle = 2$ and $\langle \alpha_1, \alpha_2 \rangle = -1$:

Bar degree 1. Generated by $[e^\alpha]$ for $\alpha \in \Lambda \setminus \{0\}$.

Bar degree 2. The key differential is

$$d([e^{\alpha_1} | e^{\alpha_2}] \otimes 1) = \varepsilon(\alpha_1, \alpha_2) [e^{\alpha_1 + \alpha_2}] \otimes 1$$

since $\langle \alpha_1, \alpha_2 \rangle = -1$. This maps the element $[e^{\alpha_1} | e^{\alpha_2}]$ of lattice degree $\alpha_1 + \alpha_2$ to $[e^{\alpha_1 + \alpha_2}]$ of the same lattice degree, with coefficient $\varepsilon(\alpha_1, \alpha_2)$.

Bar degree 3.

$$d([e^{\alpha_1} | e^{-\alpha_1 - \alpha_2} | e^{\alpha_2}] \otimes \eta_{12} \wedge \eta_{23}) = \varepsilon \cdot [e^0]$$

since both adjacent pairs have inner product -1 . Since $e^0 = \mathbf{1}$ lies in the augmentation (i.e., $[\mathbf{1}] = 0$ in the reduced bar complex $\bar{\mathbf{B}} = \mathbf{B}/\mathbb{C} \cdot \mathbf{1}$), this element is a *cycle*, not an exact element. It realizes the Weyl group relation $s_{\alpha_1} s_{\alpha_2} s_{\alpha_1} = s_{\alpha_2} s_{\alpha_1} s_{\alpha_2}$ as a homology class in the bar complex.

The nontrivial differentials encode the A_2 root system structure: simple poles occur precisely for pairs of roots whose sum is again a root.

PROPOSITION B.5.5 (D_4 bar complex and triality;). For the D_4 root lattice, the bar complex $\bar{\mathbf{B}}(V_{D_4})$ admits an action of the triality group $S_3 \cong \text{Out}(D_4)$ permuting the three conjugacy classes of roots. The induced action on homology $H_*(\bar{\mathbf{B}}(V_{D_4}))$ reflects the triality symmetry of the $\widehat{\mathfrak{so}}_8$ current algebra at level 1.

Proof. The D_4 root lattice has 24 roots, all of the form $\pm e_i \pm e_j$ ($i \neq j$). These form a single orbit under the Weyl group $W(D_4)$. The outer automorphism group $\text{Out}(D_4) \cong S_3$ acts as graph automorphisms of the D_4 Dynkin diagram, permuting the three “legs” and hence permuting the three nontrivial cosets of $D_4^*/D_4 \cong (\mathbb{Z}/2\mathbb{Z})^2$ (vector, spinor, and conjugate spinor representations). Note: the spinor and conjugate spinor vectors lie in $D_4^* \setminus D_4$, not in the root lattice itself.

Step 1. Triality action on bar complex. The triality automorphism σ acts on the lattice as a graph automorphism of the D_4 Dynkin diagram, permuting the three “legs.” This extends to an automorphism

of V_{D_4} via $\sigma(e^\alpha) = e^{\sigma(\alpha)}$. Since the bar construction is functorial (any algebra automorphism induces a coalgebra automorphism of the bar complex), σ acts on $\bar{\mathbf{B}}(V_{D_4})$.

Step 2. Action on homology. In bar degree 1, the generators are $[e^\alpha]$ for each of the 24 roots α . The triality permutes these roots (preserving inner products). In bar degree 2, the differential $d([e^{\alpha_1} | e^{\alpha_2}]) = \varepsilon(\alpha_1, \alpha_2) [e^{\alpha_1 + \alpha_2}]$ (when $\langle \alpha_1, \alpha_2 \rangle = -1$) intertwines with σ since σ preserves inner products and the cocycle is equivariant (the standard Frenkel–Lepowsky–Meurman cocycle for D_4 is triality-invariant up to coboundary).

Step 3. Conclusion. The S_3 -action on $H_*(\bar{\mathbf{B}}(V_{D_4}))$ is the representation-theoretic manifestation of the triality symmetry: the three fundamental representations of $\mathfrak{so}_8$ (vector, spinor, conjugate spinor) are permuted by outer automorphisms, and this permutation lifts to the bar complex level. $\square$

PROPOSITION B.5.6 (*E_8 bar complex and self-duality*;). For the E_8 root lattice, the lattice algebra V_{E_8} is self-dual, so its dual coalgebra is computed by the same E_8 -graded bar complex $\bar{\mathbf{B}}(V_{E_8})$, reflecting the unimodularity and self-duality of E_8 . The bar complex decomposes as

$$\bar{\mathbf{B}}(V_{E_8}) = \bigoplus_{\gamma \in E_8} \bar{\mathbf{B}}(V_{E_8})_\gamma$$

with $|E_8/2E_8| = 2^8 = 256$ sectors modulo $2E_8$. The 240 roots of E_8 each contribute a 1-dimensional summand in bar degree 1.

Proof. *Step 1.* Lattice decomposition. The bar complex decomposes along the E_8 -grading:

$$\bar{\mathbf{B}}(V_{E_8}) = \bigoplus_{\gamma \in E_8} \bar{\mathbf{B}}(V_{E_8})_\gamma.$$

The zero sector $\gamma = 0$ is the bar complex of the rank-8 Heisenberg algebra $\bar{\mathbf{B}}(\mathcal{H}_8)$, whose bar differential vanishes (the Heisenberg OPE has only a double pole, so $\mathcal{H}_8^\dagger \simeq \text{Sym}^{\text{ch}}(V^*)$ by Theorem E.3.13).

Step 2. Root contributions. In bar degree 1, each root α of E_8 contributes a generator $[e^\alpha]$ in the sector $\gamma = \alpha$. Since E_8 has 240 roots, $\dim \bar{\mathbf{B}}^1 = 240$ (in the root sectors). In bar degree 2, the differential is $d([e^{\alpha_1} | e^{\alpha_2}]) = \varepsilon(\alpha_1, \alpha_2) [e^{\alpha_1 + \alpha_2}]$ when $\langle \alpha_1, \alpha_2 \rangle = -1$. For E_8 , each root α has exactly 56 neighbors β with $\langle \alpha, \beta \rangle = -1$ (so that $\alpha + \beta$ is again a root), as follows from the root system geometry: the 240 roots partition by inner product with α as $1 + 56 + 126 + 56 + 1$.

Step 3. Self-duality. By Theorem B.6.2, $(V_{E_8}^\varepsilon)^\dagger = (V_{E_8}^{\varepsilon^{-1}})^c$. Since E_8 is unimodular ($E_8 = E_8^*$), the cocycle ε for E_8 satisfies $\varepsilon^{-1} = \varepsilon$: the standard FLM cocycle takes values in $\{\pm 1\}$, so $\varepsilon(\alpha, \beta)^{-1} = \varepsilon(\alpha, \beta)$ for all α, β . Therefore $(V_{E_8}^\varepsilon)^\dagger \cong V_{E_8}^\varepsilon$ as a coalgebra.

Step 4. Sector count. Modulo $2E_8$, the lattice has $|E_8/2E_8| = 2^{\text{rank}(E_8)} = 2^8 = 256$ classes (since $\Lambda/2\Lambda \cong (\mathbb{Z}/2\mathbb{Z})^d$ for any rank- d lattice), giving 256 sectors in the bar complex. $\square$

THEOREM B.5.7 (*Unimodular lattice self-duality*;). Let Λ be an even unimodular lattice. Then V_Λ is Koszul self-dual:

$$V_\Lambda^\dagger \cong V_\Lambda$$

with the bar-cobar quasi-isomorphism $\Omega^{\text{ch}}(\bar{\mathbf{B}}(V_\Lambda)) \xrightarrow{\sim} V_\Lambda$ providing bar-cobar inversion (a separate, general phenomenon).

Proof. By Theorem B.6.2, $V_\Lambda^\dagger = (V_\Lambda^{\varepsilon^{-1}})^c$. For the standard FLM cocycle $\varepsilon : \Lambda \times \Lambda \rightarrow \{\pm 1\}$, we have $\varepsilon^{-1} = \varepsilon$ (since $\varepsilon(\alpha, \beta)^{-1} = \varepsilon(\alpha, \beta)$ for all α, β), so $V_\Lambda^{\varepsilon^{-1}} = V_\Lambda^\varepsilon$. Hence $V_\Lambda^{\varepsilon^{-1}} \cong V_\Lambda^\varepsilon$ as vertex algebras.

The coalgebra structure on the dual side matches the algebra structure on the original side (since the cocycle is self-inverse up to coboundary), giving $V_\Lambda^! \cong V_\Lambda$.

The bar-cobar QI follows from Theorem B.6.3: the twisting morphism τ is Koszul, so $\Omega^{\text{ch}}(\bar{\mathbf{B}}(V_\Lambda)) \xrightarrow{\sim} V_\Lambda$. $\square$

B.6 KOSZUL DUALITY FOR LATTICE ALGEBRAS

Definition B.6.1 (Inverse cocycle). For a cocycle $\varepsilon: \Lambda \times \Lambda \rightarrow \mathbb{C}^\times$, the *inverse cocycle* is $\varepsilon^{-1}(\alpha, \beta) := \varepsilon(\alpha, \beta)^{-1}$. The cocycle condition is preserved under inversion, and the commutator satisfies $c_{\varepsilon^{-1}}(\alpha, \beta) = c_\varepsilon(\alpha, \beta)^{-1}$. In particular, if ε is symmetric, so is ε^{-1} .

THEOREM B.6.2 (*Dual coalgebra of lattice vertex algebra;*). The dual coalgebra of the lattice E_1 -chiral algebra V_Λ^ε is:

$$(V_\Lambda^\varepsilon)^i := H^*(\bar{\mathbf{B}}^{\text{ch}}(V_\Lambda^\varepsilon)) = (V_\Lambda^{\varepsilon^{-1}})^c,$$

the coalgebra structure on the lattice vertex algebra with inverse cocycle. Consequently the Koszul dual algebra $(V_\Lambda^\varepsilon)^!$ is the linear/Verdier dual of this coalgebra. More precisely:

- (i) The underlying graded vector space of $(V_\Lambda^\varepsilon)^i$ is V_Λ^* .
- (ii) The coalgebra structure is determined by ε^{-1} : the coproduct $\Delta: V_\Lambda^* \rightarrow V_\Lambda^* \otimes V_\Lambda^*$ has structure constants $\varepsilon(\alpha, \beta)^{-1}$.
- (iii) For symmetric ε , the dual coalgebra is again a (co)lattice vertex algebra with the same symmetry type.

Proof. The bar coalgebra is computed by the bar construction, and its cohomology coalgebra gives the dual coalgebra. The product $\mu: V_\Lambda \otimes V_\Lambda \rightarrow V_\Lambda$ has structure constants $\varepsilon(\alpha, \beta)$ from the group algebra multiplication $e^\alpha \cdot e^\beta = \varepsilon(\alpha, \beta) e^{\alpha+\beta}$. The dual coalgebra is extracted from the bar complex $\bar{\mathbf{B}}^{\text{ch}}(V_\Lambda^\varepsilon)$. In the bar construction, each tensor factor is desuspended by s^{-1} , and the bar differential involves the product μ composed with Koszul signs from the desuspension. For the lattice algebra, where $\mu(e^\alpha \otimes e^\beta) = \varepsilon(\alpha, \beta) e^{\alpha+\beta}$ with $|\varepsilon(\alpha, \beta)| = \pm 1$, the desuspension introduces a sign $(-1)^{|\alpha||\beta|}$ that, combined with the bilinearity of ε , produces the cocycle inversion: the bar-complex coproduct has structure constants $\varepsilon(\alpha, \beta)^{-1}$. Since ε^{-1} is again a valid cocycle, $(V_\Lambda^{\varepsilon^{-1}})^c$ is a valid coalgebra, and the dual coalgebra is identified with it; the dual algebra is then obtained by linear/Verdier duality. $\square$

THEOREM B.6.3 (*Koszul morphism for lattice algebras;*). The canonical twisting morphism $\tau: \bar{\mathbf{B}}(V_\Lambda^\varepsilon) \rightarrow V_\Lambda^\varepsilon$ is a Koszul morphism: the twisted complex

$$\bar{\mathbf{B}}(V_\Lambda^\varepsilon) \otimes_\tau V_\Lambda^\varepsilon$$

is acyclic.

Proof. The proof uses the lattice weight filtration.

Step 1: Filtration setup. Filter the twisted complex by total lattice weight: define $F^p(\bar{\mathbf{B}}(V_\Lambda^\varepsilon) \otimes_\tau V_\Lambda^\varepsilon)$ to consist of elements whose total lattice weight $\sum_i |\alpha_i|^2 \geq p$ (where $|\alpha|^2 = \langle \alpha, \alpha \rangle$ for the inner product on Λ , which is positive-definite by assumption). Since Λ is positive-definite, each total degree n contains only finitely many lattice vectors of bounded weight, so the filtration is bounded below and convergent.

Step 2: E_1 identification. The differential d_0 on the associated graded E_0 is the bar differential for the Heisenberg subalgebra $\mathcal{H}_d \subset V_\Lambda^\varepsilon$ (the zero-weight sector, generated by the oscillator modes a_n^i , $n < 0$).

This is because the leading-order OPE at weight p is between a weight- p vertex operator and the unit: the lattice exponentials are constant on gr and only the Heisenberg structure contributes to d_0 .

Step 3: Acyclicity at E_1 . By the Heisenberg bar-cobar quasi-isomorphism (Theorem E.3.13, applied to $\mathcal{H}_d$), the twisted complex for the Heisenberg algebra is acyclic: $H^*(\bar{\mathbf{B}}(\mathcal{H}_d) \otimes_{\tau} \mathcal{H}_d) = 0$ in positive degree. Hence $E_1^{p,q} = 0$ for $p + q > 0$, and the spectral sequence collapses at E_1 .

Step 4: Cocycle phases. The cocycle $\varepsilon(\alpha, \beta) \in \{\pm 1\}$ appears as a sign in the differential of the twisted complex, but the underlying graded vector spaces depend only on Λ (not on the choice of ε). Since the acyclicity at E_1 is established for all choices of ε simultaneously (the Heisenberg part d_0 is ε -independent), the twisted complex is acyclic for every valid 2-cocycle.

Step 5: Convergence. Since the filtration is bounded below in each total degree and $E_1^{p,q} = 0$ for $p + q > 0$, the spectral sequence converges to zero in positive total degree, establishing acyclicity of $\bar{\mathbf{B}}(V_{\Lambda}^{\varepsilon}) \otimes_{\tau} V_{\Lambda}^{\varepsilon}$ as required. $\square$

Remark B.6.4 (Self-duality for unimodular lattices). When Λ is unimodular ($\Lambda = \Lambda^*$) and the cocycle ε satisfies $\varepsilon^{-1} \sim \varepsilon$ (cohomologous), the Koszul dual $(V_{\Lambda}^{\varepsilon})^!$ is isomorphic to $V_{\Lambda}^{\varepsilon}$ itself (as a coalgebra). This is the case for E_8 : the lattice vertex algebra V_{E_8} is *Koszul self-dual*. (Note: the Heisenberg algebra $\mathcal{H}_k$ is Koszul but *not* self-dual: $\mathcal{H}_k^! \simeq \text{Sym}^{ch}(V^*)$ by Theorem E.3.13. Self-duality is a special feature of the E_8 lattice structure.)

Remark B.6.5 (Koszul dual kappa for non-unimodular lattices). For a general even lattice Λ (not necessarily unimodular), the Koszul dual $V_{\Lambda}^!$ of Theorem B.6.2 satisfies the free-field complementarity (Theorem K.7.1):

$$\kappa_{\text{latt}}(V_{\Lambda}) + \kappa_{\text{latt}}(V_{\Lambda}^!) = 0, \quad \kappa_{\text{latt}}(V_{\Lambda}^!) = -\text{rank}(\Lambda). \quad (\text{B.6})$$

Three cases illustrate the range of this identity.

- (i) *Rank 1 (Heisenberg).* $V_{\mathbb{Z}} = \mathcal{H}_k$ at $k = 1$ has $\kappa_{\text{latt}} = 1$ and $\mathcal{H}_1^! \simeq \text{Sym}^{ch}(V^*)$ with $\kappa_{\text{latt}}(\mathcal{H}_1^!) = -1$ (Theorem E.3.13). The Koszul dual is the curved chiral symmetric algebra, *not* $\mathcal{H}_{-1}$: these are different algebras with the same numerical kappa.
- (ii) *Even unimodular lattices* (E_8 , Leech, all Niemeier). Theorem B.5.7 gives $V_{\Lambda}^! \cong V_{\Lambda}$, so the complementarity $\kappa + \kappa' = 0$ becomes $2\kappa_{\text{latt}} = 0$; this is consistent only because the self-dual identification is as *coalgebras*, and $\kappa_{\text{latt}}(V_{\Lambda}^!)$ is computed on the coalgebra side where the sign of the curvature reverses. For the Leech lattice, $\kappa_{\text{latt}}(V_{\Lambda_{24}}) = 24$ and $\kappa_{\text{latt}}(V_{\Lambda_{24}}^!) = -24$.
- (iii) *Non-unimodular lattices* (D_4 , A_2 , general Λ). Here $V_{\Lambda}^! = (V_{\Lambda}^{\varepsilon^{-1}})^c \not\cong V_{\Lambda}$: the Koszul dual is a genuinely different lattice chiral algebra, with negative kappa $\kappa_{\text{latt}}(V_{\Lambda}^!) = -\text{rank}(\Lambda) < 0$. Such negative-kappa algebras lie outside the unitary regime ($\kappa > 0$); the Koszul dual is a curved E_1 -chiral coalgebra whose curvature $m_0 = -\text{rank}(\Lambda) \omega$ has the opposite sign to the original.

The negative sign of $\kappa_{\text{latt}}(V_{\Lambda}^!)$ is the lattice shadow of the general principle that Koszul duality reverses the sign of curvature in the bar complex (cf. the Heisenberg case, Theorem E.3.13, where $m_0 = -k \omega$).

Remark B.6.6 (Structural form of the lattice Koszul dual). Theorem B.6.2 identifies $V_{\Lambda}^! = (V_{\Lambda}^{\varepsilon^{-1}})^c$ at the level of coalgebra structure constants. We describe what this coalgebra looks like as a chiral algebra at the Heisenberg-sector level, where the lattice exponentials are stripped away and only the oscillator modes remain.

- (i) *Rank 1.* The lattice VOA $V_{\mathbb{Z}} = \mathcal{H}_1$ is a single free boson at level 1. Its Koszul dual is $\mathcal{H}_1^\dagger \simeq \text{Sym}^{\text{ch}}(V^*)$ (Theorem E.3.13): the curved commutative chiral algebra on the dual vector space, with curvature $m_0 = -\omega$. Equivalently, $\mathcal{H}_1^\dagger \simeq \text{CE}(\mathfrak{h}_{-1})$ (the Chevalley–Eilenberg algebra of the abelian Lie algebra at level -1), with $c(\mathcal{H}_1^\dagger) = -1$ and $\kappa_{\text{latt}}(\mathcal{H}_1^\dagger) = -1$. This is *not* the $\beta\gamma$ system (which has two generators); it is the one-generator curved commutative chiral algebra.
- (ii) *General rank d .* For an even lattice Λ of rank d , the Heisenberg subalgebra $\mathcal{H}_d \subset V_\Lambda$ is a tensor product of d free bosons. By the tensor product compatibility of Koszul duality (Theorem B.7.1 and Corollary 13.13.28), the Heisenberg sector of $V_\Lambda^\dagger$ is

$$\mathcal{H}_d^\dagger \simeq \text{Sym}^{\text{ch}}(\Lambda^* \otimes \omega_X),$$

the rank- d curved commutative chiral algebra with curvature $m_0 = -d\omega$. Equivalently, $\mathcal{H}_d^\dagger \simeq \text{CE}(\mathfrak{h}_{-1}^{\oplus d})$, with central charge $c(\mathcal{H}_d^\dagger) = -d$ and $\kappa_{\text{latt}}(\mathcal{H}_d^\dagger) = -d$, consistent with (B.6). The lattice exponentials of $V_\Lambda^\dagger$ are then governed by the inverse cocycle ε^{-1} on Λ^* , dressing each sector $(V_\Lambda^\dagger)_\gamma$ for $\gamma \in \Lambda^*$ with the dual oscillator Fock space.

- (iii) *Leech lattice ($d = 24$).* The Leech lattice VOA $V_{\Lambda_{24}}$ has $c = 24$, $\kappa_{\text{latt}} = 24$, and is Koszul self-dual as a coalgebra (Theorem B.5.7). Its Koszul dual has $c(V_{\Lambda_{24}}^\dagger) = -24$ and $\kappa_{\text{latt}}(V_{\Lambda_{24}}^\dagger) = -24$. The value $c = -24$ matches the rank with reversed sign, reflecting the 24-fold tensor product structure $\mathcal{H}_1^{\otimes 24} \mapsto (\mathcal{H}_1^\dagger)^{\otimes 24}$ under Koszul duality. By contrast, the Monster module $V^\natural$ has $c = 24$ but $\kappa_{\text{Vir}}(V^\natural) = c/2 = 12$ (Remark B.9.7): the Koszul dual of $V^\natural$ lies in the Virasoro complementarity class ($K_{\text{Vir}} = 13$), while the Koszul dual of $V_{\Lambda_{24}}$ lies in the free-field class ($K_{\text{latt}} = 0$). The shadow tower separates the two: all twenty-four Niemeier lattice VOAs share $\kappa_{\text{latt}} = 24$, class **G**, finite shadow depth; $V^\natural$ has $\kappa_{\text{Vir}} = 12$, class **M**, infinite shadow depth.

The structural content of $K_{\text{latt}} = 0$ is that $V_\Lambda \otimes V_\Lambda^\dagger$ carries a trivially curved bar complex: the curvatures $m_0 = +d\omega$ and $m_0^\dagger = -d\omega$ cancel under the tensor product, so the total complex has $m_0^{\text{tot}} = 0$. This is the chiral algebraic shadow of the classical fact that tensoring a lattice with its dual produces an orthogonal direct sum $\Lambda \oplus \Lambda^*$ whose bilinear form is split (hyperbolic).

Table B.1: Master table: vertex algebra families as lattice constructions.

Family	Lattice origin	Operation	Chapter
Heisenberg $\mathcal{H}_d$	Any Λ , rank d	Zero sector	B
$\widehat{\mathfrak{g}}$ at level 1	Root lattice $\Lambda_{\mathfrak{g}}$	FKS (Thm B.4.1)	9
$\widehat{\mathfrak{g}}$ at level k	Rescaled lattice	Sublattice embedding	9
W -algebras $\mathcal{W}_k(\mathfrak{g})$	$\Lambda_{\mathfrak{g}}$	BRST/DS reduction	10
bc ghosts	$\mathbb{Z}\alpha, \langle \alpha, \alpha \rangle = -1$	Odd lattice	8
Lattice VOA V_Λ	Λ (even)	Direct construction	B
Orbifold $(V_\Lambda)^\sigma$	Λ/σ	Fixed-point subalgebra	B.7
Overlattice V_{Λ_I}	$\Lambda_I \supset \Lambda$	Extension by I	B.7

B.7 FUNCTORIAL PROPERTIES AND LATTICE OPERATIONS

Each lattice operation from Definition B.1.5 lifts to a functorial operation on vertex algebras, and these lifts are compatible with the bar construction.

B.7.1 DIRECT SUM

THEOREM B.7.1 (*Tensor product from direct sum*;). For even lattices Λ_1, Λ_2 with cocycles $\varepsilon_1, \varepsilon_2$:

$$V_{\Lambda_1 \oplus \Lambda_2}^{\varepsilon_1 \otimes \varepsilon_2} \cong V_{\Lambda_1}^{\varepsilon_1} \otimes V_{\Lambda_2}^{\varepsilon_2} \quad (\text{B.7})$$

where $(\varepsilon_1 \otimes \varepsilon_2)((\alpha_1, \alpha_2), (\beta_1, \beta_2)) = \varepsilon_1(\alpha_1, \beta_1) \varepsilon_2(\alpha_2, \beta_2)$.

Proof. The state space decomposes as $\mathcal{H}_{\Lambda_1 \oplus \Lambda_2} \otimes \mathbb{C}[\Lambda_1 \oplus \Lambda_2] \cong (\mathcal{H}_{\Lambda_1} \otimes \mathbb{C}[\Lambda_1]) \otimes (\mathcal{H}_{\Lambda_2} \otimes \mathbb{C}[\Lambda_2])$. The vertex operator for $e^{(\alpha_1, \alpha_2)}$ factors as $Y(e^{\alpha_1}, z) \otimes Y(e^{\alpha_2}, z)$ since the oscillators for Λ_1 and Λ_2 commute (orthogonality of the direct sum). $\square$

COROLLARY B.7.2 (*Künneth for bar complexes [299]*;). Under the isomorphism (B.7):

$$\bar{\mathbf{B}}(V_{\Lambda_1} \otimes V_{\Lambda_2}) \simeq \bar{\mathbf{B}}(V_{\Lambda_1}) \otimes \bar{\mathbf{B}}(V_{\Lambda_2}).$$

Proof. The bar construction of a tensor product of vertex algebras is quasi-isomorphic to the tensor product of bar constructions, by the Eilenberg–Zilber/Künneth theorem for the bar construction (cf. Chapter 3). The lattice grading ensures the relevant spectral sequence converges. $\square$

B.7.2 SUBLATTICE EMBEDDING

PROPOSITION B.7.3 (*Sublattice maps*;). An embedding of even lattices $\iota: \Lambda' \hookrightarrow \Lambda$ induces:

- (i) An embedding of vertex algebras $\iota_*: V_{\Lambda'}^{\varepsilon} \hookrightarrow V_{\Lambda}^{\varepsilon}$ (restriction of the cocycle).
- (ii) A map of bar complexes $\bar{\mathbf{B}}(\iota_*): \bar{\mathbf{B}}(V_{\Lambda'}) \rightarrow \bar{\mathbf{B}}(V_{\Lambda})$.
- (iii) On homology, the induced map respects the lattice grading: the γ -sector of $H_*(\bar{\mathbf{B}}(V_{\Lambda'}))$ maps to the $\iota(\gamma)$ -sector of $H_*(\bar{\mathbf{B}}(V_{\Lambda}))$.

Proof. (i) The inclusion $\iota: \Lambda' \hookrightarrow \Lambda$ induces an embedding of group algebras $\mathbb{C}[\Lambda'] \hookrightarrow \mathbb{C}[\Lambda]$ (sending $e^{\gamma} \mapsto e^{\iota(\gamma)}$) and of Heisenberg algebras $\mathcal{H}_{\Lambda'} \hookrightarrow \mathcal{H}_{\Lambda}$ (the lattice is a subspace of the target space). The cocycle on Λ' is the restriction $\iota^* \varepsilon(\gamma, \gamma') = \varepsilon(\iota(\gamma), \iota(\gamma'))$. The vertex algebra structure is preserved because the state–field correspondence $Y(e^{\gamma}, z) = V_{\gamma}(z)$ restricts to $Y(e^{\iota(\gamma)}, z)$, and the OPE singularities are determined by the inner product which is preserved by ι .

(ii) The bar construction $\bar{\mathbf{B}}$ is a functor from chiral algebras to chiral coalgebras. The embedding ι_* is a morphism of chiral algebras, so $\bar{\mathbf{B}}(\iota_*)$ is a well-defined coalgebra map. Concretely, the configuration space integrals defining the bar differential on $\bar{\mathbf{B}}(V_{\Lambda'})$ are computed using the OPE of $V_{\Lambda'}$, which is the restriction of the OPE of V_{Λ} , so $\bar{\mathbf{B}}(\iota_*)$ commutes with differentials.

(iii) The lattice grading is defined by total lattice charge $\gamma_{\text{tot}} = \sum_i \gamma_i$ for a bar element $s^{-1} e^{\gamma_1} \otimes \dots \otimes s^{-1} e^{\gamma_n}$. Since ι maps Λ' -elements to Λ -elements via a group homomorphism, $\iota(\gamma_{\text{tot}}) = \sum_i \iota(\gamma_i) = \iota(\gamma)_{\text{tot}}$, so the γ -sector of $\bar{\mathbf{B}}(V_{\Lambda'})$ maps into the $\iota(\gamma)$ -sector of $\bar{\mathbf{B}}(V_{\Lambda})$. The differential preserves lattice charge (the product $e^{\alpha} \cdot e^{\beta} = \varepsilon(\alpha, \beta) e^{\alpha+\beta}$ preserves total charge), so the grading is compatible on homology. $\square$

B.7.3 OVERLATTICE EXTENSION

THEOREM B.7.4 (*Overlattice vertex algebra [175];*). Let Λ be an even lattice and $I \subset D(\Lambda) = \Lambda^*/\Lambda$ an isotropic subgroup. The overlattice Λ_I is even, and:

$$V_{\Lambda_I} \cong \bigoplus_{\gamma \in I} V_{\Lambda}^{\gamma}$$

where V_{Λ}^{γ} denotes the γ -twisted module for V_{Λ} , defined as follows.

Definition B.7.5 (*Twisted module for lattice VOA*). For a coset $\gamma \in \Lambda^*/\Lambda$, the γ -twisted module for the lattice VOA V_{Λ} is:

$$V_{\Lambda}^{\gamma} = \mathcal{H} \otimes \mathbb{C}[\gamma + \Lambda]$$

where $\mathcal{H}$ is the Heisenberg Fock space and $\mathbb{C}[\gamma + \Lambda]$ is the group algebra of the coset. The vertex operators act by $Y(e^{\alpha}, z) = E^{-}(\alpha, z)E^{+}(\alpha, z)e^{\alpha}z^{\langle \alpha, - \rangle}$ with the shift $z^{\langle \alpha, \gamma \rangle}$ in the monodromy. When $\gamma \neq 0$, the fields $Y(v, z)$ have branch cuts of order $\langle \alpha, \gamma \rangle \bmod \mathbb{Z}$, making this a genuine twisted (non-local) module.

Proof. Step 1: State space decomposition. Since $\Lambda \subset \Lambda_I$ is a sublattice of finite index, the group algebra decomposes as $\mathbb{C}[\Lambda_I] = \bigoplus_{\gamma \in \Lambda_I/\Lambda} \mathbb{C}[\gamma + \Lambda]$. Tensoring with the Fock space gives:

$$V_{\Lambda_I} = \mathcal{H} \otimes \mathbb{C}[\Lambda_I] = \bigoplus_{\gamma \in \Lambda_I/\Lambda} \mathcal{H} \otimes \mathbb{C}[\gamma + \Lambda] = \bigoplus_{\gamma \in I} V_{\Lambda}^{\gamma},$$

where the last equality identifies $\Lambda_I/\Lambda \cong I$ (by definition of the overlattice) and $\mathcal{H} \otimes \mathbb{C}[\gamma + \Lambda] = V_{\Lambda}^{\gamma}$.

Step 2: Cocycle extension. A 2-cocycle ε on Λ extends to Λ_I if and only if $\varepsilon(\alpha, \beta)\varepsilon(\beta, \alpha) = (-1)^{\langle \alpha, \beta \rangle}$ holds for all $\alpha, \beta \in \Lambda_I$. For $\gamma, \gamma' \in I$ and $\lambda, \lambda' \in \Lambda$, we need $(-1)^{\langle \gamma + \lambda, \gamma' + \lambda' \rangle}$ to be well-defined modulo coboundaries. The isotropicity condition $\langle \gamma, \gamma' \rangle \in \mathbb{Z}$ for all $\gamma, \gamma' \in I$ ensures this: the bilinear form on the discriminant group $D(\Lambda)$ restricts to zero on I , so the Λ -cocycle extends without obstruction.

Step 3: Vertex algebra structure. With the extended cocycle, the vertex operators $Y(e^{\gamma + \lambda}, z)$ for $\gamma \in I$, $\lambda \in \Lambda$ satisfy the same OPE as for Λ (locality, associativity, vacuum axiom), since these follow from the cocycle identity and the lattice inner product. The resulting structure on $\bigoplus_{\gamma \in I} V_{\Lambda}^{\gamma}$ is a vertex algebra, and the decomposition is an isomorphism of vertex algebras by construction. $\square$

Example B.7.6 (*Heterotic lattices*). The two even unimodular lattices of rank 16 arise as overlattices:

- (i) $E_8 \oplus E_8$: already unimodular, no extension needed.
- (ii) $D_{16}^{+} = (D_{16})_I$ where $I = \{0, [\text{spinor}]\} \cong \mathbb{Z}/2\mathbb{Z}$ is the isotropic subgroup generated by the spinor class in $D(\Lambda_{D_{16}}) \cong (\mathbb{Z}/2\mathbb{Z})^2$.

The corresponding vertex algebras $V_{E_8 \oplus E_8}$ and $V_{D_{16}^{+}}$ give the two heterotic string theories. Their bar complexes are non-isomorphic despite having the same rank and determinant.

B.7.4 ORBIFOLD CONSTRUCTION

Construction B.7.7 (*Orbifold vertex algebra*). For $\sigma \in \text{Aut}(\Lambda)$ of finite order N , the *orbifold vertex algebra* is the fixed-point subalgebra:

$$(V_{\Lambda}^{\varepsilon})^{\sigma} = \{v \in V_{\Lambda}^{\varepsilon} : \sigma \cdot v = v\},$$

where σ acts on V_{Λ} by $\sigma(e^{\alpha}) = e^{\sigma(\alpha)}$ and $\sigma(\alpha_{-n}) = (\sigma\alpha)_{-n}$ on Heisenberg oscillators.

When σ preserves the cocycle ($\varepsilon(\sigma\alpha, \sigma\beta) = \varepsilon(\alpha, \beta)$), this is a vertex subalgebra.

Table B.2: Functorial operations on lattice algebras and their bar complexes.

Operation	Vertex algebra	Bar complex	Koszul dual
Direct sum $\Lambda_1 \oplus \Lambda_2$	$V_{\Lambda_1} \otimes V_{\Lambda_2}$	$\bar{\mathbf{B}}_1 \otimes \bar{\mathbf{B}}_2$	$V_{\Lambda_1}^! \otimes V_{\Lambda_2}^!$
Sublattice $\Lambda' \hookrightarrow \Lambda$	$V_{\Lambda'} \hookrightarrow V_{\Lambda}$	$\bar{\mathbf{B}}_{\Lambda'} \rightarrow \bar{\mathbf{B}}_{\Lambda}$	$V_{\Lambda}^! \twoheadrightarrow V_{\Lambda'}^!$
Overlattice $\Lambda_I \supset \Lambda$	$V_{\Lambda_I} = \bigoplus_I V_{\Lambda}^{\gamma}$	$\bar{\mathbf{B}}_{\Lambda_I} = \bigoplus_I \bar{\mathbf{B}}_{\gamma}$	$V_{\Lambda_I}^! = \bigoplus_I (V_{\Lambda}^{\gamma})^!$
Orbifold V_{Λ}^{σ}	$(V_{\Lambda})^{\sigma}$	$\bar{\mathbf{B}}(V_{\Lambda})^{\sigma}$	$(V_{\Lambda}^!)^{\sigma}$
Rescaling $\sqrt{k}\Lambda$	$V_{\sqrt{k}\Lambda}$	Level- k bar complex	Level- k dual
BRST reduction	$H_{Q_{\text{DS}}}^0(V_{\Lambda})$	$H_{Q_{\text{DS}}}^*(\bar{\mathbf{B}}(V_{\Lambda}))$	W-algebra Koszul dual

Remark B.7.8 (The derivation chain). The functorial operations of this section (direct sum, sublattice embedding, overlattice extension, and orbifold) compose into a single derivation chain:

$$\text{Lattice } \Lambda \xrightarrow{\text{FKS}} \text{Kac-Moody} \xrightarrow{\text{BRST}} \text{W-algebras} \xrightarrow{\text{orbifold}} \text{non-simply-laced}$$

At each step, the bar complex transforms functorially (by Theorems B.5.2 and B.6.2), so the Koszul duality theory of Part I applies throughout.

B.8 CHIRAL HOCHSCHILD COHOMOLOGY OF LATTICE ALGEBRAS

THEOREM B.8.1 (*Lattice chiral Hochschild cohomology*;). For an even integral lattice Λ :

$$CH^n(V_{\Lambda}, V_{\Lambda}) = \bigoplus_{\alpha \in \Lambda} CH^n(V_{\Lambda}, V_{\Lambda}^{\alpha})$$

and the degree-zero component ($\alpha = 0$) is:

$$CH^n(V_{\Lambda}, V_{\Lambda}^0) \cong H^n(\Lambda, V_{\Lambda}^{\Lambda})$$

where $V_{\Lambda}^{\Lambda} = V_{\Lambda}^0 = \mathcal{H}$ denotes the Λ -invariants (the degree-zero sector under the lattice grading) and $H^n(\Lambda, -)$ is group cohomology of the free abelian group Λ . The non-zero sectors $\alpha \neq 0$ contribute additional classes that depend on the lattice geometry.

Proof. The lattice vertex algebra decomposes as $V_{\Lambda} = \bigoplus_{\alpha \in \Lambda} V_{\Lambda}^{\alpha}$ where $V_{\Lambda}^{\alpha} = \mathcal{H} \otimes e^{\alpha}$ is the α -isotypic component.

The chiral Hochschild complex respects this grading:

$$CC_{\text{ch}}^n(V_{\Lambda}, V_{\Lambda}) = \bigoplus_{\alpha_1, \dots, \alpha_n, \beta} \text{Hom}(V_{\Lambda}^{\alpha_1} \otimes \dots \otimes V_{\Lambda}^{\alpha_n}, V_{\Lambda}^{\beta}).$$

The differential preserves $\sum_i \alpha_i = \beta$, and the resulting spectral sequence (filtering by lattice degree) collapses at E_2 to give:

$$CH^*(V_{\Lambda}, V_{\Lambda}) = \bigoplus_{\alpha \in \Lambda} CH^*(V_{\Lambda}, V_{\Lambda}^{\alpha}).$$

For $\alpha = 0$, this identifies with the group cohomology $H^*(\Lambda, V_{\Lambda}^{\Lambda})$ via the standard bar resolution for $\Lambda \cong \mathbb{Z}^d$. $\square$

COROLLARY B.8.2 (*Unimodular case*;). For a unimodular lattice Λ (so $D(\Lambda) = 0$), the chiral chiral Hochschild cohomology reduces to:

$$CH^n(V_\Lambda, V_\Lambda) \cong H^n(\Lambda, \mathcal{H})$$

where $\mathcal{H}$ is the Heisenberg Fock space (the Λ -invariant sector when $\Lambda = \Lambda^*$).

Proof. When Λ is unimodular, $D(\Lambda) = \Lambda^*/\Lambda = 0$, so the discriminant contributions vanish and the chiral Hochschild complex reduces to the group cohomology complex $C^*(\Lambda, \mathbb{C})$ by the preceding theorem. $\square$

Example B.8.3 (*A_1 chiral Hochschild cohomology*). For $\Lambda = A_1 \cong \mathbb{Z}$, the group cohomology of $\mathbb{Z}$ is:

$$H^n(\mathbb{Z}, M) = \begin{cases} M^\mathbb{Z} & n = 0, \\ M_\mathbb{Z} & n = 1, \\ 0 & n \geq 2. \end{cases}$$

Hence $CH^n(V_{A_1}, V_{A_1})$ is concentrated in degrees 0 and 1. This reflects the rigidity of the $\widehat{\mathfrak{sl}}_2$ current algebra at level 1: it has a 1-dimensional space of first-order deformations (the level) and no higher obstructions.

B.9 HIGHER GENUS

At higher genus, the lattice grading on the bar complex persists and interacts with the geometry of moduli spaces to produce modular objects.

PROPOSITION B.9.1 (*Genus-1 partition function*;). For an even lattice Λ of rank d , the genus-1 partition function of V_Λ is:

$$Z_1(V_\Lambda, \tau) = \frac{\Theta_\Lambda(\tau)}{[\eta(\tau)]^d}$$

where $\Theta_\Lambda(\tau) = \sum_{\alpha \in \Lambda} q^{\langle \alpha, \alpha \rangle / 2}$ is the theta series of Λ (with $q = e^{2\pi i \tau}$) and $\eta(\tau) = q^{1/24} \prod_{n=1}^{\infty} (1 - q^n)$ is the Dedekind eta function.

Proof. The partition function traces over the state space: $Z_1 = \text{tr}_{V_\Lambda} q^{L_0 - c/24}$. The Heisenberg sector contributes $1/\eta(\tau)^d$ (the bosonic oscillator partition function for d free bosons), and the lattice sum $\sum_{\alpha \in \Lambda} q^{h_\alpha} = \sum_{\alpha} q^{\langle \alpha, \alpha \rangle / 2} = \Theta_\Lambda(\tau)$ accounts for the lattice momentum modes. $\square$

THEOREM B.9.2 (*Modular invariance*;). For an even unimodular lattice Λ of rank d , the partition function $Z_1(V_\Lambda, \tau)$ is S -invariant: $Z_1(V_\Lambda, -1/\tau) = Z_1(V_\Lambda, \tau)$. Under $T : \tau \mapsto \tau + 1$, the partition function transforms as $Z_1(\tau + 1) = e^{-\pi i d/12} Z_1(\tau)$; full $\text{SL}_2(\mathbb{Z})$ -invariance holds if and only if $d \equiv 0 \pmod{24}$.

Proof. By Poisson summation, $\Theta_\Lambda(-1/\tau) = (\tau/i)^{d/2} |\Lambda^*/\Lambda|^{1/2} \Theta_{\Lambda^*}(\tau)$. For unimodular $\Lambda = \Lambda^*$, this gives $\Theta_\Lambda(-1/\tau) = (\tau/i)^{d/2} \Theta_\Lambda(\tau)$. Combined with $\eta(-1/\tau) = \sqrt{\tau/i} \eta(\tau)$, we obtain $Z_1(-1/\tau) = Z_1(\tau)$.

For the T -transformation $\tau \mapsto \tau + 1$: $\Theta_\Lambda(\tau + 1) = \Theta_\Lambda(\tau)$ (since $\langle \alpha, \alpha \rangle \in 2\mathbb{Z}$ for even Λ) and $\eta(\tau + 1) = e^{\pi i/12} \eta(\tau)$, giving $Z_1(\tau + 1) = e^{-\pi i d/12} Z_1(\tau)$. For $d \equiv 0 \pmod{24}$ this is exact invariance; in general, Z_1 transforms as a modular function of the appropriate level.

For $d = 8$ (E_8): the T -phase is $e^{-8\pi i/12} = e^{-2\pi i/3} \neq 1$, so $Z_1(\tau + 1) = e^{-2\pi i/3} Z_1(\tau)$; the partition function is S -invariant but *not* T -invariant. Equivalently, $Z_1 = E_4(\tau)/\eta(\tau)^8 = j(\tau)^{1/3}$ transforms under T with a cube-root-of-unity multiplier, making it a modular function for the congruence subgroup $\Gamma(3)$.

but not for the full $\mathrm{SL}_2(\mathbb{Z})$. Full modular invariance holds only for $d \equiv 0 \pmod{24}$ (e.g., the Leech lattice with $d = 24$). $\square$

Remark B.9.3 (Higher genus and Siegel modular forms). At genus g , the partition function generalizes to

$$Z_g(V_\Lambda, \Omega) = \frac{\Theta_\Lambda^{(g)}(\Omega)}{[\det(\mathrm{Im} \Omega)]^{d/2}} \cdot (\text{oscillator contribution})$$

where Ω is the period matrix, $\Theta_\Lambda^{(g)}$ is the Siegel theta series, and the denominator involves the determinant of the imaginary part of Ω . For unimodular even lattices, $\Theta_\Lambda^{(g)}$ transforms as a Siegel modular form of weight $d/2$ for $\mathrm{Sp}(2g, \mathbb{Z})$, as discussed in Chapter K.7.1.

The lattice grading on the bar complex persists at all genera. At genus g , the bar differential acquires corrections from the cohomology of $\overline{\mathcal{M}}_{g,n}$, but these corrections preserve the total lattice degree. The spectral sequence computing bar complex homology at genus g has E_1 page given by the genus-0 bar complex (with its lattice decomposition), and the higher differentials d_r for $r \geq 1$ encode the genus- g quantum corrections studied in Part I.

B.9.1 THE NIEMEIER SHADOW ATLAS

The twenty-four Niemeier lattices are the even unimodular lattices in dimension 24. They form a finite classification: each is determined by its root system $R(\Lambda)$, which satisfies Niemeier's constraint that all irreducible components have the same Coxeter number h . The twenty-fourth lattice, with $R = \emptyset$, is the Leech lattice Λ_{Leech} .

THEOREM B.9.4 (Niemeier shadow universality;). Let Λ be any of the twenty-four Niemeier lattices. Then:

- (i) $\kappa(V_\Lambda) = \mathrm{rank}(\Lambda) = 24$ for all twenty-four lattices.
- (ii) $S_r(V_\Lambda) = 0$ for all $r \geq 3$: every Niemeier lattice VOA is class **G** with shadow depth 2.
- (iii) The genus- g scalar amplitude is $F_g(V_\Lambda) = 24 \lambda_g^{\mathrm{FP}}(\text{UNIFORM-WEIGHT})$ for all $g \geq 1$, identical for all twenty-four lattices. In particular,

$$F_1 = 1, \quad F_2 = \frac{7}{240}, \quad F_3 = \frac{31}{40320}, \quad F_4 = \frac{127}{6451200}.$$

- (iv) The planted-forest correction vanishes: $\delta_{\mathrm{pf}}^{(g,0)}(V_\Lambda) = 0$ for all $g \geq 2$, since $S_3 = 0$.
- (v) The complementarity pairing for the lattice VOA family is the free-field / Ext $\leftrightarrow$ Sym pattern $\kappa_{\mathrm{latt}}(V_\Lambda) + \kappa_{\mathrm{latt}}(V_\Lambda^\dagger) = 0_{(\mathrm{lattice}, \mathrm{type} \, i)}$ (not the Virasoro value 13; Theorem K.7.1).

Proof. Part (i) is Theorem B.14.2 applied to rank-24 lattices. Part (ii) follows from the Gaussian class characterization: lattice VOAs are generated by weight-1 currents $J^a(z)$ whose OPE $J^a(z)J^b(w) \sim \langle a, b \rangle / (z-w)^2$ is purely quadratic, so the shadow obstruction tower terminates at degree 2 (Corollary B.14.4). Part (iii) uses $\kappa = 24$ and the Faber–Pandharipande numbers $\lambda_g^{\mathrm{FP}} = (2^{2g-1} - 1) |B_{2g}| / (2^{2g-1} (2g)!)$ (Theorem K.7.1). Part (iv) follows from the explicit formula $\delta_{\mathrm{pf}}^{(2,0)} = S_3(10S_3 - \kappa)/48$ (Proposition ??) with $S_3 = 0$. Part (v) is the lattice complementarity of §B.10. $\square$

The shadow obstruction tower is blind to the root system: all twenty-four Niemeier lattices produce identical shadow data. The *distinguishing invariants* live outside the shadow tower, in the arithmetic structure of the lattice theta series.

PROPOSITION B.9.5 (*Niemeier theta series decomposition*;). The genus-1 theta series of a Niemeier lattice Λ with $|R(\Lambda)|$ roots decomposes as

$$\Theta_{\Lambda}(\tau) = E_{12}(\tau) + c_{\Lambda}(\Lambda) \Delta(\tau),$$

where E_{12} is the normalized Eisenstein series of weight 12, $\Delta = \eta^{24}$ is the Ramanujan cusp form, and

$$c_{\Lambda}(\Lambda) = \frac{691 |R(\Lambda)| - 65520}{691}.$$

In particular:

- (i) The Leech lattice ($|R| = 0$) has $c_{\Lambda} = -65520/691$, and $\Theta_{\text{Leech}}(\tau) = E_{12} - (65520/691) \Delta$: the coefficient of q is $65520/691 + (-65520/691) \cdot 1 = 0$ (no norm-2 vectors).
- (ii) For D_{24} ($|R| = 1104$): $c_{\Lambda} = (691 \cdot 1104 - 65520)/691 = 697344/691$.
- (iii) For $3E_8$ ($|R| = 720$): $c_{\Lambda} = (691 \cdot 720 - 65520)/691 = 432000/691$.
- (iv) For $24A_1$ ($|R| = 48$): $c_{\Lambda} = (691 \cdot 48 - 65520)/691 = -32352/691$.

Proof. The space $M_{12}(\text{SL}_2(\mathbb{Z}))$ has dimension 2, spanned by E_{12} and Δ . The constant term of Θ_{Λ} is $r_{\Lambda}(0) = 1$ (the zero vector), which equals the constant term of E_{12} (normalized to 1). Since $\Delta = q - 24q^2 + \dots$ has zero constant term, c_{Λ} is determined by the coefficient of q : $r_{\Lambda}(1) = |R(\Lambda)|$ and $E_{12} = 1 + (65520/691) \sum_{n \geq 1} \sigma_{11}(n) q^n$ gives $c_{\Lambda} = (|R(\Lambda)| - 65520\sigma_{11}(1)/691) \cdot 691/\tau(1) = (691 |R| - 65520)/691$. $\square$

THEOREM B.9.6 (*Genus-2 Siegel theta series of Niemeier lattices*;). For any Niemeier lattice Λ , the genus-2 Siegel theta series $\Theta_{\Lambda}^{(2)}(\Omega) \in M_{12}(\text{Sp}(4, \mathbb{Z}))$ satisfies:

- (i) $\dim M_{12}(\text{Sp}(4, \mathbb{Z})) = 3$ and $\dim S_{12}(\text{Sp}(4, \mathbb{Z})) = 1$ (Igusa). The generators of the even-weight Igusa ring are $E_4, E_6, \chi_{10}, \chi_{12}$, where χ_{10} and χ_{12} are Igusa cusp forms. The three weight-12 monomials are E_4^3, E_6^2 , and χ_{12} ; the unique cusp form is χ_{12} .
- (ii) $\Theta_{\Lambda}^{(2)} = E_{12}^{(2)} + (\text{Klingen}) + (\text{cusp})$, where $E_{12}^{(2)}$ is the Siegel Eisenstein series of weight 12.
- (iii) For the Leech lattice: the cusp component is nonzero (Proposition S.23.5), and the Saito–Kurokawa lift $\chi_{12} = \text{SK}(f_{22})$ appears with nonzero coefficient in the cusp projection. The Böcherer coefficient $B_{f_{22}}(D)$ provides algebraic access to $L(1/2, \pi_{f_{22}} \times \chi_D)$ (Theorem S.23.6).
- (iv) For all twenty-four lattices, the scalar shadow amplitude $F_2 = 7/240$ is identical, but the Siegel theta series $\Theta_{\Lambda}^{(2)}$ distinguishes the lattices: genuinely genus-2 arithmetic (beyond the shadow tower) separates lattices that the shadow obstruction tower cannot.

Proof. The Igusa ring dimensions are classical (Igusa 1962, Aoki–Ibukiyama 2005). The Siegel–Weil theorem identifies the genus theta series $\sum_{[\Lambda] \in \text{genus}} |\text{Aut}(\Lambda)|^{-1} \Theta_{\Lambda}^{(2)} / \sum |\text{Aut}|^{-1}$ with $E_{12}^{(2)}$. Individual lattice theta series differ from $E_{12}^{(2)}$ by Klingen Eisenstein and cusp components. For the Leech lattice, $r_2(\Lambda_{\text{Leech}}, T_0) = 0$ at $T_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ while $a_{E_{12}}(T_0) > 0$ (Kitaoka positivity), giving nonzero cusp content (Proposition S.23.5). Part (iv) follows from Theorem B.9.4(iii). $\square$

Remark B.9.7 (The Monster module $V^{\natural}$ and the Niemeier shadow atlas). The FLM moonshine module $V^{\natural}$ has $c = 24$ but is *not* a lattice VOA: $\dim V_1^{\natural} = 0$ (no weight-1 currents), so there is no rank-24 Heisenberg subalgebra. The modular characteristic is determined by the Virasoro sector alone: $\kappa(V^{\natural}) = c/2 = 12$ (the modular characteristic is determined by the Virasoro sector alone since $\dim V_1^{\natural} = 0$; the weight-2 Griess algebra generators do not contribute to κ because κ is the genus-1 bar complex obstruction, which for $V^{\natural}$ reduces to the Virasoro obstruction $c/2$; verified by five independent paths in `compute/lib/moonshine_shadow_depth.py`), which differs from $\kappa(V_{\Lambda}) = 24$ for Niemeier lattice VOAs. This is a genuine shadow-tower distinction: the modular characteristic separates $V^{\natural}$ from all twenty-four Niemeier lattices.

The Monster module is class **M** (infinite shadow depth) on the T -line. The critical discriminant on this line is $\Delta = 8\kappa S_4 = 8 \cdot 12 \cdot 10 / (24 \cdot 142) = 20/71 \neq 0$ (using the Virasoro $S_4 = 10/(c(5c+22))$ at $c = 24$ and $\kappa = 12$), so the single-line dichotomy (Theorem 13.22.160) forces infinite shadow depth. The Griess algebra at weight 2 ($\dim V_2^{\natural} = 196884$) introduces genuinely nonlinear OPE structure on the additional primary lines. The McKay–Thompson series $T_{1A}(\tau) = J(\tau) = j(\tau) - 744 = q^{-1} + 196884q + 21493760q^2 + \cdots$ is the Hauptmodul for $\mathrm{SL}_2(\mathbb{Z})$, and the coefficients decompose into Monster representations: $196884 = 196883 + 1$, $21493760 = 21296876 + 196883 + 1$ (the Conway–Norton monstrous moonshine). The shadow obstruction tower at the scalar level gives $F_1(V^{\natural}) = 12/24 = 1/2$, which is *half* the Niemeier value $F_1 = 1$.

For umbral moonshine (Cheng–Duncan–Harvey): each Niemeier lattice Λ with root system R determines an umbral group $G_{\Lambda} = \mathrm{Aut}(\Lambda)/W(R)$ acting on a graded module whose dimensions are coefficients of a mock modular form. The Mathieu case $\Lambda = 24A_1$, $G = M_{24}$, connects to the K_3 elliptic genus decomposition. The shadow obstruction tower of V_{Λ} detects the umbral structure through the *mock modular shadow*: the genus-1 propagator is $E_2^*(\tau)$ (quasi-modular, not holomorphic), and the mock modular completion of the umbral module involves the shadow of E_2^* in the sense of Zagier.

B.9.2 THE THREE THEOREMS FOR LATTICE ALGEBRAS

Remark B.9.8 (Main theorems for lattice VOAs). The computations of this chapter provide an abelian verification of the main theorems of Part I. Each verification reveals structure invisible in the abstract theory:

1. *Theorem A* (Theorem 11.1.84). Applied to V_{Λ} , the bar-cobar adjunction shows that the lattice bar complex concentrates in conformal-weight-graded degrees, with the concentration pattern governed by the root system of Λ (Theorem B.5.2). The Koszul dual is identified as the lattice algebra with inverse cocycle (Theorem B.6.2), so the duality is visible at the level of 2-cocycles on Λ .
2. *Theorem B* (Theorem 13.18.4). For unimodular lattices, the self-duality of Theorem B.5.7 forces the spectral sequence to collapse: the bar complex resolves V_{Λ} by free Heisenberg modules, and the inversion quasi-isomorphism has no higher corrections.
3. *Theorem C* (Theorem 13.15.14). The central charge $c(V_{\Lambda}) = d$ (the lattice rank) satisfies $c + c^{\dagger} = 2d$ (Theorem 1.3.8). The genus- g obstruction class is $\mathrm{obs}_g = d \cdot \lambda_g$ (Theorem B.8.1), with obstruction parameter $\kappa = d$ equal to the rank.

B.10 CATALOG OF LATTICE KOSZUL DUAL PAIRS

The lattice engine produces Koszul dual pairs for every even lattice. Table B.4 summarizes the results.

Table B.3: The twenty-four Niemeier lattices: shadow data and genus-1 theta series. All have $\kappa = 24$, class $\mathbf{G}$, $S_r = 0$ for $r \geq 3$. The column c_Δ gives the coefficient in $\Theta_\Delta = E_{12} + c_\Delta \cdot \Delta$. The column $|R|$ is the number of roots. The Coxeter number h is uniform across all simple components (Niemeier's constraint).

#	Root system	$ R $	h	c_Δ
1	D_{24}	1104	46	697344/691

Table B.4: Lattice Koszul dual pairs and genus-1 bar complex data.

Lattice Λ	Rank	$V_{\Lambda}^!$	$\Theta_{\Lambda}(\tau)$	Self-dual?
A_1	1	$(V_{A_1}^{\varepsilon^{-1}})^c$	$\theta_3(2\tau)$	No
A_2	2	$(V_{A_2}^{\varepsilon^{-1}})^c$	$\theta_3^{A_2}(\tau)$	No
D_4	4	$(V_{D_4}^{\varepsilon^{-1}})^c$	$\frac{1}{2}(\theta_3^4 + \theta_4^4)$	No
D_8	8	$(V_{D_8}^{\varepsilon^{-1}})^c$	$\Theta_{D_8}(\tau)$	No
E_6	6	$(V_{E_6}^{\varepsilon^{-1}})^c$	$\Theta_{E_6}(\tau)$	No
E_7	7	$(V_{E_7}^{\varepsilon^{-1}})^c$	$\Theta_{E_7}(\tau)$	No
E_8	8	V_{E_8}	$E_4(\tau)$	Yes
$E_8 \oplus E_8$	16	$V_{E_8 \oplus E_8}$	$E_4(\tau)^2$	Yes
D_{16}^+	16	$V_{D_{16}^+}$	$E_4(\tau)^2$	Yes
Leech	24	V_{Leech}	$\Theta_{\text{Leech}}/\eta^{24} = j - 720$	Yes

PROPOSITION B.10.1 (*Koszul self-duality criterion*;). V_{Λ} is Koszul self-dual if and only if Λ is unimodular (i.e., $\Lambda = \Lambda^*$) and the FLM cocycle ε is self-inverse up to coboundary. The even unimodular lattices in rank d exist only for $d \equiv 0 \pmod{8}$; the count is 1 for $d = 8$, 2 for $d = 16$, 24 for $d = 24$ (Niemeier lattices), and grows rapidly thereafter.

Proof. The “only if” direction: if $V_{\Lambda}^! \cong V_{\Lambda}$, then by Theorem B.6.2, $V_{\Lambda}^{\varepsilon^{-1}} \cong V_{\Lambda}^{\varepsilon}$, which requires $\Lambda^* = \Lambda$ (unimodularity, since the dual lattice enters via the coalgebra structure) and $\varepsilon^{-1} \sim \varepsilon$. The “if” direction is Theorem B.5.7. The existence condition $d \equiv 0 \pmod{8}$ for even unimodular lattices is classical (signature constraints from the Milnor–Husemoller classification). $\square$

PROPOSITION B.10.2 (D_4 and triality;). The D_4 lattice is *not* unimodular: $\det(\text{Gram}_{D_4}) = 4$ and $D_4^*/D_4 \cong (\mathbb{Z}/2\mathbb{Z})^2$. In particular, V_{D_4} is *not* Koszul self-dual; its Koszul dual is $(V_{D_4}^{\varepsilon^{-1}})^c$ by Theorem B.6.2.

The overlattice $D_4^+ = D_4 \cup (D_4 + s)$ (adding the spinor class $s = \frac{1}{2}(1, 1, 1, 1)$) is unimodular but *odd*: $\langle s, s \rangle = 1 \notin 2\mathbb{Z}$, so $D_4^+ \cong \mathbb{Z}^4$ as lattices. Even unimodular overlattices D_n^+ exist only for $n \equiv 0 \pmod{8}$ (e.g., $D_8^+ \cong E_8$). Triality (the S_3 symmetry of the D_4 Dynkin diagram) permutes the three nontrivial cosets in D_4^*/D_4 (vector, spinor, and conjugate spinor) and acts as an outer automorphism of the D_4 root system.

Proof. The discriminant computation $D_4^*/D_4 \cong (\mathbb{Z}/2\mathbb{Z})^2$ shows $D_4 \neq D_4^*$, so V_{D_4} is not unimodular and Theorem B.5.7 does not apply; Theorem B.6.2 gives $V_{D_4}^! \cong (V_{D_4}^{\varepsilon^{-1}})^c \not\cong V_{D_4}$. The overlattice D_4^+ is unimodular ($[D_4^+ : D_4] = 2$ and $\det = 4/4 = 1$) but odd ($\langle s, s \rangle = 1$), so Theorem B.5.7 does not apply. The triality action on D_4^*/D_4 is the standard S_3 -symmetry permuting the three nontrivial cosets. $\square$

PROPOSITION B.10.3 (*Lattice twisted-sector charge inversion on the bar surface*;). Let Λ be an even lattice with Koszul dual $V_{\Lambda}^! \cong (V_{\Lambda}^{\varepsilon^{-1}})^c$ (Theorem B.6.2). For the twisted sector V_{Λ}^{γ} with $\gamma \in \Lambda^*/\Lambda$, the bar complex records the discriminant character γ through the module-insertion monodromy, and Verdier reversal sends that charge to its inverse:

$$\gamma \longmapsto -\gamma \quad \text{in } D(\Lambda) = \Lambda^*/\Lambda.$$

In particular, inversion permutes the discriminant sectors, so the number of simple twisted sectors is unchanged.

Proof. The bar construction applied to the twisted module $V_\Lambda^\gamma = \mathcal{H} \otimes \mathbb{C}[\gamma + \Lambda]$ produces a comodule over $\bar{B}(V_\Lambda)$, which is a coalgebra over the dual lattice data. The coset $\gamma \in \Lambda^*/\Lambda$ enters the bar complex via the monodromy: the vertex operator $Y(e^\alpha, z)$ acting on V_Λ^γ has monodromy $z^{\langle \alpha, \gamma \rangle}$ around the module insertion point.

Under the bar construction, this monodromy becomes a $\langle \alpha, \gamma \rangle$ -twist in the differential on $\bar{C}_{n+1}(X)$. The Verdier involution (which underlies Koszul duality) reverses the monodromy: $z^{\langle \alpha, \gamma \rangle} \mapsto z^{-\langle \alpha, \gamma \rangle}$, mapping γ to $-\gamma$ in the discriminant group. Since $\gamma \mapsto -\gamma$ is an involution of the finite abelian group $D(\Lambda)$, it permutes the twisted sectors without changing their number. $\square$

Remark B.10.4 (What this does and does not prove). The proposition above proves only the bar-surface charge inversion $\gamma \mapsto -\gamma$. It does *not* by itself construct a semisimple pointed module-category equivalence for lattice VOAs, nor does it prove from Theorem 15.1.12 that fusion of twisted sectors or the pointed modular S -matrix is preserved. Those stronger statements would require a separate categorical comparison theorem on the lattice module categories.

Example B.10.5 (Charge inversion for the A_1 lattice sectors). For $\Lambda = A_1 = \sqrt{2}\mathbb{Z}$: the discriminant group is $D(A_1) = A_1^*/A_1 \cong \mathbb{Z}/2\mathbb{Z}$, with two simple V_{A_1} -modules: $V_{A_1}^0 = V_{A_1}$ (vacuum) and $V_{A_1}^{1/\sqrt{2}}$ (spinor). The bar-surface charge inversion of Proposition B.10.3 fixes the vacuum sector and sends the nontrivial class to its inverse, which is the same class: $-1 \equiv 1 \pmod{2}$ in $\mathbb{Z}/2\mathbb{Z}$. The pointed S -matrix $S = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ is therefore arithmetically unchanged under this sign involution on the discriminant group, consistent with the pointed fusion rule $1/2 + 1/2 = 0$ in $\mathbb{Z}/2\mathbb{Z}$.

Remark B.10.6 (Distinguishing $E_8 \oplus E_8$ from D_{16}^+). The bar complexes of $V_{E_8 \oplus E_8}$ and $V_{D_{16}^+}$ are both self-dual (both are even unimodular lattices of rank 16), but they are *non-isomorphic* as coalgebras. At genus 1, the two lattices are *indistinguishable*: both have theta function $\Theta_\Lambda(\tau) = E_4(\tau)^2$, since the space $M_8(\mathrm{SL}_2(\mathbb{Z}))$ is one-dimensional. The distinction first appears at genus 2: the Siegel theta functions $\Theta_{E_8 \oplus E_8}^{(2)}$ and $\Theta_{D_{16}^+}^{(2)}$ are distinct Siegel modular forms of weight 8, sufficing to distinguish the two even unimodular lattices of rank 16. This illustrates how the genus- g bar complex captures strictly finer information than the genus-1 bar complex.

B.II E_1 -CHIRAL ALGEBRAS FROM COCYCLE DEFORMATIONS

The preceding sections compute bar complexes of lattice algebras with *symmetric* cocycles, obtaining E_∞ -chiral algebras. Theorem B.3.2 guarantees that *any* 2-cocycle produces an E_1 -chiral algebra; non-symmetric cocycles produce *strictly* E_1 structures. The E_1 theory is developed systematically below: the bar complex moves from unordered to ordered configurations, the bar cohomology acquires new classes, and the resulting Koszul pairs provide a rich family of E_1 -chiral algebras complementing the Yangian construction of Chapter O.

B.II.1 THE ORDERED CONFIGURATION BAR COMPLEX

Construction B.II.1 (E_1 bar complex of V_Λ^ε). Let ε be a (not necessarily symmetric) normalized bimultiplicative 2-cocycle on an even lattice Λ . By Theorem B.3.2, V_Λ^ε is E_1 -chiral. Its bar complex $\bar{B}^{E_1}(V_\Lambda^\varepsilon)$ is the E_1 -chiral bar construction of Theorem II.5.4, indexed by *ordered* configurations.

Generators. In bar degree p , the generators are *ordered* tuples:

$$[e^{\alpha_1} \mid e^{\alpha_2} \mid \cdots \mid e^{\alpha_p}] \otimes \omega \in \overline{B}_\gamma^p, \quad \gamma = \sum_{i=1}^p \alpha_i \in \Lambda,$$

where $\alpha_i \in \Lambda \setminus \{0\}$ and $\omega \in \Omega^{p-1}(\overline{C}_p^{\text{ord}}(X), \log D)$ is a logarithmic form on the compactified *ordered* configuration space. Unlike the E_∞ bar complex of Construction B.5.1, there is *no* Σ_p -quotient: the elements $[e^{\alpha_1} \mid e^{\alpha_2}]$ and $[e^{\alpha_2} \mid e^{\alpha_1}]$ are independent generators.

Differential. The bar differential sums residues over collision divisors for *adjacent* pairs (the face maps of the associahedron):

$$d([e^{\alpha_1} \mid \cdots \mid e^{\alpha_p}] \otimes 1) = \sum_{i=1}^{p-1} \varepsilon(\alpha_i, \alpha_{i+1}) \delta_{\langle \alpha_i, \alpha_{i+1} \rangle, -1} [e^{\alpha_1} \mid \cdots \mid e^{\alpha_i + \alpha_{i+1}} \mid \cdots \mid e^{\alpha_p}] \otimes 1. \quad (\text{B.8})$$

The Kronecker delta selects the simple pole condition. The cocycle $\varepsilon(\alpha_i, \alpha_{i+1})$ enters with its value at the *specific ordered pair* (α_i, α_{i+1}) . For a non-symmetric cocycle, permuting the pair changes this coefficient.

Remark B.11.2 (Comparison with the E_∞ bar complex). For a symmetric cocycle, the Borchers symmetry $\varepsilon(\alpha, \beta) = (-1)^{\langle \alpha, \beta \rangle} \varepsilon(\beta, \alpha)$ allows one to pass to the Σ_n -coinvariants, recovering the E_∞ bar complex of Construction B.5.1 on unordered configurations. In bar degree 2, this identifies $[e^\alpha \mid e^\beta]$ with $(-1)^{\langle \alpha, \beta \rangle} [e^\beta \mid e^\alpha]$.

For a non-symmetric cocycle, no such identification is possible: the ratio $\varepsilon(\alpha, \beta)/\varepsilon(\beta, \alpha) \neq (-1)^{\langle \alpha, \beta \rangle}$, so the Σ_2 -action on ordered pairs is not compatible with the differential. The E_1 bar complex is therefore strictly larger than any symmetric quotient.

B.11.2 ROOT-OF-UNITY DEFORMATION FAMILIES

Specializing the root-of-unity deformation of Remark B.2.7 to construct explicit families of strictly E_1 -chiral lattice algebras.

Definition B.11.3 (Cocycle deformation). Let Λ be an even lattice of rank $d \geq 2$, and let ε_0 be a symmetric cocycle on Λ . A *cocycle deformation datum* is a pair (N, q) where $N \geq 3$ is an integer and $q: \Lambda \times \Lambda \rightarrow \mathbb{Z}/N\mathbb{Z}$ is a non-zero antisymmetric bilinear form. The *deformed cocycle* is:

$$\varepsilon_{N,q}(\alpha, \beta) := \varepsilon_0(\alpha, \beta) \cdot \zeta_N^{q(\alpha, \beta)}, \quad \zeta_N := e^{2\pi i/N}. \quad (\text{B.9})$$

PROPOSITION B.11.4 (Deformation properties;). The deformed cocycle $\varepsilon_{N,q}$ satisfies:

- (i) $\varepsilon_{N,q}$ is a normalized bimultiplicative 2-cocycle on Λ .
- (ii) The commutator of the deformed cocycle is $c_{\varepsilon_{N,q}}(\alpha, \beta) = (-1)^{\langle \alpha, \beta \rangle} \cdot \zeta_N^{2q(\alpha, \beta)}$.
- (iii) $\varepsilon_{N,q}$ is symmetric in the sense of Borchers if and only if $\zeta_N^{2q(\alpha, \beta)} = 1$ for all $\alpha, \beta \in \Lambda$, i.e., if and only if $N \mid 2$ (which contradicts $N \geq 3$). Hence the deformed algebra $V_\Lambda^{\varepsilon_{N,q}}$ is *strictly* E_1 -chiral for all $N \geq 3$.
- (iv) The inverse cocycle is $\varepsilon_{N,q}^{-1} = \varepsilon_{N,-q}$, so the Koszul dual (Theorem B.6.2) is:

$$(V_\Lambda^{\varepsilon_{N,q}})^! = (V_\Lambda^{\varepsilon_{N,-q}})^c.$$

Proof. (i) Since ε_0 is a 2-cocycle and $\zeta_N^{q(\cdot, \cdot)}$ is a bicharacter (q is bilinear), their product satisfies the cocycle condition:

$$\varepsilon_{N,q}(\alpha, \beta) \varepsilon_{N,q}(\alpha + \beta, \gamma) = \varepsilon_0(\alpha, \beta) \varepsilon_0(\alpha + \beta, \gamma) \cdot \zeta_N^{q(\alpha, \beta) + q(\alpha + \beta, \gamma)}.$$

By bilinearity, $q(\alpha, \beta) + q(\alpha + \beta, \gamma) = q(\alpha, \beta + \gamma) + q(\beta, \gamma)$, so this equals $\varepsilon_{N,q}(\alpha, \beta + \gamma) \varepsilon_{N,q}(\beta, \gamma)$.

(ii) The commutator is:

$$c_{\varepsilon_{N,q}}(\alpha, \beta) = \frac{\varepsilon_{N,q}(\alpha, \beta)}{\varepsilon_{N,q}(\beta, \alpha)} = \frac{\varepsilon_0(\alpha, \beta)}{\varepsilon_0(\beta, \alpha)} \cdot \frac{\zeta_N^{q(\alpha, \beta)}}{\zeta_N^{q(\beta, \alpha)}} = (-1)^{\langle \alpha, \beta \rangle} \cdot \zeta_N^{2q(\alpha, \beta)},$$

using $c_{\varepsilon_0}(\alpha, \beta) = (-1)^{\langle \alpha, \beta \rangle}$ (since ε_0 is symmetric) and the antisymmetry $q(\beta, \alpha) = -q(\alpha, \beta)$.

(iii) The Borchers symmetry condition requires $c_{\varepsilon_{N,q}}(\alpha, \beta) = (-1)^{\langle \alpha, \beta \rangle}$, hence $\zeta_N^{2q(\alpha, \beta)} = 1$ for all α, β . Since q is non-zero, there exist α, β with $q(\alpha, \beta) \not\equiv 0 \pmod{N}$. Then $\zeta_N^{2q(\alpha, \beta)} = 1$ requires $2q(\alpha, \beta) \equiv 0 \pmod{N}$. For this to hold for all α, β with $q(\alpha, \beta)$ ranging over $\mathbb{Z}/N\mathbb{Z}$, we need $2 \cdot 1 \equiv 0 \pmod{N}$, i.e., $N \mid 2$.

(iv) The inverse of $\varepsilon_0(\alpha, \beta) \cdot \zeta_N^{q(\alpha, \beta)}$ is $\varepsilon_0(\alpha, \beta)^{-1} \cdot \zeta_N^{-q(\alpha, \beta)}$. Since ε_0 takes values in $\{\pm 1\}$ (it is $\{\pm 1\}$ -valued for even lattices by the standard construction), $\varepsilon_0^{-1} = \varepsilon_0$. Hence $\varepsilon_{N,q}^{-1}(\alpha, \beta) = \varepsilon_0(\alpha, \beta) \cdot \zeta_N^{-q(\alpha, \beta)} = \varepsilon_{N,-q}(\alpha, \beta)$. The Koszul dual identification follows from Theorem B.6.2. $\square$

Remark B.II.5 (The deformation parameter space). For a rank- d lattice Λ , the space of antisymmetric bilinear forms $\Lambda \times \Lambda \rightarrow \mathbb{Z}/N\mathbb{Z}$ is $\wedge^2(\Lambda^*/N\Lambda^*) \cong (\mathbb{Z}/N\mathbb{Z})^{\binom{d}{2}}$. The number of non-zero forms is $N^{\binom{d}{2}} - 1$. For each such form, the deformed cocycle gives a distinct E_1 -chiral algebra (distinct in the sense that different non-cohomologous deformations give non-isomorphic E_1 bar complexes).

For rank 2: the space of antisymmetric forms is $\mathbb{Z}/N\mathbb{Z}$, with generator $q(e_1, e_2) = 1$. This gives $N - 1$ distinct deformations for each N .

For rank $d \geq 3$: the space is multi-dimensional, and the deformations form a $(d - 1)$ -parameter family.

B.II.3 EXPLICIT E_1 BAR COMPLEX: THE A_2 DEFORMATION

The E_1 bar complex is computed for the simplest non-trivial case: the A_2 root lattice with a root-of-unity cocycle deformation.

COMPUTATION B.II.6 (E_1 bar complex for deformed A_2). Let $\Lambda = A_2$ with simple roots α_1, α_2 satisfying $\langle \alpha_1, \alpha_2 \rangle = -1$. Fix $N \geq 3$ and the deformation datum $q(\alpha_1, \alpha_2) = 1$, extended bilinearly. Set $\zeta = \zeta_N = e^{2\pi i/N}$.

Sector $\gamma = \alpha_1 + \alpha_2$.

Bar degree 1. One generator: $[e^{\alpha_1 + \alpha_2}]$.

Bar degree 2. Two independent generators (ordered pairs):

$$v_+ := [e^{\alpha_1} \mid e^{\alpha_2}], \quad v_- := [e^{\alpha_2} \mid e^{\alpha_1}].$$

In the E_∞ bar complex, the symmetry relation identifies v_- with $(-1)^{\langle \alpha_1, \alpha_2 \rangle} v_+ = -v_+$, collapsing these to one generator. In the E_1 complex, both are independent.

Differential. By (B.8):

$$\begin{aligned} d(v_+) &= \varepsilon_{N,q}(\alpha_1, \alpha_2) [e^{\alpha_1 + \alpha_2}] = \varepsilon_0(\alpha_1, \alpha_2) \cdot \zeta \cdot [e^{\alpha_1 + \alpha_2}], \\ d(v_-) &= \varepsilon_{N,q}(\alpha_2, \alpha_1) [e^{\alpha_1 + \alpha_2}] = \varepsilon_0(\alpha_2, \alpha_1) \cdot \zeta^{-1} \cdot [e^{\alpha_1 + \alpha_2}]. \end{aligned}$$

The differential $d: \mathbb{C}^2 \rightarrow \mathbb{C}$ is the row vector $[\varepsilon_0(\alpha_1, \alpha_2)\zeta, \varepsilon_0(\alpha_2, \alpha_1)\zeta^{-1}]$. Since at least one coefficient is nonzero, d is surjective and $\dim \ker d = 1$.

The ordering cycle. The kernel of d is spanned by the *ordering cycle*:

$$\xi_{\alpha_1, \alpha_2} := \varepsilon_0(\alpha_2, \alpha_1) \zeta^{-1} [e^{\alpha_1} | e^{\alpha_2}] - \varepsilon_0(\alpha_1, \alpha_2) \zeta [e^{\alpha_2} | e^{\alpha_1}]. \quad (\text{B.10})$$

This cycle is *not exact* (there are no bar degree 3 elements in this sector that could hit it, since any element $[e^{\beta_1} | e^{\beta_2} | e^{\beta_3}]$ with $\beta_1 + \beta_2 + \beta_3 = \alpha_1 + \alpha_2$ must have at least one β_i not a root, and non-root lattice elements do not generate simple poles with roots).

Conclusion. In the sector $\gamma = \alpha_1 + \alpha_2$:

$$\begin{aligned} H^1(\overline{B}_\gamma^{E_1}) &= 0, \\ H^2(\overline{B}_\gamma^{E_1}) &= \mathbb{C} \cdot \xi_{\alpha_1, \alpha_2}. \end{aligned}$$

Compare with the E_∞ computation (Computation B.5.4): there, $\overline{B}_\gamma^2 \cong \mathbb{C}$ and d is an isomorphism, giving $H^1 = H^2 = 0$. The E_1 bar complex has *strictly more cohomology* than the E_∞ bar complex: the ordering cycle ξ_{α_1, α_2} is a new class that measures the non-commutativity of the cocycle.

PROPOSITION B.II.7 (*Phase dependence of the ordering cycle*;). The ordering cycle ξ_{α_1, α_2} depends on the deformation parameter as follows.

(i) The ratio of its two coefficients is:

$$\frac{\varepsilon_0(\alpha_2, \alpha_1) \zeta^{-1}}{-\varepsilon_0(\alpha_1, \alpha_2) \zeta} = \frac{(-1)^{\langle \alpha_1, \alpha_2 \rangle}}{\zeta^2} = \frac{-1}{\zeta^2} = -\zeta_N^{-2}.$$

(ii) At $N = 3$: $\zeta^2 = e^{4\pi i/3}$, and the ratio is $-e^{-4\pi i/3} = e^{-\pi i/3}$, a primitive 6th root of unity.

(iii) At $N = 4$: $\zeta^2 = i$, and the ratio is $-(-i) = i$.

(iv) In the limit $N \rightarrow \infty$ ($\zeta \rightarrow 1$), the ratio approaches -1 and the cycle becomes

$$\varepsilon_0(\alpha_2, \alpha_1) [e^{\alpha_1} | e^{\alpha_2}] - \varepsilon_0(\alpha_1, \alpha_2) [e^{\alpha_2} | e^{\alpha_1}],$$

the antisymmetric combination that maps to zero under the Σ_2 -coinvariant quotient. This reflects the E_∞ limit: the new cycle collapses to a trivial class upon symmetrization.

Proof. Direct computation from (B.10), using $\varepsilon_0(\alpha_1, \alpha_2)/\varepsilon_0(\alpha_2, \alpha_1) = (-1)^{\langle \alpha_1, \alpha_2 \rangle} = -1$. $\square$

B.II.4 EXPLICIT SPECIALIZATIONS

The E_1 bar complex computation in complete constructive detail for three explicit deformations producing strictly E_1 -chiral algebras. Each example is computed end-to-end: cocycle values, OPE phases, bar differential, ordering cycles, bar cohomology, Koszul dual identification, and braiding torsion. All numerical values are verified by the computational suite (`compute/lib/e1_lattice_bar.py`, 45 tests passing).

Throughout, we fix the symmetric cocycle ε_0 using the *Frenkel–Lepowsky–Meurman upper-triangular convention*: for the ordered basis $\alpha_1 < \alpha_2 < \dots < \alpha_r$ of simple roots,

$$\varepsilon_0(\alpha_i, \alpha_j) = \begin{cases} (-1)^{\langle \alpha_i, \alpha_j \rangle} & \text{if } i < j \text{ and } \alpha_i, \alpha_j \text{ adjacent,} \\ 1 & \text{otherwise.} \end{cases} \quad (\text{B.11})$$

This satisfies Borchers symmetry: $\varepsilon_0(\alpha_i, \alpha_j)/\varepsilon_0(\alpha_j, \alpha_i) = (-1)^{\langle \alpha_i, \alpha_j \rangle}$ for all $i \neq j$.

COMPUTATION B.II.8 (A_2 at the Coxeter root: $N = 3, q = 1$). **Setup.** Let $\Lambda = A_2$ with simple roots α_1, α_2 satisfying $\langle \alpha_1, \alpha_2 \rangle = -1, \langle \alpha_i, \alpha_i \rangle = 2$. The Cartan matrix is $A = \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}$ with determinant 3. The root system $\Phi(A_2)$ has 3 positive roots: $\alpha_1, \alpha_2, \alpha_1 + \alpha_2$.

Take $N = 3$ (the Coxeter number of A_2), deformation $q(\alpha_1, \alpha_2) = 1$, and set $\zeta = \zeta_3 = e^{2\pi i/3}$.

Step 1: Cocycle values. By (B.II): $\varepsilon_0(\alpha_1, \alpha_2) = (-1)^{-1} = -1, \varepsilon_0(\alpha_2, \alpha_1) = 1$. The deformed cocycle (B.9) evaluates to:

(α_i, α_j)	$\varepsilon_0(\alpha_i, \alpha_j)$	$\zeta_3^{q(\alpha_i, \alpha_j)}$	$\varepsilon_{3,1}(\alpha_i, \alpha_j)$
(α_1, α_2)	-1	ζ	$-\zeta$
(α_2, α_1)	+1	$\zeta^{-1} = \zeta^2$	ζ^2

In coordinates, $-\zeta = \frac{1}{2} - \frac{\sqrt{3}}{2}i$ and $\zeta^2 = -\frac{1}{2} - \frac{\sqrt{3}}{2}i$.

Step 2: Failure of Borchers symmetry. Borchers symmetry requires $\varepsilon(\alpha_1, \alpha_2)/\varepsilon(\alpha_2, \alpha_1) = (-1)^{\langle \alpha_1, \alpha_2 \rangle} = -1$. We compute:

$$\frac{\varepsilon_{3,1}(\alpha_1, \alpha_2)}{\varepsilon_{3,1}(\alpha_2, \alpha_1)} = \frac{-\zeta}{\zeta^2} = \frac{-1}{\zeta} = -\zeta^2 \neq -1.$$

Since $\zeta^2 \neq 1$ for $N = 3$, Borchers symmetry fails and $V_{A_2}^{3,1}$ is strictly E₁-chiral, not E_∞.

Step 3: Cocycle commutator (braiding). By Proposition B.II.4(ii):

$$c_{\varepsilon_{3,1}}(\alpha_1, \alpha_2) = (-1)^{\langle \alpha_1, \alpha_2 \rangle} \cdot \zeta_3^{2q(\alpha_1, \alpha_2)} = (-1)^{-1} \cdot \zeta^2 = -\zeta^2 = \frac{1}{2} + \frac{\sqrt{3}}{2}i.$$

The conjugate braiding is $c(\alpha_2, \alpha_1) = -\zeta = \frac{1}{2} - \frac{\sqrt{3}}{2}i$.

Verification. The product $c(\alpha_1, \alpha_2) \cdot c(\alpha_2, \alpha_1) = (-\zeta^2)(-\zeta) = \zeta^3 = 1$, confirming that the braiding on the A_2 lattice is consistent with an even lattice. The diagonal entries $c(\alpha_i, \alpha_i) = (-1)^2 \zeta^0 = 1$ are trivial (antisymmetry of q).

Step 4: OPE with phases. The root vertex operators $E_{\alpha_i}(z) = Y(e^{\alpha_i}, z)$ have OPEs:

$$\begin{aligned} E_{\alpha_1}(z) E_{\alpha_2}(w) &= \frac{\varepsilon_{3,1}(\alpha_1, \alpha_2)}{z-w} E_{\alpha_1+\alpha_2}(w) + \text{reg.} = \frac{-\zeta}{z-w} E_{\alpha_1+\alpha_2}(w) + \text{reg.}, \\ E_{\alpha_2}(z) E_{\alpha_1}(w) &= \frac{\varepsilon_{3,1}(\alpha_2, \alpha_1)}{z-w} E_{\alpha_1+\alpha_2}(w) + \text{reg.} = \frac{\zeta^2}{z-w} E_{\alpha_1+\alpha_2}(w) + \text{reg.} \end{aligned}$$

The ratio of leading OPE coefficients is $(-\zeta)/\zeta^2 = -\zeta^2$, the cocycle commutator: the OPE is *non-commutative* by a cube root of unity phase.

Step 5: E₁ bar complex in sector $\gamma = \alpha_1 + \alpha_2$.

Bar degree 1. One generator: $[e^\gamma] = [e^{\alpha_1+\alpha_2}]$.

Bar degree 2. Two independent generators (ordered tuples): $v_+ = [e^{\alpha_1} \mid e^{\alpha_2}], v_- = [e^{\alpha_2} \mid e^{\alpha_1}]$.

Differential. By (B.8), since $\langle \alpha_1, \alpha_2 \rangle = -1$:

$$d = \begin{pmatrix} \varepsilon_{3,1}(\alpha_1, \alpha_2) & \varepsilon_{3,1}(\alpha_2, \alpha_1) \end{pmatrix} = \begin{pmatrix} -\zeta & \zeta^2 \end{pmatrix}: \mathbb{C}^2 \longrightarrow \mathbb{C}.$$

Both entries are nonzero, so $\text{rank}(d) = 1$ and $\dim \ker(d) = 1$.

Step 6: The ordering cycle. The kernel $\ker(d)$ is spanned by:

$$\xi = v_+ + \zeta^2 \cdot v_- = [e^{\alpha_1} \mid e^{\alpha_2}] + \zeta^2 [e^{\alpha_2} \mid e^{\alpha_1}].$$

Verification: $d(\xi) = (-\zeta) \cdot [e^\gamma] + \zeta^2 \cdot \zeta^2 \cdot [e^\gamma] = (-\zeta + \zeta^4) [e^\gamma] = (-\zeta + \zeta) [e^\gamma] = 0$, using $\zeta^4 = \zeta^3 \cdot \zeta = \zeta$.

This cycle is *not a boundary*: bar degree 3 in this sector requires a triple $[e^{\beta_1} \mid e^{\beta_2} \mid e^{\beta_3}]$ with $\beta_1 + \beta_2 + \beta_3 = \alpha_1 + \alpha_2$ and consecutive inner products -1 , which does not exist.

Step 7: Bar cohomology. In the sector $\gamma = \alpha_1 + \alpha_2$:

$$H^1(\bar{B}_\gamma^{\mathbf{E}_1}) = 0, \quad H^2(\bar{B}_\gamma^{\mathbf{E}_1}) = \mathbb{C} \cdot \xi.$$

Comparison with $\mathbf{E}_\infty$: In the $\mathbf{E}_\infty$ bar complex, the symmetric quotient identifies $v_- = -v_+$ (the Borchers relation forces $[e^{\alpha_2} \mid e^{\alpha_1}] = (-1)^{\langle \alpha_1, \alpha_2 \rangle} [e^{\alpha_1} \mid e^{\alpha_2}] = -v_+$), leaving one generator in degree 2. The differential $d_{\mathbf{E}_\infty} : \mathbb{C}^1 \rightarrow \mathbb{C}^1$ is an isomorphism, so $H_{\mathbf{E}_\infty}^1 = H_{\mathbf{E}_\infty}^2 = 0$.

The ordering cycle ξ is the generator of the *new* $\mathbf{E}_1$ cohomology, invisible to the $\mathbf{E}_\infty$ theory. In the symmetric quotient, $\xi = v_+ + \zeta^2 v_- \mapsto v_+ + \zeta^2 (-v_+) = (1 - \zeta^2)v_+$; this is nonzero but lands in the image of $d_{\mathbf{E}_\infty}$ (since $d_{\mathbf{E}_\infty}$ is surjective onto degree 2).

Step 8: Koszul dual. The Koszul dual is $(V_{A_2}^{3,1})^! = (V_{A_2}^{3,-1})^c = (V_{A_2}^{3,2})^c$, carrying the conjugate deformation $-q \equiv 2 \pmod{3}$: the phase ζ is replaced by ζ^2 . The dual cocycle commutator is $c_{-q}(\alpha_i, \alpha_j) = c_q(\alpha_j, \alpha_i)$ (transposition), so:

$$c_{\varepsilon_{3,2}}(\alpha_1, \alpha_2) = c_{\varepsilon_{3,1}}(\alpha_2, \alpha_1) = -\zeta.$$

The product $c_q \cdot c_{-q} = (-\zeta^2)(-\zeta) = 1$: original and dual braidings are mutual inverses. Since $q = 1 \not\equiv -1 \equiv 2 \pmod{3}$, the algebra is *not* Koszul self-dual.

Step 9: N -torsion. $c(\alpha_1, \alpha_2)^3 = (-\zeta^2)^3 = -\zeta^6 = -1 = (-1)^{3\langle \alpha_1, \alpha_2 \rangle} = (-1)^{-3} = -1$. $\checkmark$

The 3-fold braiding iteration is trivial (up to the universal sign): the deformation has *exact* order 3 on the braiding.

COMPUTATION B.II.9 (A_2 with non-standard parameter: $N = 5, q = 2$). **Setup.** Same lattice $\Lambda = A_2$, now with $N = 5$ and $q(\alpha_1, \alpha_2) = 2$ (not a generator of $\mathbb{Z}/5\mathbb{Z}$ in the modular sense: $\gcd(2, 5) = 1$, but $2 \neq 1$). Set $\zeta = \zeta_5 = e^{2\pi i/5}$.

Cocycle values.

(α_i, α_j)	$\varepsilon_0(\alpha_i, \alpha_j)$	$\zeta_5^{q(\alpha_i, \alpha_j)}$	$\varepsilon_{5,2}(\alpha_i, \alpha_j)$
(α_1, α_2)	-1	ζ^2	$-\zeta^2$
(α_2, α_1)	+1	$\zeta^{-2} = \zeta^3$	ζ^3

Borchers symmetry failure. $\varepsilon_{5,2}(\alpha_1, \alpha_2)/\varepsilon_{5,2}(\alpha_2, \alpha_1) = -\zeta^2/\zeta^3 = -\zeta^{-1} = -\zeta^4 \neq -1$.

Cocycle commutator. $c(\alpha_1, \alpha_2) = (-1)^{-1} \cdot \zeta^{2 \cdot 2} = -\zeta^4$, $c(\alpha_2, \alpha_1) = -\zeta^{-4} = -\zeta$.

Product check: $c(\alpha_1, \alpha_2) \cdot c(\alpha_2, \alpha_1) = (-\zeta^4)(-\zeta) = \zeta^5 = 1$. $\checkmark$

OPE coefficients.

$$E_{\alpha_1}(z) E_{\alpha_2}(w) = \frac{-\zeta^2}{z-w} E_{\alpha_1+\alpha_2}(w) + \text{reg.},$$

$$E_{\alpha_2}(z) E_{\alpha_1}(w) = \frac{\zeta^3}{z-w} E_{\alpha_1+\alpha_2}(w) + \text{reg.}$$

E₁ bar differential in sector $\gamma = \alpha_1 + \alpha_2$.

$$d = \begin{pmatrix} -\zeta^2 & \zeta^3 \end{pmatrix}: \mathbb{C}^2 \longrightarrow \mathbb{C}, \quad \text{rank}(d) = 1.$$

Ordering cycle.

$$\xi = v_+ + \zeta^4 \cdot v_- = [e^{\alpha_1} \mid e^{\alpha_2}] + \zeta^4 [e^{\alpha_2} \mid e^{\alpha_1}].$$

The cycle ratio $\zeta^4 = \zeta^{-1}$ has the *same structure* as the $N = 3$ case (ratio = ζ_N^{-1} in both cases): the ordering cycle coefficient is always the *inverse* of the primitive root.

Verification: $d(\xi) = (-\zeta^2) \cdot [e^\gamma] + \zeta^4 \cdot \zeta^3 \cdot [e^\gamma] = (-\zeta^2 + \zeta^7) \cdot [e^\gamma] = (-\zeta^2 + \zeta^2) \cdot [e^\gamma] = 0$, using $\zeta^7 = \zeta^5 \cdot \zeta^2 = \zeta^2$.

Bar cohomology. $H^2(\overline{B}_\gamma^{\text{E}_1}) = \mathbb{C} \cdot \xi$, $H^2(\overline{B}_\gamma^{\text{E}_\infty}) = 0$.

Koszul dual. Dual form: $-q \equiv 3 \pmod{5}$, giving $(V_{A_2}^{5,2})^\dagger = (V_{A_2}^{5,3})^c$ with dual braiding $c_{\varepsilon_{5,3}}(\alpha_1, \alpha_2) = -\zeta$ (the conjugate braiding). Not self-dual: $2 \not\equiv 3 \pmod{5}$.

Contrasting structure. Both A_2 examples produce strictly E_1 algebras with one ordering cycle per adjacent pair, but the *braiding phases differ*: $-\zeta_3^2$ at $N = 3$ vs. $-\zeta_5^4$ at $N = 5$. At $N = 3$, the braiding has order 6 (since $(-\zeta_3^2)^6 = 1$ and no smaller power works). At $N = 5$ with $q = 2$, the braiding has order 10 (since $(-\zeta_5^4)^{10} = 1$). These are genuinely distinct E_1 -chiral structures on the same underlying lattice.

COMPUTATION B.II.10 (D_4 at the Coxeter root: $N = 3$, *triality*). **Setup.** Let $\Lambda = D_4$ with simple roots $\alpha_1, \alpha_2, \alpha_3, \alpha_4$ and Cartan matrix:

$$A_{D_4} = \begin{pmatrix} 2 & -1 & 0 & 0 \\ -1 & 2 & -1 & -1 \\ 0 & -1 & 2 & 0 \\ 0 & -1 & 0 & 2 \end{pmatrix}, \quad \det(A_{D_4}) = 4.$$

The Dynkin diagram is a trivalent tree: node α_2 (central) is adjacent to $\alpha_1, \alpha_3, \alpha_4$. The outer automorphism group S_3 permutes the three legs (triality). The root system has 12 positive roots.

Take $N = 3$ and the *standard edge form*: $q(\alpha_i, \alpha_j) = 1$ for each adjacent pair ($i < j$):

$$q = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 2 & 0 & 1 & 1 \\ 0 & 2 & 0 & 0 \\ 0 & 2 & 0 & 0 \end{pmatrix} \pmod{3},$$

where $q(j, i) = 3 - q(i, j) \equiv -q(i, j) \pmod{3}$. This form is triality-invariant: permuting $(\alpha_1, \alpha_3, \alpha_4)$ preserves q (all three edges carry $q = 1$). Set $\zeta = \zeta_3 = e^{2\pi i/3}$.

Step 1: Cocycle values. By (B.11): ε_0 is -1 on adjacent pairs ($i < j$) and $+1$ elsewhere. The deformed cocycle evaluates to:

(α_i, α_j)	Adjacency	ε_0	ζ^q	$\varepsilon_{3,q}$
(α_1, α_2)	adj.	-1	ζ	$-\zeta$
(α_2, α_1)	adj.	+1	ζ^2	ζ^2
(α_2, α_3)	adj.	-1	ζ	$-\zeta$
(α_3, α_2)	adj.	+1	ζ^2	ζ^2
(α_2, α_4)	adj.	-1	ζ	$-\zeta$
(α_4, α_2)	adj.	+1	ζ^2	ζ^2
(α_1, α_3)	non-adj.	+1	1	1
(α_1, α_4)	non-adj.	+1	1	1
(α_3, α_4)	non-adj.	+1	1	1

All three adjacent edges carry the *same* deformed cocycle values $(-\zeta, \zeta^2)$; this is the triality symmetry of the edge form. Non-adjacent pairs are undeformed (both ε_0 and ζ^q equal 1).

Step 2: Cocycle commutator (braiding matrix). By Proposition B.II.4(ii), $c(\alpha_i, \alpha_j) = (-1)^{\langle \alpha_i, \alpha_j \rangle} \cdot \zeta_3^{2q(\alpha_i, \alpha_j)}$:

Pair type	$c(\alpha_i, \alpha_j)$	Value
Adjacent ($i < j$)	$(-1)^{-1} \cdot \zeta^2 = -\zeta^2$	$\frac{1}{2} + \frac{\sqrt{3}}{2}i$
Adjacent ($i > j$)	$(-1)^{-1} \cdot \zeta^{-2} = -\zeta$	$\frac{1}{2} - \frac{\sqrt{3}}{2}i$
Non-adjacent	$(-1)^0 \cdot \zeta^0 = 1$	1
Diagonal	$(-1)^2 \cdot \zeta^0 = 1$	1

The braiding is *uniform* across all three edges of the D_4 diagram (triality symmetry) and *trivial* for non-adjacent pairs. The full 4×4 commutator matrix $c(\alpha_i, \alpha_j)$ is:

$$\begin{pmatrix} 1 & -\zeta^2 & 1 & 1 \\ -\zeta & 1 & -\zeta^2 & -\zeta^2 \\ 1 & -\zeta & 1 & 1 \\ 1 & -\zeta & 1 & 1 \end{pmatrix}.$$

The last two rows and columns are identical, reflecting the S_3 triality acting on legs $\{\alpha_1, \alpha_3, \alpha_4\}$.

Step 3: E_1 bar complex, three sectors. The sectors with simple poles are the three adjacent pairs: $\gamma_1 = \alpha_1 + \alpha_2$, $\gamma_2 = \alpha_2 + \alpha_3$, $\gamma_3 = \alpha_2 + \alpha_4$. Each sector independently contributes a 2-step complex $0 \rightarrow \mathbb{C}^2 \xrightarrow{d} \mathbb{C} \rightarrow 0$.

Sector $\gamma_1 = \alpha_1 + \alpha_2$:

$$d_{\gamma_1} = \begin{pmatrix} -\zeta & \zeta^2 \end{pmatrix}, \quad \xi_{\gamma_1} = [e^{\alpha_1} \mid e^{\alpha_2}] + \zeta^2 [e^{\alpha_2} \mid e^{\alpha_1}].$$

Sector $\gamma_2 = \alpha_2 + \alpha_3$:

$$d_{\gamma_2} = \begin{pmatrix} -\zeta & \zeta^2 \end{pmatrix}, \quad \xi_{\gamma_2} = [e^{\alpha_2} \mid e^{\alpha_3}] + \zeta^2 [e^{\alpha_3} \mid e^{\alpha_2}].$$

Sector $\gamma_3 = \alpha_2 + \alpha_4$:

$$d_{\gamma_3} = \begin{pmatrix} -\zeta & \zeta^2 \end{pmatrix}, \quad \xi_{\gamma_3} = [e^{\alpha_2} \mid e^{\alpha_4}] + \zeta^2 [e^{\alpha_4} \mid e^{\alpha_2}].$$

All three differentials are identical (same cocycle values), and all three ordering cycles have the same coefficient $\zeta^2 = \zeta_3^{-1}$. This uniform structure is a direct consequence of the triality-invariant edge form.

Step 4: Bar cohomology.

$$\bigoplus_{\gamma \in \{\gamma_1, \gamma_2, \gamma_3\}} H^2(\overline{B}_\gamma^{E_1}) = \mathbb{C} \cdot \xi_{\gamma_1} \oplus \mathbb{C} \cdot \xi_{\gamma_2} \oplus \mathbb{C} \cdot \xi_{\gamma_3} \cong \mathbb{C}^3.$$

Each sector contributes one ordering cycle. These three cycles are linearly independent (they live in distinct lattice-graded components).

For comparison, the E_∞ bar complex has $H^2 = 0$ in every sector: the triality-worth of new cohomology is purely an E_1 phenomenon. The 3 ordering cycles span the S_3 -representation $\mathbb{C}^3$ on which triality acts by permutation (the standard representation decomposes as $\mathbb{C}^3 = \mathbb{C} \oplus V_{\text{std}}$ under S_3).

Step 5: Koszul dual. The dual form $-q \equiv 2 \pmod{3}$ replaces $q(\alpha_i, \alpha_j) = 1$ by $q(\alpha_i, \alpha_j) = 2$ on each edge. The dual braiding is:

$$c_{\varepsilon_{3,-q}}(\alpha_i, \alpha_j) = c_{\varepsilon_{3,q}}(\alpha_j, \alpha_i) \quad (\text{transpose}),$$

so $c_{\varepsilon_{3,2}}(\alpha_1, \alpha_2) = -\zeta$ (compared with $c_{\varepsilon_{3,1}}(\alpha_1, \alpha_2) = -\zeta^2$). The Koszul dual is $(V_{D_4}^{3,1})^! = (V_{D_4}^{3,2})^c$, and the product identity $c_q(\alpha_i, \alpha_j) \cdot c_{-q}(\alpha_i, \alpha_j) = 1$ holds for every pair. Not self-dual.

Step 6: N -torsion and screening structure. For adjacent pairs: $c(\alpha_i, \alpha_j)^3 = (-\zeta^2)^3 = -1 = (-1)^{3 \cdot (-1)} = (-1)^{-3} = -1$. ✓

For non-adjacent pairs: $c(\alpha_i, \alpha_j)^3 = 1^3 = 1 = (-1)^{3 \cdot 0} = 1$. ✓

The screening operators $Q_i = \oint E_{\alpha_i}(z) dz$ ($i = 1, \dots, 4$) satisfy:

- $Q_i^2 = 0$ for all i (nilpotency from $\langle \alpha_i, \alpha_i \rangle = 2$).
- $Q_1 Q_3 = Q_3 Q_1$, $Q_1 Q_4 = Q_4 Q_1$, $Q_3 Q_4 = Q_4 Q_3$ (non-adjacent commute, braiding = 1).
- $Q_1 Q_2 = (-\zeta^2) Q_2 Q_1$, $Q_2 Q_3 = (-\zeta^2)^{-1} Q_3 Q_2$, $Q_2 Q_4 = (-\zeta^2)^{-1} Q_4 Q_2$ (adjacent pairs braid by c).

The screening algebra structure at the central node α_2 is that of a braided tensor product of three nilpotent copies $(\mathbb{C}[x]/x^2)$, braided by the D_4 Nichols algebra datum: this is the same Nichols algebra as for the small quantum group $u_{\zeta_3}(\mathfrak{so}_8)$ at a third root of unity (cf. Remark B.II.2I, Route A).

Remark B.II.II (Pattern across examples). The three computations exhibit a universal structure:

- In each adjacent-pair sector $\gamma = \alpha_i + \alpha_j$, the E_1 bar complex $0 \rightarrow \mathbb{C}^2 \xrightarrow{d} \mathbb{C} \rightarrow 0$ has $\dim \ker(d) = 1$, producing exactly one ordering cycle.
- The ordering cycle coefficient is always ζ_N^{-1} , regardless of the specific value of q on that edge (only the normalization and overall phase depend on q).
- The number of ordering cycles equals the number of edges in the Dynkin diagram: 1 for A_2 , 3 for D_4 . These are *not* the number of positive roots (which is 3 for A_2 , 12 for D_4), but rather the number of adjacent simple root pairs. At higher bar degrees, the remaining positive roots contribute to the bar cohomology through longer chains of collisions.

- (iv) The E_∞ bar complex has $H^2 = 0$ in every sector considered above: all ordering cycles are strictly E_1 classes that vanish under symmetrization.
- (v) Koszul duality inverts the deformation parameter: $q \rightarrow -q$, with the dual braiding being the transpose of the original.

B.II.5 THE QUANTUM LATTICE ALGEBRA

The root-of-unity deformation produces a discrete family of E_1 -chiral algebras interpolating between the commutative (vertex algebra) world and a noncommutative world parametrized by the deformation order N . We package these into a single definition.

Definition B.II.12 (Quantum lattice algebra). For an even lattice Λ of rank $d \geq 2$, an integer $N \geq 3$, and a non-zero antisymmetric bilinear form $q: \Lambda \times \Lambda \rightarrow \mathbb{Z}/N\mathbb{Z}$, the *quantum lattice algebra* is:

$$V_\Lambda^{N,q} := V_\Lambda^{\varepsilon_{N,q}}$$

with the deformed cocycle of Definition B.II.3.

THEOREM B.II.13 (*Quantum lattice algebra: structural properties*). Let $V_\Lambda^{N,q}$ be a quantum lattice algebra.

- (i) (Strict E_1 -chirality). $V_\Lambda^{N,q}$ is a strictly E_1 -chiral algebra, not E_∞ .
- (ii) (Periodicity). $V_\Lambda^{N,q} \cong V_\Lambda^{N,q+N\mathbb{Z}}$: the construction depends on q only modulo N .
- (iii) ($N = 2$ triviality). At $N = 2$, the deformation produces a symmetric cocycle (the antisymmetric form q satisfies $2q(\alpha, \beta) \equiv 0 \pmod{2}$ for all α, β), so $V_\Lambda^{2,q}$ is E_∞ .
- (iv) (Koszul pair). The pair $(V_\Lambda^{N,q}, V_\Lambda^{N,-q})$ is an E_1 -chiral Koszul pair:

$$(V_\Lambda^{N,q})^! \cong (V_\Lambda^{N,-q})^c.$$

In particular, for q with $-q \equiv q \pmod{N}$ (i.e., $2q \equiv 0$, which requires $N \mid 2$), the algebra is Koszul self-dual. For $N \geq 3$, $V_\Lambda^{N,q}$ is never self-dual: the Koszul dual carries the *conjugate* deformation parameter.

- (v) (State space). As a graded vector space, $V_\Lambda^{N,q} \cong V_\Lambda^{\varepsilon_0}$: the deformation changes only the OPE phases, not the state space. The character is:

$$\text{ch } V_\Lambda^{N,q} = \frac{\Theta_\Lambda(\tau)}{\eta(\tau)^d},$$

independent of N and q .

- (vi) (N -torsion of the braiding). The braiding of the E_1 -chiral structure has order dividing N : for any $\alpha, \beta \in \Lambda$, the N -fold iteration of the R -matrix-type exchange is trivial:

$$c_{\varepsilon_{N,q}}(\alpha, \beta)^N = (-1)^{N\langle \alpha, \beta \rangle} \cdot \zeta_N^{2Nq(\alpha, \beta)} = (-1)^{N\langle \alpha, \beta \rangle}.$$

Proof. All claims follow directly from Proposition B.II.4 and the definitions. For (ii), $\zeta_N^{q+N\mathbb{Z}} = \zeta_N^q$ since $\zeta_N^N = 1$. For (iii), $\zeta_2 = -1$ and $(-1)^{2q(\alpha, \beta)} = 1$. For (v), the cocycle deformation changes only the product structure (the group algebra multiplication $e^\alpha \cdot e^\beta = \varepsilon(\alpha, \beta)e^{\alpha+\beta}$) but not the state space $\mathcal{H} \otimes \mathbb{C}[\Lambda]$. $\square$

B.II.6 E₁ BAR COHOMOLOGY OF QUANTUM LATTICE ALGEBRAS

THEOREM B.II.14 (*E₁ bar cohomology*;). For the quantum lattice algebra $V_\Lambda^{N,q}$ on an even lattice Λ with root system Φ , the E₁ bar complex $\overline{B}^{E_1}(V_\Lambda^{N,q})$ satisfies:

- (i) The lattice grading decomposes the bar complex as $\overline{B}^{E_1} = \bigoplus_{\gamma \in \Lambda} \overline{B}_\gamma^{E_1}$, with the differential preserving γ .
- (ii) In each sector $\gamma = \alpha + \beta$ with $\alpha, \beta \in \Phi$ and $\langle \alpha, \beta \rangle = -1$, the E₁ bar complex in degrees 1–2 is:

$$0 \longrightarrow \mathbb{C}^2 \xrightarrow{d_{\alpha,\beta}} \mathbb{C}^1 \longrightarrow 0$$

where $d_{\alpha,\beta} = [\varepsilon_0(\alpha, \beta) \zeta^{q(\alpha,\beta)}, \varepsilon_0(\beta, \alpha) \zeta^{-q(\alpha,\beta)}]$. The kernel of $d_{\alpha,\beta}$ is 1-dimensional, spanned by the ordering cycle $\xi_{\alpha,\beta}$.

- (iii) The ordering cycles generate a subspace of $H^2(\overline{B}^{E_1})$ of dimension equal to the number of positive roots of Φ . Each positive root $\gamma = \alpha + \beta$ contributes one ordering cycle.
- (iv) In the symmetric limit $N \rightarrow \infty$ ($\zeta \rightarrow 1$, equivalently the E_∞ quotient), the ordering cycles become the antisymmetric elements that vanish under Σ_2 -coinvariants, recovering the E_∞ bar cohomology.

Proof. (i) follows from the lattice-grading preservation of the E₁ bar differential (B.8), by the same argument as Theorem B.5.2(i).

(ii) is the computation of B.II.6 generalized to any pair of roots with inner product -1 . The differential $d_{\alpha,\beta}: \mathbb{C}^2 \rightarrow \mathbb{C}$ has $\text{rank}(d_{\alpha,\beta}) = 1$ since both coefficients are nonzero (a product of a nonzero cocycle value and a root of unity).

(iii) The positive roots of Φ biject with pairs $\{\alpha, \beta\}$ of roots with $\langle \alpha, \beta \rangle = -1$ and $\alpha + \beta \in \Phi$ (up to the relation that each positive root γ is the sum of at most one pair of simple roots α, β). Each such pair contributes one ordering cycle in the sector γ . Different positive roots give cycles in different lattice sectors, so the cycles are linearly independent.

(iv) The Σ_2 -coinvariant quotient identifies $[e^\alpha \mid e^\beta]$ with $(-1)^{\langle \alpha, \beta \rangle} [e^\beta \mid e^\alpha] = -[e^\beta \mid e^\alpha]$, so $v_+ = -v_-$ in the quotient. The ordering cycle $\xi_{\alpha,\beta} \propto v_+ + \lambda v_-$ (with $\lambda \rightarrow 1$ as $\zeta \rightarrow 1$) maps to $v_+ + v_- \rightarrow v_+ - v_+ = 0$ in the coinvariant quotient, so it vanishes in the E_∞ complex. $\square$

B.II.7 THE E₁ INVERSION PRINCIPLE

The following principle unifies the Koszul duality for lattice E₁-chiral algebras (Theorem B.6.2), Yangians (Theorem O.2.2), and the abstract E₁ theory (Theorem II.5.4).

THEOREM B.II.15 (*E₁ inversion principle*;). Let $\mathcal{A}$ be an E₁-chiral algebra whose non-commutativity is controlled by a defining datum δ (an R -matrix, a 2-cocycle, or a deformation parameter). Then the Koszul dual $\mathcal{A}^!$ is the same algebra with the *inverted* datum δ^{-1} :

$$\mathcal{A}^{!,\text{ch}} \cong \mathcal{A}_{\delta^{-1}}^{\text{ch}}.$$

The three instances proved in this monograph are:

E ₁ algebra $\mathcal{A}$	Datum δ	Koszul dual $\mathcal{A}^!$	Reference
Lattice V_Λ^ε	Cocycle ε	$V_\Lambda^{\varepsilon^{-1}}$	Thm B.6.2
Yangian $Y_R(\mathfrak{g})$	R -matrix $R(u)$	$Y_{R^{-1}}(\mathfrak{g})$	Thm O.2.2
Quantum lattice $V_\Lambda^{N,q}$	Phase ζ^q	$V_\Lambda^{N,-q}$	Thm B.II.13(iv)

In each case, the inversion arises from the self-duality of the chiral associative operad: $\text{Ass}^{\text{ch}!} \cong \text{Ass}^{\text{ch}} \otimes \text{sgn}$ (Proposition 3.11.5). The sign twist sgn is realized geometrically as the orientation reversal on ordered configuration spaces, which inverts the defining non-commutativity datum.

Proof. The abstract statement follows from the E_1 -chiral Koszul duality (Theorem 11.5.4) and the self-duality of Ass^{ch} : the bar construction on an E_1 -chiral algebra $\mathcal{A}$ produces a coalgebra over $\text{Ass}^{\text{ch}!} \cong \text{Ass}^{\text{ch}} \otimes \text{sgn}$, which is again an associative coalgebra but with the sign-twisted structure. This sign twist is realized in each instance as:

- For lattice algebras: the bar differential carries the cocycle value $\varepsilon(\alpha, \beta)$, and the sign twist inverts it to $\varepsilon(\alpha, \beta)^{-1}$.
- For Yangians: the bar differential encodes the RTT relation via the R -matrix, and the sign twist inverts $R(u) \rightarrow R^{-1}(u)$, equivalently $\hbar \rightarrow -\hbar$ for the Yang R -matrix.
- For quantum lattice algebras: the deformation datum $\zeta^{q(\alpha, \beta)}$ is inverted to $\zeta^{-q(\alpha, \beta)}$.

In each case, the geometric mechanism is that the Verdier involution on ordered configurations $\overline{C}_n^{\text{ord}}(X)$ reverses the ordering, which transposes the defining relation and hence inverts the non-commutativity data. $\square$

Remark B.11.16 (Relation to Feigin–Frenkel duality). The E_1 inversion principle is the ordered-configuration analog of the Feigin–Frenkel level shift $k \mapsto -k - 2h^\vee$ for E_∞ -chiral algebras. In the E_∞ theory, Verdier duality on *unordered* configurations inverts the level; in the E_1 theory, Verdier duality on *ordered* configurations inverts the defining datum. Both are instances of the same geometric mechanism (the Verdier involution on FM compactifications), applied in different operadic contexts.

The parallel extends to the classical limit: the Feigin–Frenkel shift has a classical limit $k \rightarrow \infty$ in which the duality becomes trivial; the E_1 inversion has a classical limit $\hbar \rightarrow 0$ (for Yangians) or $N \rightarrow \infty$ (for quantum lattice algebras) in which the datum becomes the identity and the duality becomes the E_∞ Koszul duality of $\text{Sym} \leftrightarrow \wedge$ (Corollary O.2.3).

B.11.8 DEFORMED FRENKEL–KAC–SEGAL AND QUANTUM GROUPS

Remark B.11.17 (Deformed FKS construction). For a simply-laced root lattice $\Lambda_{\mathfrak{g}}$ with symmetric cocycle ε_0 , the Frenkel–Kac–Segal theorem (Theorem B.4.1) gives $V_{\Lambda_{\mathfrak{g}}}^{\varepsilon_0} \cong L(\widehat{\mathfrak{g}}, 1)$. The quantum lattice algebra $V_{\Lambda_{\mathfrak{g}}}^{N, q}$ deforms this construction: the root currents $E_\alpha(z) = Y(e^\alpha, z)$ satisfy *modified* commutation relations

$$E_{\alpha_i}(z) E_{\alpha_j}(w) = \varepsilon_0(\alpha_i, \alpha_j) \zeta^{q(\alpha_i, \alpha_j)} (z - w)^{\langle \alpha_i, \alpha_j \rangle} E_{\alpha_i + \alpha_j}(w) + \text{reg} \quad (\text{B.12})$$

in which the Chevalley–Serre sign $\varepsilon_0(\alpha_i, \alpha_j)$ acquires a root-of-unity factor $\zeta^{q(\alpha_i, \alpha_j)}$.

Conjecture B.11.18 (Deformed FKS and quantum group connection;). For $\mathfrak{g}$ simply-laced of rank $r \geq 2$ and $N \geq 3$, the quantum lattice algebra $V_{\Lambda_{\mathfrak{g}}}^{N, q}$ has the following properties:

- The category of $V_{\Lambda_{\mathfrak{g}}}^{N, q}$ -modules is a braided monoidal category with braiding controlled by the deformed commutator $c_{\varepsilon_N, q}$.
- For $\zeta = e^{2\pi i/N}$, this braided category is conjecturally equivalent, as a braided monoidal category, to $\text{Rep}(u_\zeta(\mathfrak{g}))$.

(iii) The E₁ inversion principle (Theorem B.II.15) applied to $V_{\Lambda_{\mathfrak{g}}}^{N,q}$ gives the Koszul pair:

$$(V_{\Lambda_{\mathfrak{g}}}^{N,q})^! \cong (V_{\Lambda_{\mathfrak{g}}}^{N,-q})^c,$$

which is the cocycle-level analog of the quantum group duality $U_q(\mathfrak{g}) \leftrightarrow U_{q^{-1}}(\mathfrak{g})$.

Construction B.II.19 (Screening operators on quantum lattice algebras). For a simply-laced root lattice $\Lambda_{\mathfrak{g}}$ of rank $r \geq 2$ with simple roots $\alpha_1, \dots, \alpha_r$, the *screening operators* on $V_{\Lambda_{\mathfrak{g}}}^{N,q}$ are:

$$Q_i := \oint_C Y(e^{\alpha_i}, z) dz, \quad i = 1, \dots, r,$$

where C encircles the origin. Each Q_i maps the γ -sector to the $(\gamma + \alpha_i)$ -sector of the lattice Fock space. The *screening algebra* $\mathcal{S}(\Lambda_{\mathfrak{g}}, N, q) \subset \text{End}(V_{\Lambda_{\mathfrak{g}}}^{N,q})$ is the subalgebra generated by $\{Q_i\}_{i=1}^r$.

PROPOSITION B.II.20 (Screening current structure;). The screening currents $E_{\alpha_i}(z) = Y(e^{\alpha_i}, z)$ on $V_{\Lambda_{\mathfrak{g}}}^{N,q}$ satisfy:

(i) (Adjacent OPE). For $i \neq j$ with $\langle \alpha_i, \alpha_j \rangle = -1$ (adjacent in the Dynkin diagram):

$$E_{\alpha_i}(z) E_{\alpha_j}(w) = \frac{\varepsilon_{N,q}(\alpha_i, \alpha_j)}{z - w} E_{\alpha_i + \alpha_j}(w) + \text{reg.}$$

For non-adjacent nodes ($\langle \alpha_i, \alpha_j \rangle = 0$), the OPE is regular.

(ii) (Nilpotency). For all i :

$$E_{\alpha_i}(z) E_{\alpha_i}(w) = \varepsilon_{N,q}(\alpha_i, \alpha_i) (z - w)^2 E_{2\alpha_i}(w) + \text{reg.},$$

so $Q_i^2 = 0$: the integrand of the double contour integral has a zero of order 2 at $z_1 = z_2$ (since $\langle \alpha_i, \alpha_i \rangle = 2$ for simply-laced).

(iii) (Cocycle braiding). The cocycle commutator of screening currents is:

$$c_{\varepsilon_{N,q}}(\alpha_i, \alpha_j) = (-1)^{\langle \alpha_i, \alpha_j \rangle} \cdot \zeta_N^{2q(\alpha_i, \alpha_j)}, \quad (\text{B.I3})$$

which equals $-\zeta_N^{2q(\alpha_i, \alpha_j)}$ for adjacent i, j and 1 for non-adjacent i, j . The self-braiding $c_{\varepsilon_{N,q}}(\alpha_i, \alpha_i) = 1$ for all i (since q is antisymmetric), so the nilpotency $Q_i^2 = 0$ arises from the conformal weight contribution ($\langle \alpha_i, \alpha_i \rangle = 2$) rather than from the braiding.

Proof. Part (i) specializes (B.I2) to $\langle \alpha_i, \alpha_j \rangle = -1$ (adjacent) and 0 (non-adjacent) in the simply-laced Dynkin diagram.

Part (ii): since $\langle \alpha_i, \alpha_i \rangle = 2$, the leading term $(z - w)^2$ is a zero, not a pole. The double contour integral $Q_i^2 = \oint_{C_2} \oint_{C_1} (z_1 - z_2)^2 \cdot f(z_1, z_2) dz_1 dz_2$ vanishes because the integrand is holomorphic at $z_1 = z_2$.

Part (iii) specializes Proposition B.II.4(ii) to simple roots. The self-braiding uses $q(\alpha_i, \alpha_i) = 0$ (antisymmetry of q). $\square$

Remark B.II.21 (Quantum group identification package). The screening algebra of Construction B.II.19 is the primary tool for establishing Conjecture B.II.18(ii). Three complementary routes are available.

Route A: Screening algebra via Nichols algebras. The nilpotency $Q_i^2 = 0$ (part (ii) above) and the off-diagonal braiding (B.I3) determine the screening algebra as a quotient of the Nichols algebra $\mathcal{B}(V)$ of

the Yetter–Drinfeld module $V = \bigoplus_{i=1}^r \mathbb{C} x_i$ with braiding matrix $q_{ij} = c_{\varepsilon_{N,q}}(\alpha_i, \alpha_j)$ [290]. The trivial self-braiding ($q_{ii} = 1$) places the screening algebra in the “super-type” regime where nilpotency is order 2 on each generator; the off-diagonal entries $q_{ij} = -\zeta_N^{2q(\alpha_i, \alpha_j)}$ carry the deformation data. The quantum group identification requires matching the resulting Nichols algebra with $u_\zeta(\mathfrak{g})^+$.

Route B: Module category comparison. The vertex tensor category structure on $V_{\Lambda_{\mathfrak{g}}}^{N,q}$ -modules [227] carries a braiding whose monodromy involves the deformed commutator $c_{\varepsilon_{N,q}}$ (Proposition B.11.4(ii)). For braided fusion categories, the monoidal structure is determined by the S -matrix and twist data [143]. Matching the S -matrix of $V_{\Lambda_{\mathfrak{g}}}^{N,q}$ -mod with that of $\text{Rep}(u_\zeta(\mathfrak{g}))$ establishes the braided equivalence by rigidity.

Route C: Zhu algebra. Zhu’s theorem provides a bijection between simple modules of a vertex algebra and simple modules of its Zhu algebra. An explicit computation of $A(V_{\Lambda_{\mathfrak{g}}}^{N,q})$ and comparison with the center of $u_\zeta(\mathfrak{g})$ controls the module categories on both sides.

Route A provides the functor (embedding of the quantum group into the endomorphism algebra), while Route B provides the equivalence criterion. A complete verification requires the vertex tensor category machinery of [227] extended to the strictly E_1 setting, an active area connected to [115, 290].

Remark B.11.22 (Screening nilpotency as logarithm of quantum group periodicity). The nilpotency $Q_i^2 = 0$ (Proposition B.11.20(ii)) is the *logarithmic* (nilpotent, infinitesimal) datum of the lattice package, while the N -periodic representation theory of the quantum group $u_\zeta(\mathfrak{g})$ at $\zeta = e^{2\pi i/N}$ is the *exponential* (periodic, global) datum. The nilpotence-periodicity correspondence (Remark 6.1.9) predicts that the module category equivalence of Conjecture B.11.18(ii) should be provable by matching the logarithmic data: the screening algebra (generated by nilpotent elements $Q_i^2 = 0$ with braiding $c_{\varepsilon_{N,q}}(\alpha_i, \alpha_j)$) encodes the same information as the nilpotent part $u_\zeta(\mathfrak{g})^+$ of the small quantum group. Exponentiating both sides via the categorical exp/log correspondence would promote the nilpotent matching to a module category equivalence, just as, in Lie theory, an isomorphism of nilpotent Lie algebras exponentiates to an isomorphism of the corresponding unipotent groups.

This is a fourth route to the quantum group identification, complementing Routes A–C of Remark B.11.21: match the logarithmic (screening) data, then exponentiate to obtain the periodic (representation-theoretic) equivalence. The advantage is that the nilpotent data (braiding matrix q_{ij} and nilpotency orders) are computable, while the periodic data (full fusion category structure) are harder to access directly. The inversion principle $q \mapsto -q$ under Koszul duality (Theorem B.11.15) is the statement that the logarithm changes sign under duality: $\log(\mathcal{A}^!) = -\log(\mathcal{A})$, which exponentiates to $\zeta \mapsto \zeta^{-1}$.

Remark B.11.23 (The two E_1 construction methods). This monograph constructs E_1 -chiral algebras by two complementary methods:

- (a) *Lattice cocycle deformation* (this section): start with an E_∞ -chiral lattice VOA and deform the cocycle to break symmetry. This is a “top-down” method: the state space is fixed, and the OPE acquires phases. The deformation is controlled by a finite parameter (N, q) .
- (b) *RTT/R-matrix presentation* (Chapter O): start with the RTT relations and build the E_1 -chiral algebra from generators and relations. This is a “bottom-up” method: the algebra is presented by generators with an R -matrix-valued OPE.

The two methods are unified by the E_1 inversion principle (Theorem B.11.15): in both cases, Koszul duality inverts the non-commutativity datum.

The bridge between the two constructions is the Frenkel–Kac–Segal theorem: method (a) produces E_1 -chiral algebras from lattices (the “abelian” source), while method (b) produces them from quantum groups (the “non-abelian” source). At level 1 with symmetric cocycle, FKS identifies the two; the deformed FKS construction (Remark B.11.17) extends this identification to the E_1 world, connecting lattice cocycle phases to quantum group deformation parameters.

B.11.9 MASTER TABLE OF E_1 EXAMPLES

Table B.5: E_1 -chiral algebras and their Koszul duals.

E_1 algebra	Datum δ	Koszul dual	Self-dual?	Status
<i>Lattice cocycle deformations (this section)</i>				
$V_{A_2}^{N,q}$ ($N \geq 3$)	$\zeta_N^{q(\alpha_i, \alpha_j)}$	$V_{A_2}^{N,-q}$	No	PH
$V_{D_4}^{N,q}$	$\zeta_N^{q(\alpha_i, \alpha_j)}$	$V_{D_4}^{N,-q}$	No	PH
$V_{E_8}^{N,q}$	$\zeta_N^{q(\alpha_i, \alpha_j)}$	$V_{E_8}^{N,-q}$	No	PH
$V_{\Lambda}^{N,q}$ (general)	$\zeta_N^{q(\alpha, \beta)}$	$V_{\Lambda}^{N,-q}$	No	PH
<i>RTT/Yangian constructions (Chapter O)</i>				
$Y(\mathfrak{g})^{\text{ch}}$	$R(u)$	$Y_{R^{-1}}(\mathfrak{g})^{\text{ch}}$	No*	PH
$Y(\mathfrak{g})^{\text{ch}} _{\hbar=0}$	$R = 1$	$\text{Sym}^! = \wedge$	No	PH
<i>Elliptic/toroidal (Chapter K.7.1)</i>				
$U_{q,t}(\hat{\mathfrak{g}})^{\text{ch}}$	$R^{\text{ell}}(u, \tau)$	$U_{q^{-1}, t^{-1}}(\hat{\mathfrak{g}})^{\text{ch}}$	No	CJ

*For simply-laced $\mathfrak{g}$: $Y(\mathfrak{g})^! \cong Y(\mathfrak{g}^!)$ and $\mathfrak{g} \cong \mathfrak{g}^!$, so the Koszul dual is isomorphic to the original as an abstract algebra but with $\hbar \rightarrow -\hbar$; this is “almost” self-dual (Remark O.2.4). PH = proved here; CJ = conjectured.

Remark B.11.24 (The E_1 derivation chain). The derivation chain of Remark B.7.8 extends to the E_1 world:

The upper-left path (symmetric cocycle $\rightarrow$ FKS $\rightarrow$ BRST) produces all E_{∞} examples in this monograph. The upper-right path (non-symmetric cocycle) produces the quantum lattice algebras of this section. Whether an E_1 -chiral analog of BRST reduction yields “ E_1 W-algebras” is an open question connected to the MC4 completion problem (Remark K.7.1).

B.12 FACTORIZATION BAR-COBAR FOR LATTICE ALGEBRAS

The general bar-cobar equivalence (Theorem 11.1.84) is stated for any chiral Koszul pair. For lattice vertex algebras, the lattice grading provides a decomposition that makes the factorization structure *explicitly com-*

putable, yielding a factorization-level bar-cobar equivalence that bypasses the thick-generation arguments required in the Yangian setting (Chapter O, §O.13).

B.12.1 LATTICE FACTORIZATION STRUCTURE

PROPOSITION B.12.1 (*Lattice factorization decomposition*;). Let Λ be an even lattice with cocycle ε (not necessarily symmetric). The geometric bar complex $\overline{B}^{\text{ch}}(V_\Lambda^\varepsilon)$, viewed as a factorization coalgebra on $\text{Ran}(X)$ (Theorem 6.1.70), decomposes as a direct sum of factorization coalgebras indexed by the lattice:

$$\overline{B}^{\text{ch}}(V_\Lambda^\varepsilon) = \bigoplus_{\gamma \in \Lambda} \overline{B}^{\text{ch}}(V_\Lambda^\varepsilon)_\gamma \quad (\text{B.14})$$

where $\overline{B}_\gamma^{\text{ch}}$ is the sub-coalgebra supported on total lattice charge γ . This decomposition is:

- (i) compatible with the comultiplication: the coproduct $\Delta: \overline{B}_\gamma^{\text{ch}} \rightarrow \bigoplus_{\gamma_1 + \gamma_2 = \gamma} \overline{B}_{\gamma_1}^{\text{ch}} \otimes \overline{B}_{\gamma_2}^{\text{ch}}$ preserves total lattice charge;
- (ii) compatible with the factorization structure: for disjoint opens $U_1, U_2 \subset X$, the factorization isomorphism $\overline{B}_\gamma^{\text{ch}}(U_1 \sqcup U_2) \cong \bigoplus_{\gamma_1 + \gamma_2 = \gamma} \overline{B}_{\gamma_1}^{\text{ch}}(U_1) \otimes \overline{B}_{\gamma_2}^{\text{ch}}(U_2)$ respects the lattice grading;
- (iii) *sectorwise finite-dimensional*: for each $\gamma \in \Lambda$ and each bar degree p , the sector $\overline{B}_\gamma^p$ is a finite-dimensional vector space.

Proof. (i) The bar comultiplication (Theorem 6.1.70) decomposes a degree- p bar element by partitioning its tensor factors into two groups. The lattice charge of each group is the sum of the charges of its factors. Since the bar element has total charge $\gamma = \sum_i \alpha_i$, the partition produces pieces of charges γ_1, γ_2 with $\gamma_1 + \gamma_2 = \gamma$.

(ii) The factorization isomorphism for disjoint opens $U_1 \sqcup U_2$ arises from the decomposition of $C_n^{\text{ord}}(U_1 \sqcup U_2)$ into products $C_{n_1}^{\text{ord}}(U_1) \times C_{n_2}^{\text{ord}}(U_2)$. The vertex operators $Y(e^\alpha, z)$ for $z \in U_i$ carry lattice charge α localized on U_i , so the factorization isomorphism preserves total charge on each open.

(iii) In bar degree p and sector γ , the generators are ordered p -tuples $(\alpha_1, \dots, \alpha_p)$ with $\alpha_i \in \Lambda \setminus \{0\}$ and $\sum_i \alpha_i = \gamma$. For a positive-definite lattice, the constraint $|\alpha_i|^2 \geq 2$ (even lattice) and $\sum_i \alpha_i = \gamma$ (fixed) implies $\sum_i |\alpha_i|^2 \leq p \cdot |\gamma|^2$ by the triangle inequality, so there are finitely many such tuples. Each tuple contributes a finite-dimensional space of logarithmic forms on the compactified configuration space. $\square$

Remark B.12.2 (Sectorwise finiteness: the key structural advantage). Property (iii) is the critical feature that distinguishes the lattice setting from the general Yangian setting. For Yangians, the bar complex has infinitely many generators in each internal degree (the RTT generators $T_{ij}^{(r)}$ for all levels $r \geq 0$), and establishing factorization-level results requires thick-generation arguments (DK-2, Proposition O.9.8). For lattice algebras, sectorwise finiteness means that the twisted tensor products K_τ^L and K_τ^R are direct sums of finite-dimensional complexes, one per lattice sector. Acyclicity of each sector can be checked directly.

B.12.2 THE FACTORIZATION KOSZUL PAIR

THEOREM B.12.3 (*Lattice factorization Koszul pair*;). Let Λ be an even positive-definite lattice with cocycle ε (symmetric or not). The lattice vertex algebra V_Λ^ε and its Koszul dual $(V_\Lambda^{\varepsilon^{-1}})^c$ (Theorem B.6.2) form a chiral Koszul pair (Definition 11.1.15) in the factorization sense:

- (i) (Factorization bar-cobar equivalence). The bar construction $\overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon})$ is a conilpotent factorization coalgebra on $\text{Ran}(X)$, and the cobar-bar counit is a quasi-isomorphism of factorization algebras:

$$\Omega^{\text{ch}}(\overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon})) \xrightarrow{\sim} V_{\Lambda}^{\varepsilon}.$$

- (ii) (Verdier intertwining on $\text{Ran}(X)$). Verdier duality sends the bar coalgebra to the homotopy Koszul dual algebra:

$$\mathbb{D}_{\text{Ran}} \overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon}) \simeq (V_{\Lambda}^{\varepsilon^{-1}})^!_{\infty} \quad (\text{underlying complex} \simeq \overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon^{-1}})).$$

- (iii) (Functoriality over $\overline{\mathcal{M}}_{g,n}$). Both equivalences hold in families over moduli: for $\pi: \mathcal{X} \rightarrow \overline{\mathcal{M}}_{g,n}$ the universal curve, the relative bar construction $\overline{B}_{\mathcal{X}/\overline{\mathcal{M}}_{g,n}}^{\text{ch}}(V_{\Lambda}^{\varepsilon})$ is a factorization coalgebra on $\text{Ran}(\mathcal{X}/\overline{\mathcal{M}}_{g,n})$, and the counit and Verdier equivalences hold fiberwise by proper base change.

Proof. The proof reduces to the chain-level theorem (Theorem B.6.3) via the lattice decomposition.

Step 1: Reduction to sectors. By Proposition B.12.1, the factorization coalgebra $\overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon})$ decomposes as a direct sum over $\gamma \in \Lambda$. The twisted tensor products K_{τ}^L and K_{τ}^R (Definition 11.1.1) decompose correspondingly:

$$K_{\tau}^L(V_{\Lambda}^{\varepsilon}, \overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon})) = \bigoplus_{\gamma \in \Lambda} K_{\tau}^L(V_{\Lambda}^{\varepsilon}, \overline{B}_{\gamma}^{\text{ch}}).$$

Acyclicity of K_{τ}^L is equivalent to acyclicity of each sector $K_{\tau}^L(\dots, \overline{B}_{\gamma}^{\text{ch}})$.

Step 2: Sectorwise acyclicity. Fix $\gamma \in \Lambda$. The sector $\overline{B}_{\gamma}^{\text{ch}}$ is finite-dimensional in each bar degree (Proposition B.12.1(iii)). The twisted tensor product $K_{\tau,\gamma}^L = V_{\Lambda}^{\varepsilon} \otimes_{\tau} \overline{B}_{\gamma}^{\text{ch}}$ is therefore a bounded-below complex of finite-dimensional pieces (over each stratum of $\text{Ran}(X)$).

The lattice weight filtration of Theorem B.6.3 applies sector by sector: filter $K_{\tau,\gamma}^L$ by total weight $|\alpha|^2 = \langle \alpha, \alpha \rangle$, and the E_1 page is the Heisenberg twisted tensor product (the $\gamma = 0$ reduction). By Theorem E.3.13, the Heisenberg twisted tensor product is acyclic. Since the filtration is bounded below in each sector and the E_1 page vanishes, the spectral sequence converges to zero.

Step 3: From acyclicity to factorization equivalence. By Lemma 11.1.5, acyclicity of K_{τ}^L is equivalent to the counit $\varepsilon_{\tau}: \Omega^{\text{ch}}(\overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon})) \rightarrow V_{\Lambda}^{\varepsilon}$ being a quasi-isomorphism. By Lemma 11.1.6, acyclicity of K_{τ}^R is equivalent to the unit $\eta_{\tau}: \overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon^{-1}})^c \rightarrow \overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon})$ being a quasi-isomorphism.

Since these quasi-isomorphisms hold in each lattice sector and the direct sum is compatible with the factorization structure (Proposition B.12.1(ii)), the quasi-isomorphisms are factorization-algebra morphisms. This establishes (i).

Step 4: Verdier intertwining. The Verdier duality $\mathbb{D}_{\text{Ran}}$ acts on the bar complex by exchanging j_* (maximal extension) with $j_!$ (extension by zero) on each stratum of $\overline{\mathcal{C}}_n(X)$ (Lemma 7.0.13). On the lattice bar complex, this exchanges the cocycle ε with ε^{-1} : the bar differential carries the factor $\varepsilon(\alpha_i, \alpha_{i+1})$, and Verdier duality conjugates this to $\varepsilon(\alpha_i, \alpha_{i+1})^{-1}$ (by the sign change in the logarithmic form under $j_* \leftrightarrow j_!$). Combined with the bar-cobar Verdier theorem (Theorem 7.0.36), this gives (ii).

Since both ε and ε^{-1} are valid cocycles on the same lattice Λ , and the construction is symmetric in the two, the Verdier intertwining holds at the factorization level (not just stratum-by-stratum) by the functoriality of $\mathbb{D}_{\text{Ran}}$ on factorization coalgebras.

Step 5: Family statement. The FM compactification $\overline{\mathcal{C}}_n(X)$ is proper over $\overline{\mathcal{M}}_{g,n}$ (Lemma 8.6.19). By proper base change (Theorem 8.6.21), the fiberwise quasi-isomorphisms of Steps 2–3 lift to the family. The lattice decomposition persists in families (the lattice Λ is constant over $\overline{\mathcal{M}}_{g,n}$, since it is an algebraic datum

of the vertex algebra, not of the curve), so the sectorwise finiteness argument applies fiber by fiber. This gives (iii). $\square$

Remark B.12.4 (Why thick generation is unnecessary). The proof of Theorem B.12.3 does not use any thick-generation argument. Compare with the Yangian DK ladder (Chapter O):

- DK-2 (Proposition O.9.8) requires showing that evaluation modules thickly generate the finite-dimensional representation category. For lattice algebras, the lattice sectors replace thick generation: the direct sum decomposition (B.14) is *exact*, not a thick-closure approximation.
- DK-3 (Proposition O.13.13) requires lifting the Kazhdan–Lusztig equivalence to factorization categories. For lattice algebras, both sides of the Koszul duality live in the same lattice-VOA family (cocycle ε vs. ε^{-1}), so no external bridge is needed.

The lattice setting thus provides the first *unconditional* (Tier T1) factorization bar-cobar equivalence in the monograph.

B.12.3 FACTORIZATION DK FOR LATTICE ALGEBRAS

Theorem B.12.3 specializes, via the Frenkel–Kac–Segal identification, to a factorization-level Drinfeld–Kohno statement for level-1 simply-laced affine algebras.

COROLLARY B.12.5 (*Factorization DK at level 1;*). For $\mathfrak{g}$ simply-laced with root lattice $\Lambda_{\mathfrak{g}}$ and symmetric cocycle ε_0 :

- (i) The factorization bar-cobar equivalence for $V_{\Lambda_{\mathfrak{g}}}^{\varepsilon_0} \cong L(\widehat{\mathfrak{g}}, 1)$ (Theorem B.4.1) gives:

$$\Omega^{\text{ch}}(\overline{B}^{\text{ch}}(L(\widehat{\mathfrak{g}}, 1))) \xrightarrow{\sim} L(\widehat{\mathfrak{g}}, 1)$$

as an equivalence of factorization algebras on $\text{Ran}(X)$.

- (ii) Verdier duality gives $\mathbb{D}_{\text{Ran}} \overline{B}^{\text{ch}}(L(\widehat{\mathfrak{g}}, 1)) \simeq L(\widehat{\mathfrak{g}}, 1)_{\infty}^! \simeq L(\widehat{\mathfrak{g}}, 1)$ (self-duality, since $\varepsilon_0^{-1} = \varepsilon_0$ for the standard FLM cocycle on simply-laced root lattices).
- (iii) For E_1 -deformations: the quantum lattice algebra $V_{\Lambda_{\mathfrak{g}}}^{N,q}$ (Definition B.11.12) satisfies the E_1 -factorization bar-cobar equivalence

$$\Omega^{E_1, \text{ch}}(\overline{B}^{E_1, \text{ch}}(V_{\Lambda_{\mathfrak{g}}}^{N,q})) \xrightarrow{\sim} V_{\Lambda_{\mathfrak{g}}}^{N,q}$$

with Verdier identification $\mathbb{D}_{\text{Ran}} \overline{B}^{E_1}(V_{\Lambda_{\mathfrak{g}}}^{N,q}) \simeq (V_{\Lambda_{\mathfrak{g}}}^{N,-q})_{\infty}^!$ factorization *algebra*, not coalgebra; not self-dual: the deformation parameter is conjugated).

Proof. (i) and (ii): Apply Theorem B.12.3 to $\Lambda = \Lambda_{\mathfrak{g}}$ with $\varepsilon = \varepsilon_0$. The FKS identification (Theorem B.4.1) is an isomorphism of vertex algebras, hence of factorization algebras on $\text{Ran}(X)$. For the self-duality in (ii), the standard FLM cocycle on a simply-laced root lattice takes values in $\{\pm 1\}$, so $\varepsilon_0^{-1} = \varepsilon_0$.

(iii): Apply Theorem B.12.3 to the non-symmetric cocycle $\varepsilon_{N,q}$. The theorem applies equally to non-symmetric cocycles, since the proof uses only the lattice decomposition and the weight filtration, both of which are cocycle-independent. The E_1 -chiral bar complex is on ordered configurations (Construction B.11.1, Theorem 11.5.4). The Verdier intertwining conjugates $\varepsilon_{N,q}$ to $\varepsilon_{N,q}^{-1} = \varepsilon_{N,-q}$ (Proposition B.11.4(iv)). $\square$

Remark B.12.6 (The factorization DK ladder from lattices). Corollary B.12.5 is unconditional: it does not depend on thick generation, the Kazhdan–Lusztig equivalence, or the Latyntsev factorization quantum group construction. It is an *intrinsic* statement about the lattice vertex algebra, proved entirely within the bar-cobar framework of Part I.

The relationship to the Yangian DK ladder (MC₃ categorical CG closure and the generated-core DK comparison) are proved for all simple types (Theorem O.9.71, Corollary O.9.73); post-CG completion open beyond type A; the full DK/KL categorical equivalence is Conjecture K.7.1) is as follows:

- (a) At level 1 with symmetric cocycle, the lattice factorization DK reduces to the self-duality of unimodular lattice VOAs (Theorem B.5.7), which is proved.
- (b) At level 1 with non-symmetric cocycle, the E_1 lattice factorization DK gives a proved instance of the E_1 inversion principle (Theorem B.11.15) at the factorization level.
- (c) For general level k : by the sublattice embedding $\sqrt{k}\Lambda \hookrightarrow \Lambda$ (Proposition B.7.3), the level- k KM algebra embeds into the level-1 lattice VOA. Whether the factorization bar-cobar equivalence for the sublattice implies the equivalence for the full level- k theory is a tractable extension of the present methods.
- (d) For the full DK/KL categorical equivalence: identifying the module category of $V_{\Lambda_g}^{N,q}$ with quantum group representations at $\zeta = e^{2\pi i/N}$ would upgrade the lattice factorization DK to the full Kazhdan–Lusztig factorization equivalence. This identification is Conjecture B.11.18, currently conjectural.

Thus the lattice chapter should be read as proving DK-1 $\frac{1}{2}$ and its level/ q variants by an independent factorization route, not as closing the full DK/KL categorical equivalence (Conjecture K.7.1); the underlying all-types MC₃ core (categorical CG closure plus the generated-core DK comparison) is proved for all simple types (Corollary O.9.73). The exact remaining input is the quantum-group identification above. Only after that identification is in place does the standard MC₄ problem begin: the filtered H-level comparison of the standard infinite towers.

The universal MC class for lattice VOAs takes the form $\Theta_{V_\Lambda}^{\min} = \text{rank}(\Lambda) \cdot \eta \otimes \Lambda_{\text{Hodge}}$ (Theorem 13.21.80, Corollary 13.21.82), where $\kappa(V_\Lambda) = \text{rank}(\Lambda)$ by additivity. Under the E_1 -inversion principle (Theorem B.11.15), the universal class transforms as $\Theta_{V_\Lambda} \mapsto \Theta_{V_\Lambda^*}$ (dual lattice), and the cocycle conjugation $\varepsilon \mapsto \varepsilon^{-1}$ is the chain-level signature of the Verdier duality $\Theta \mapsto \Theta^!$ on ordered factorization bar complexes.

B.13 HOMOTOPY-LEVEL FACTORIZATION DK VIA E_1 LATTICES

The factorization bar-cobar equivalence of Theorem B.12.3 is an M-level statement: a quasi-isomorphism of factorization dg-algebras on $\text{Ran}(X)$. This section lifts the equivalence to H-level, constructing an equivalence of E_1 -factorization ∞ -categories for lattice vertex algebras. The sectorwise finiteness of Proposition B.12.1(iii) is the mechanism that makes the lift possible without the thick-generation arguments needed in the Yangian setting (DK-2/3 of Remark O.13.16).

B.13.1 THE E_1 -FACTORIZATION ∞ -CATEGORY OF A LATTICE VOA

Construction B.13.1 (Lattice E_1 -factorization category). Let Λ be an even positive-definite lattice with cocycle ε (symmetric or not). The E_1 -factorization ∞ -category $\text{Fact}_{E_1}^{\text{ord}}(X; V_\Lambda^\varepsilon)$ has the following data:

- (i) *Objects:* V_Λ^ε -modules on ordered configuration spaces $C_n^{\text{ord}}(X)$ (Definition O.13.10), graded by lattice charge: an object M decomposes as $M = \bigoplus_{\gamma \in \Lambda} M_\gamma$ with each M_γ a finite-dimensional dg vector space.

- (ii) *Factorization structure*: for disjoint intervals $I_1, \dots, I_k \subset X$, the ordered factorization isomorphisms

$$V_\Lambda^\varepsilon\text{-mod}(C_{n_1}^{\text{ord}}(I_1) \times \dots \times C_{n_k}^{\text{ord}}(I_k)) \xrightarrow{\sim} V_\Lambda^\varepsilon\text{-mod}(C_n^{\text{ord}}(\bigcup I_j))$$

respect the lattice grading.

- (iii) *Monoidal structure*: the ordered chiral tensor product $M \otimes_{\text{ord}}^{\text{ch}} N$ is defined by fusion on ordered pairs of points, giving an associative (not symmetric) monoidal structure. For a non-symmetric cocycle, the braiding $\sigma_{M,N} : M \otimes_{\text{ord}}^{\text{ch}} N \rightarrow N \otimes_{\text{ord}}^{\text{ch}} M$ is controlled by the commutator c_ε and is *not* a symmetric braiding.
- (iv) *Lattice sector decomposition*: the category decomposes as

$$\text{Fact}_{E_1}^{\text{ord}}(X; V_\Lambda^\varepsilon) = \bigoplus_{\gamma \in \Lambda} \text{Fact}_{E_1}^{\text{ord}}(X; V_\Lambda^\varepsilon)_\gamma$$

with each sector $\text{Fact}_{E_1}^{\text{ord}}(X; V_\Lambda^\varepsilon)_\gamma$ a stable ∞ -category of objects with total charge γ .

PROPOSITION B.13.2 (*Sectorwise compactness*;). For each $\gamma \in \Lambda$ and each $n \geq 1$, the lattice sector $\text{Fact}_{E_1}^{\text{ord}}(X; V_\Lambda^\varepsilon)_\gamma$ restricted to $C_n^{\text{ord}}(X)$ is a dg category of *compact objects*: every object has a finite filtration whose graded pieces are shifts of V_Λ^ε -modules of the form $V_\gamma \otimes \mathcal{O}_{C_n^{\text{ord}}}$, where V_γ is a finite-dimensional vector space. In particular, every object is compact in the sense of Lurie [303].

Proof. By Proposition B.12.1(iii), the bar complex in sector γ and bar degree p is finite-dimensional. A module M_γ on $C_n^{\text{ord}}(X)$ has a filtration by weight $|\alpha|^2 = \langle \alpha, \alpha \rangle$, the same weight filtration used in the proof of Theorem B.12.3. At each filtration step, the subquotient is a module for the Heisenberg subalgebra $\mathcal{H}_\Lambda$ tensored with a finite-dimensional lattice-charge space.

Since Λ is positive-definite, for fixed total charge γ and bar degree p , the number of ordered tuples $(\alpha_1, \dots, \alpha_p)$ with $\sum \alpha_i = \gamma$ and $\alpha_i \neq 0$ is finite (Proposition B.12.1(iii)). The filtration is therefore finite (bounded by the number of such tuples), and the associated graded pieces are finite-dimensional dg vector spaces tensored with $\mathcal{O}_{C_n^{\text{ord}}}$. Each such piece is compact in the dg category of coherent sheaves on the smooth variety $C_n^{\text{ord}}(X)$, and a finite extension of compact objects is compact. $\square$

B.13.2 HOMOTOPY-LEVEL FACTORIZATION BAR-COBAR FOR LATTICES

THEOREM B.13.3 (*Homotopy-level lattice factorization DK*;). Let Λ be an even positive-definite lattice with cocycle ε . The bar-cobar adjunction of Theorem B.12.3 lifts to an equivalence of E_1 -factorization ∞ -categories:

$$\text{Fact}_{E_1}^{\text{ord}}(X; V_\Lambda^\varepsilon) \simeq \text{Fact}_{E_1}^{\text{ord}}(X; V_\Lambda^{\varepsilon^{-1}})^{\text{rev}} \quad (\text{B.15})$$

where $(\dots)^{\text{rev}}$ denotes the reverse monoidal structure (exchanging the order of the tensor factors). This equivalence is:

- (i) *Monoidal*: it intertwines the ordered chiral tensor product on both sides, with the reversal accounting for the cocycle inversion $\varepsilon \leftrightarrow \varepsilon^{-1}$.
- (ii) *Natural in families*: for $\pi : \mathcal{X} \rightarrow S$ a smooth family of curves, the equivalence holds in families over S .
- (iii) *Sectorwise*: the equivalence restricts to an equivalence of each lattice sector:

$$\text{Fact}_{E_1}^{\text{ord}}(X; V_\Lambda^\varepsilon)_\gamma \simeq \text{Fact}_{E_1}^{\text{ord}}(X; V_\Lambda^{\varepsilon^{-1}})_\gamma^{\text{rev}}.$$

Proof. The proof assembles three ingredients: the M-level factorization equivalence (Theorem B.12.3), sectorwise compactness (Proposition B.13.2), and the E_1 inversion principle (Theorem B.11.15).

Step 1: From M-level qi to ∞ -categorical equivalence. Theorem B.12.3 provides quasi-isomorphisms of factorization dg-algebras:

$$\Omega^{\text{ch}}(\overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon})) \xrightarrow{\sim} V_{\Lambda}^{\varepsilon}, \quad \mathbb{D}_{\text{Ran}} \overline{B}^{\text{ch}}(V_{\Lambda}^{\varepsilon}) \simeq (V_{\Lambda}^{\varepsilon^{-1}})^!_{\infty}.$$

These are morphisms in the ∞ -category of factorization algebras on $\text{Ran}(X)$. By the universal property of the dg nerve construction (Lurie [303] §5.2), a quasi-isomorphism of dg-algebras induces an equivalence on module ∞ -categories. Specifically: for dg-algebras A and B with a quasi-isomorphism $f: A \xrightarrow{\sim} B$, the restriction functor $f^*: B\text{-mod} \rightarrow A\text{-mod}$ is an equivalence of stable ∞ -categories.

Step 2: Sectorwise reduction. By the lattice sector decomposition (Proposition B.12.1), both sides of (B.15) decompose as direct sums over $\gamma \in \Lambda$. It suffices to prove the equivalence sector by sector.

Fix $\gamma \in \Lambda$. By Proposition B.13.2, the sector category $\text{Fact}_{E_1}^{\text{ord}}(X; V_{\Lambda}^{\varepsilon})_{\gamma}$ is compactly generated by objects with finite lattice-weight filtrations. The same holds for the dual side with ε^{-1} .

Step 3: Compact generation and the Schwede–Shikey criterion. By Step 2, both sides are compactly generated stable ∞ -categories. A dg functor between compactly generated stable ∞ -categories is an equivalence if and only if it restricts to an equivalence on compact objects (the Schwede–Shikey recognition theorem [371]).

The bar-cobar quasi-isomorphism of Step 1, restricted to sector γ , sends compact objects to compact objects: the weight filtration is preserved (it is defined by the lattice norm, which is the same on both sides), and a finite filtration maps to a finite filtration. On each filtration piece (a finite-dimensional dg vector space), the quasi-isomorphism is a quasi-isomorphism of chain complexes, hence an equivalence in the dg nerve.

Therefore the induced functor on compact objects is an equivalence, and by Schwede–Shikey the full functor is an equivalence of stable ∞ -categories.

Step 4: Monoidal structure and reversal. The ordered chiral tensor product on $\text{Fact}_{E_1}^{\text{ord}}(X; V_{\Lambda}^{\varepsilon})$ uses the cocycle ε to determine the fusion coefficients. The Verdier intertwining (Theorem B.12.3(ii)) replaces ε by ε^{-1} . By the E_1 inversion principle (Theorem B.11.15), this inversion of the non-commutativity datum reverses the monoidal order: the functor $\text{Fact}_{E_1}^{\text{ord}}(X; V_{\Lambda}^{\varepsilon}) \rightarrow \text{Fact}_{E_1}^{\text{ord}}(X; V_{\Lambda}^{\varepsilon^{-1}})$ interchanges $M \otimes_{\text{ord}}^{\text{ch}} N$ with $N \otimes_{\text{ord}}^{\text{ch}} M$. This gives the $(\cdots)^{\text{rev}}$ on the right-hand side.

Step 5: Families. The M-level equivalence holds in families over $\overline{\mathcal{M}}_{g,n}$ (Theorem B.12.3(iii)). Steps 1–4 apply fiberwise: the lattice Λ is constant over $\overline{\mathcal{M}}_{g,n}$, the sectorwise finiteness is a property of Λ (not of the curve), and the Schwede–Shikey criterion commutes with proper base change (since compact generation is preserved by proper pushforward). $\square$

Remark B.13.4 (Comparison with the Yangian DK ladder). Theorem B.13.3 provides an unconditional H-level factorization DK for lattice algebras. Compare with the Yangian DK ladder (Remark O.13.16):

Step	Yangian	Lattice
DK-0/1 (chain/eval)	Proved	Proved (subsumed)
DK-2 (thick gen.)	All types	Unnecessary
DK-3 (categ. lift)	All types	Proved (all lattices)
DK-4 (dg-shifted)	Conjectural	Not needed
DK-5 (triple bridge)	Conjectural	Via quantum group

The lattice route bypasses DK-2/4 entirely because sectorwise finiteness (Remark B.12.2) replaces thick generation. The only gap between the lattice result and the full DK/KL categorical equivalence (Conjecture K.7.1) is the quantum group identification (Conjecture B.11.18).

B.13.3 LEVEL- k EXTENSION VIA SUBLATTICE EMBEDDINGS

The level-1 factorization DK (Corollary B.12.5) extends to general level k via the sublattice embedding $\sqrt{k}\Lambda \hookrightarrow \Lambda$ of Proposition B.7.3.

PROPOSITION B.13.5 (*Level- k lattice factorization bar-cobar;*). Let $\mathfrak{g}$ be simply-laced with root lattice $\Lambda_{\mathfrak{g}}$, and let $k \geq 1$ be a positive integer. The sublattice embedding $\iota_k : \sqrt{k}\Lambda_{\mathfrak{g}} \hookrightarrow \Lambda_{\mathfrak{g}}$ (Proposition B.7.3) induces a factorization bar-cobar equivalence for the level- k sublattice VOA:

$$\Omega^{\text{ch}}(\overline{B}^{\text{ch}}(V_{\sqrt{k}\Lambda_{\mathfrak{g}}}^{\varepsilon_0})) \xrightarrow{\sim} V_{\sqrt{k}\Lambda_{\mathfrak{g}}}^{\varepsilon_0} \quad (\text{B.16})$$

as an equivalence of factorization algebras on $\text{Ran}(X)$. This lifts to an E_1 -factorization ∞ -category equivalence:

$$\text{Fact}_{E_1}^{\text{ord}}(X; V_{\sqrt{k}\Lambda_{\mathfrak{g}}}^{\varepsilon_0}) \simeq \text{Fact}_{E_1}^{\text{ord}}(X; V_{\sqrt{k}\Lambda_{\mathfrak{g}}}^{\varepsilon_0^{-1}})^{\text{rev}}. \quad (\text{B.17})$$

Proof. The lattice $\sqrt{k}\Lambda_{\mathfrak{g}}$ is even and positive-definite: $\langle \sqrt{k}\alpha, \sqrt{k}\beta \rangle_{\sqrt{k}\Lambda} = k\langle \alpha, \beta \rangle_{\Lambda}$, which is even since $\Lambda_{\mathfrak{g}}$ is even. The cocycle restricts: $\iota_k^* \varepsilon_0(\sqrt{k}\alpha, \sqrt{k}\beta) = \varepsilon_0(k\alpha, k\beta) = \varepsilon_0(\alpha, \beta)^{k^2}$, which is a valid symmetric cocycle on $\sqrt{k}\Lambda_{\mathfrak{g}}$.

Apply Theorem B.12.3 to the lattice $\sqrt{k}\Lambda_{\mathfrak{g}}$ with the restricted cocycle. All hypotheses are satisfied: the lattice is even positive-definite and the cocycle is normalized bimultiplicative. This gives (B.16).

The homotopy-level factorization equivalence (B.17) follows from Theorem B.13.3 applied to $\sqrt{k}\Lambda_{\mathfrak{g}}$. $\square$

THEOREM B.13.6 (*Level- k factorization DK for KM algebras;*). For $\mathfrak{g}$ simply-laced and $k \geq 1$, the coset decomposition

$$V_{\Lambda_{\mathfrak{g}}}^{\varepsilon_0} = \bigoplus_{[\gamma] \in \Lambda_{\mathfrak{g}}/\sqrt{k}\Lambda_{\mathfrak{g}}} V_{\sqrt{k}\Lambda_{\mathfrak{g}}}^{\varepsilon_0} \text{-module}_{\gamma}$$

expresses the level-1 lattice VOA as a finite direct sum of modules for the level- k sublattice VOA. Combining with (B.16):

- (i) The factorization bar-cobar equivalence for $V_{\sqrt{k}\Lambda_{\mathfrak{g}}}$ is *unconditional* (does not require thick generation or the KL equivalence).

(ii) The E_1 -factorization ∞ -category of $V_{\sqrt{k}\Lambda_{\mathfrak{g}}}$ -modules decomposes by coset representatives:

$$\mathrm{Fact}_{E_1}^{\mathrm{ord}}(X; V_{\Lambda_{\mathfrak{g}}}^{\varepsilon_0}) \simeq \bigoplus_{[\gamma] \in \Lambda_{\mathfrak{g}}/\sqrt{k}\Lambda_{\mathfrak{g}}} \mathrm{Fact}_{E_1}^{\mathrm{ord}}(X; V_{\sqrt{k}\Lambda_{\mathfrak{g}}}^{\varepsilon_0})_{\gamma}.$$

(iii) The number of cosets $|\Lambda_{\mathfrak{g}}/\sqrt{k}\Lambda_{\mathfrak{g}}| = k^{\mathrm{rank}(\mathfrak{g})/2} \cdot |\Lambda_{\mathfrak{g}}^*/\Lambda_{\mathfrak{g}}|$ equals the number of integrable $\widehat{\mathfrak{g}}_k$ -modules at level k (for $k = 1$: this is $|\Lambda_{\mathfrak{g}}^*/\Lambda_{\mathfrak{g}}|$, the number of minuscule weights plus the identity).

Proof. Step 1: Coset decomposition. The sublattice $\sqrt{k}\Lambda_{\mathfrak{g}} \subset \Lambda_{\mathfrak{g}}$ has index $[\Lambda_{\mathfrak{g}} : \sqrt{k}\Lambda_{\mathfrak{g}}] = k^{\mathrm{rank}(\mathfrak{g})/2} \cdot |\Lambda_{\mathfrak{g}}^*/\Lambda_{\mathfrak{g}}|$ (the index of $k\Lambda$ in Λ is k^d for a rank- d lattice, and rescaling $\sqrt{k}\Lambda \hookrightarrow \Lambda$ has index $k^{d/2}$ for the $\sqrt{k}$ -rescaled inner product; the factor $|\Lambda_{\mathfrak{g}}^*/\Lambda_{\mathfrak{g}}|$ accounts for the possible non-unimodularity of $\Lambda_{\mathfrak{g}}$).

The group algebra decomposes as $\mathbb{C}[\Lambda_{\mathfrak{g}}] = \bigoplus_{[\gamma]} \mathbb{C}[\sqrt{k}\Lambda_{\mathfrak{g}} + \gamma]$ over coset representatives. Since the Heisenberg algebra $\mathcal{H}_{\Lambda}$ acts on each coset sector independently, the VOA decomposes as a direct sum of $V_{\sqrt{k}\Lambda_{\mathfrak{g}}}$ -modules.

Step 2: Factorization compatibility. Each coset module $V_{\sqrt{k}\Lambda_{\mathfrak{g}}}\text{-mod}_{\gamma}$ is a factorization module on $\mathrm{Ran}(X)$: the factorization isomorphism for disjoint opens preserves the coset $[\gamma]$ because the total lattice charge is additive and elements of $\sqrt{k}\Lambda_{\mathfrak{g}}$ map to $\sqrt{k}\Lambda_{\mathfrak{g}}$, so the coset class is preserved.

Step 3: Module count. For the simply-laced root lattice $\Lambda_{\mathfrak{g}}$, the dual lattice $\Lambda_{\mathfrak{g}}^*$ satisfies $\Lambda_{\mathfrak{g}}^*/\Lambda_{\mathfrak{g}} \cong Z(\widetilde{G})$, the center of the simply connected group. At level $k = 1$: $|\Lambda_{\mathfrak{g}}/\sqrt{1}\Lambda_{\mathfrak{g}}| = |\Lambda_{\mathfrak{g}}^*/\Lambda_{\mathfrak{g}}|$, which equals the number of integrable highest-weight modules of $\widehat{\mathfrak{g}}$ at level 1 (these are the $|Z(\widetilde{G})|$ minuscule representations plus the vacuum). For general k , the count $k^{d/2} \cdot |Z(\widetilde{G})|$ agrees with the number of integrable $\widehat{\mathfrak{g}}_k$ -modules by the Kac–Walton formula. $\square$

B.13.4 QUANTUM LATTICE ALGEBRAS AT ROOTS OF UNITY

The level- k factorization DK extends to the E_1 setting by incorporating the root-of-unity deformation.

THEOREM B.13.7 (*Quantum lattice factorization DK*;). For $\mathfrak{g}$ simply-laced, $N \geq 3$, and $q: \Lambda_{\mathfrak{g}} \times \Lambda_{\mathfrak{g}} \rightarrow \mathbb{Z}/N\mathbb{Z}$ a non-zero antisymmetric bilinear form, the quantum lattice algebra $V_{\Lambda_{\mathfrak{g}}}^{N,q}$ (Definition B.11.12) satisfies:

(i) E_1 -factorization bar-cobar:

$$\Omega^{E_1, \mathrm{ch}}(\overline{B}^{E_1, \mathrm{ch}}(V_{\Lambda_{\mathfrak{g}}}^{N,q})) \xrightarrow{\sim} V_{\Lambda_{\mathfrak{g}}}^{N,q}$$

as an equivalence of E_1 -factorization algebras on $\mathrm{Ran}(X)$.

(ii) *Homotopy-level equivalence*: the E_1 -factorization ∞ -category equivalence

$$\mathrm{Fact}_{E_1}^{\mathrm{ord}}(X; V_{\Lambda_{\mathfrak{g}}}^{N,q}) \simeq \mathrm{Fact}_{E_1}^{\mathrm{ord}}(X; V_{\Lambda_{\mathfrak{g}}}^{N,-q})^{\mathrm{rev}}. \quad (\text{B.18})$$

(iii) E_1 *inversion*: the equivalence realizes the E_1 inversion principle (Theorem B.11.15) at the factorization-categorical level: the Koszul dual $(V_{\Lambda_{\mathfrak{g}}}^{N,q})^! \cong (V_{\Lambda_{\mathfrak{g}}}^{N,-q})^c$ (Proposition B.11.4(iv)) governs the Verdier dual factorization category.

Proof. (i) is Corollary B.12.5(iii), already proved.

(ii) Apply Theorem B.13.3 to $\Lambda = \Lambda_{\mathfrak{g}}$ with cocycle $\varepsilon_{N,q}$. The lattice $\Lambda_{\mathfrak{g}}$ is even and positive-definite, and $\varepsilon_{N,q}$ is a valid cocycle (Proposition B.11.4(i)). The inverse cocycle is $\varepsilon_{N,q}^{-1} = \varepsilon_{N,-q}$ (Proposition B.11.4(iv)). Theorem B.13.3 gives (B.18).

(iii) The Verdier identification $\mathbb{D}_{\text{Ran}} \overline{B}^{E_1}(V^{N,q}) \simeq (V^{N,-q})_\infty^!$ (Corollary B.12.5(iii)) identifies the Verdier dual bar complex with the bar complex of the Koszul dual. At the ∞ -categorical level, this says that the Verdier dual of $\text{Fact}_{E_1}^{\text{ord}}(X; V^{N,q})$ is governed by the Koszul dual $(V^{N,q})^! = (V^{N,-q})^c$, which is the factorization-categorical realization of the E_1 inversion principle. $\square$

B.13.5 BRIDGE TO YANGIAN DERIVED KOSZUL DUALITY

The lattice family is the bridge between two worlds. On one side stand the commutative/ E_∞ -chiral families (Heisenberg, lattice, free fermion) where every Koszul pair is unconditional and the full factorization-categorical DK equivalence is proved. On the other side stand the associative/ E_1 -chiral families (Yangians, RTT algebras) where DK involves spectral parameters, R -matrices, and the full braided structure of quantum groups. The following two propositions are the explicit hinges of the bridge: they show that the lattice DK equivalence, at level 1 and for simply-laced $\mathfrak{g}$, is compatible with the Frenkel–Kac–Segal identification and therefore implies the Yangian DK equivalence on the evaluation locus.

PROPOSITION B.13.8 (*Lattice–Yangian DK bridge at level 1;*). For $\mathfrak{g}$ simply-laced, the following diagram of equivalences commutes:

$$\begin{array}{ccc} \text{Fact}_{E_1}^{\text{ord}}(X; V_{\Lambda_{\mathfrak{g}}}^{\varepsilon_0}) & \xrightarrow[\sim]{\text{Thm B.13.3}} & \text{Fact}_{E_1}^{\text{ord}}(X; V_{\Lambda_{\mathfrak{g}}}^{\varepsilon_0})^{\text{rev}} \\ \cong \downarrow \text{FKS} & & \text{FKS} \downarrow \cong \\ \text{Fact}_{E_1}^{\text{ord}}(X; L(\widehat{\mathfrak{g}}, 1)) & \xrightarrow[\text{DK}]{\sim} & \text{Fact}_{E_1}^{\text{ord}}(X; L(\widehat{\mathfrak{g}}, 1))^{\text{rev}} \end{array}$$

where the vertical isomorphisms are the Frenkel–Kac–Segal identification (Theorem B.4.1). The bottom equivalence is the level-1 case of the Yangian DK theorem (Theorem O.9.18 for $k = 1$).

Proof. The FKS identification $V_{\Lambda_{\mathfrak{g}}}^{\varepsilon_0} \cong L(\widehat{\mathfrak{g}}, 1)$ is an isomorphism of vertex algebras, hence induces an equivalence of factorization module categories. The top equivalence is Theorem B.13.3 for the unimodular case (where $\varepsilon_0^{-1} = \varepsilon_0$ by the FLM symmetry, so $(\cdots)^{\text{rev}}$ acts on the same algebra).

Commutativity of the square follows from the functoriality of the bar-cobar construction: the bar complex of V^{ε_0} maps isomorphically to the bar complex of $L(\widehat{\mathfrak{g}}, 1)$ under FKS, and the Verdier intertwining commutes with this isomorphism because FKS preserves the cocycle structure.

The bottom equivalence is therefore an independent proof of DK-o/1 for level-1 KM algebras, obtained without the RTT generators or thick-generation arguments of the Yangian approach. For $\mathfrak{g} = \mathfrak{sl}_N$, this recovers the $k = 1$ case of Theorem O.9.18. $\square$

Conjecture B.13.9 (*Lattice approach to DK-5 at roots of unity;*). If the quantum group identification (Conjecture B.11.18(ii)) holds (i.e., if the module category of $V_{\Lambda_{\mathfrak{g}}}^{N,q}$ is equivalent to $\text{Rep}(u_\zeta(\mathfrak{g}))$ as a braided monoidal category), then the quantum lattice factorization DK (Theorem B.13.7) gives the full triple bridge of Conjecture O.13.51:

$$\text{Fact}_{E_1}^{\text{ord}}(X; V_{\Lambda_{\mathfrak{g}}}^{N,q}) \simeq \text{Rep}(u_\zeta(\mathfrak{g})) \simeq \text{Fact}_{E_1}^{\text{ord}}(X; V_{\Lambda_{\mathfrak{g}}}^{N,-q})^{\text{rev}}.$$

In particular:

- (i) For N the Coxeter number h of $\mathfrak{g}$, this would recover the Kazhdan–Lusztig equivalence at the critical root of unity $\zeta = e^{2\pi i/h}$.

- (ii) The $q \rightarrow -q$ inversion in the lattice setting corresponds to $\zeta \rightarrow \zeta^{-1}$ in the quantum group, which is the Drinfeld unitarization $U_q \leftrightarrow U_{q^{-1}}$.

Remark B.13.10 (Status and reducibility of the quantum group identification). Conjecture B.13.9 reduces the full factorization DK (MC₃, beyond the type A evaluation-generated core which is now proved) to the single open problem of the quantum group identification (Conjecture B.11.18(ii)). This is a statement purely about the representation theory of the quantum lattice VOA; it does not involve bar complexes, configuration spaces, or factorization algebras.

The identification is supported by the following evidence:

- (a) *Classical KL precedent* ($\mathfrak{g} = \mathfrak{sl}_2$): the Kazhdan–Lusztig equivalence [257] establishes $\widehat{\mathfrak{sl}}_2\text{-mod}_k \simeq \text{Rep}(u_\zeta(\mathfrak{sl}_2))$ at $\zeta = e^{2\pi i/(k+2)}$ for all admissible levels k . Since $V_{A_1} \cong L(\widehat{\mathfrak{sl}}_2, 1)$ by FKS, this is the rank-1 prototype. The quantum lattice algebra framework requires $\text{rank} \geq 2$ (Definition B.11.12), so $\mathfrak{sl}_2$ falls outside its direct scope, but the KL equivalence provides the motivating model.
- (b) *Smallest test case* ($\mathfrak{g} = \mathfrak{sl}_3$, A_2 lattice): the quantum lattice algebra $V_{A_2}^{N,q}$ is the simplest instance where the cocycle deformation is non-trivial. The screening operators (Construction B.11.19) satisfy $Q_i^2 = 0$ and have off-diagonal braiding $-\zeta^{2q(\alpha_1, \alpha_2)}$ (Proposition B.11.20). At $N = h = 3$ (Coxeter number), comparison with $u_\zeta(\mathfrak{sl}_3)$ at $\zeta = e^{2\pi i/3}$ is a finite verification.
- (c) For general simply-laced $\mathfrak{g}$ at $N = h$ (the Coxeter number): the lattice approach would provide a purely vertex-algebraic proof of the KL equivalence at the critical root of unity.

The three-route package for the identification is described in Remark B.11.21. The conjectural status of (ii) is the sole obstacle between the lattice package and the full DK/KL categorical equivalence (MC₃ CG decomposition is proved on the evaluation-generated core for all simple types; post-CG completion open beyond type A, Corollary O.9.73; the remaining obstacles are the post-CG packets and the quantum-group identification).

Remark B.13.11 (Summary: the lattice DK package). The results of §B.12–B.13 establish:

- (1) Unconditional factorization bar-cobar for all even positive-definite lattices, symmetric or not (Theorem B.12.3).
- (2) Homotopy-level E_1 -factorization category equivalence for all lattice VOAs (Theorem B.13.3).
- (3) Level- k extension via sublattice embeddings (Proposition B.13.5, Theorem B.13.6).
- (4) Full quantum lattice factorization DK (Theorem B.13.7).
- (5) Bridge to Yangian DK at level 1 (Proposition B.13.8).
- (6) Conditional full DK/KL equivalence via quantum group identification (Conjecture B.13.9).

The lattice route is the most complete factorization DK package in this monograph: steps (1)–(5) are unconditional (proved here), and the only remaining hypothesis for the full DK/KL equivalence is (6), which is a representation-theoretic statement independent of the bar-cobar/factorization framework.

Homotopy template (Convention 1.10.1): Type II (equivalence). Steps (1)–(5) are M-level proved, H-level proved. Step (6) is M-level conditional, H-level conditional.

B.14 GENUS-1 SECTORWISE BAR COMPLEX AND CURVATURE-BRAIDING ORTHOGONALITY

The sectorwise structure that makes lattice DK unconditional at genus 0 persists at genus 1. The result is a clean factorization of the genus-1 bar complex into modular (Cartan) and braiding (root) components, proving that the E_1 -chiral genus theory for lattice algebras is a *deformation of the E_∞ theory in the root sectors only*.

B.14.1 THE GENUS-1 PROPAGATOR PRESERVES SIMPLE-POLE RESIDUES

On an elliptic curve $E_\tau = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$, the genus-0 propagator $\eta_{ij}^{(0)} = d \log(z_i - z_j)$ is replaced by

$$\eta_{ij}^{(1)} = \left[\zeta_\tau(z_{ij}) + \frac{\pi}{\text{Im}(\tau)} \text{Im}(z_{ij}) \right] (dz_i - dz_j),$$

where ζ_τ is the Weierstrass ζ -function. The non-holomorphic correction $\frac{\pi}{\text{Im}(\tau)} \text{Im}(z_{ij})$ ensures well-definedness on E_τ at the cost of breaking holomorphicity.

PROPOSITION B.14.1 (*Simple-pole residues unchanged at genus 1;*). The residue of $\eta_{ij}^{(1)}$ at $z_i = z_j$ equals 1, the same as genus 0. Consequently, all OPE coefficients extracted from simple poles (i.e., all vertex-operator OPEs $e^{\alpha_i}(z) e^{\alpha_j}(w)$ with $\langle \alpha_i, \alpha_j \rangle = -1$) are *unchanged* at genus 1.

Proof. The Weierstrass ζ -function has Laurent expansion $\zeta_\tau(z) = z^{-1} + O(z)$, so $\text{Res}_{z=0} \zeta_\tau(z) dz = 1$. The correction $\frac{\pi}{\text{Im}(\tau)} \text{Im}(z)$ is regular at $z = 0$, contributing zero to the residue. $\square$

B.14.2 SECTORWISE CURVATURE: THE ORTHOGONALITY THEOREM

THEOREM B.14.2 (*Curvature-braiding orthogonality for quantum lattice VOAs;*). For a quantum lattice algebra $V_\Lambda^{N,q}$ on E_τ :

- (i) *Cartan sector.* In the sector $\gamma = 0$ (Heisenberg/Cartan generators), the genus-1 bar differential satisfies $d_{\text{fib}}^2 = \text{rank}(\Lambda) \cdot \omega_1$, where $\omega_1 = c_1(\mathbb{E}) \in H^2(\overline{\mathcal{M}}_1)$ is the first Chern class of the Hodge bundle.
- (ii) *Root sectors.* In every adjacent-root sector $\gamma = \alpha_i + \alpha_j$ with $\langle \alpha_i, \alpha_j \rangle = -1$, the genus-1 bar differential satisfies $d_{\text{fib}}^2 = 0$. The E_1 ordering cycles persist unchanged from genus 0.
- (iii) *Modular characteristic.* $\kappa(V_\Lambda^{N,q}) = \text{rank}(\Lambda)$, independent of the deformation parameters (N, q) .
- (iv) *Genus-1 free energy.* $F_1(V_\Lambda^{N,q}) = \text{rank}(\Lambda)/24$, matching the Heisenberg genus-1 free energy at level 1 summed over $\text{rank}(\Lambda)$ independent bosons.
- (v) *Complementarity.* For the lattice-VOA family the pairing is $\kappa_{\text{latt}}(V_\Lambda^{N,q}) + \kappa_{\text{latt}}((V_\Lambda^{N,q})^\dagger) = 0_{(\text{lattice, type i})}$: the combined bar complex at genus 1 is an honest cochain complex.

Proof. The bar complex $\overline{B}_{E_\tau}(V_\Lambda^{N,q})$ decomposes as a direct sum $\bigoplus_{\gamma \in \Lambda} \overline{B}_\gamma$ indexed by the lattice vector $\gamma = \alpha_1 + \dots + \alpha_n$ of the bar element $[e^{\alpha_1} \dots e^{\alpha_n}]$. This decomposition persists at genus 1 because the lattice Λ is constant over $\overline{\mathcal{M}}_{1,1}$: the fiber of each sector does not jump.

Cartan sector ($\gamma = 0$). The only OPEs contributing to the bar differential involve the Cartan generators $h_a(z) h_b(w) \sim A_{ab}/(z-w)^2$, which have double poles. The genus-1 propagator on E_τ replaces $d \log(z_i - z_j)$ by the Arakelov Green's function, and the modified Arnold relation $\mathcal{A}_3^{(1)} = 2\pi i \cdot \omega_{\text{vol}}^{(1)} \neq 0$ produces

the curvature $d_{\text{fib}}^2 = \sum_{a=1}^r 1 \cdot \omega_1 = r \cdot \omega_1$ by Theorem 2.7.2 applied independently to each of the r Cartan bosons. The deformation cocycle $\varepsilon_{N,q}$ does not enter: the Cartan OPEs are determined by the inner product $\langle \alpha_i, \alpha_j \rangle$ alone.

Root sectors ($\gamma = \alpha_i + \alpha_j$, $\langle \alpha_i, \alpha_j \rangle = -1$). The bar differential extracts the residue of the simple pole $e^{\alpha_i}(z) e^{\alpha_j}(w) \sim \varepsilon(\alpha_i, \alpha_j) e^{\alpha_i + \alpha_j}(w)/(z - w)$. By Proposition B.14.1, the simple-pole residue is unchanged at genus 1. Therefore $d_{\text{fib}}^{(1)} = d_{\text{fib}}^{(0)}$ in each root sector, and in particular $(d_{\text{fib}}^{(1)})^2 = 0$. The E_1 ordering cycle $\xi = [e^{\alpha_i} | e^{\alpha_j}] - \lambda [e^{\alpha_j} | e^{\alpha_i}]$ (with $\lambda = -\varepsilon_{N,q}(\alpha_i, \alpha_j)/\varepsilon_{N,q}(\alpha_j, \alpha_i)$) remains a cocycle, and its cohomology class is unchanged.

Independence from (N, q) . The curvature $r \cdot \omega_1$ lives entirely in the Cartan sector, which depends only on the Cartan matrix $A_{ab} = \langle \alpha_i, \alpha_j \rangle$. The cocycle $\varepsilon_{N,q}$ enters only the root sectors, where $d_{\text{fib}}^2 = 0$. Hence $\kappa(V_{\Lambda}^{N,q}) = r$ for all (N, q) .

Complementarity. The Koszul dual $(V_{\Lambda}^{N,q})^!$ has Cartan level -1 per boson (the sign flip from Verdier duality on configuration spaces), giving $\kappa((V_{\Lambda}^{N,q})^!) = -r$. In the lattice-VOA sector, free-field / Ext $\leftrightarrow$ Sym duality, distinct from the Virasoro value 13) the pairing vanishes: $\kappa_{\text{lattice}}(V_{\Lambda}^{N,q}) + \kappa_{\text{lattice}}((V_{\Lambda}^{N,q})^!) = 0$ $\square$

Remark B.14.3 (The orthogonality principle). The factorization $B^{(1)}(V_{\Lambda}^{N,q}) \simeq B_{\text{Cartan}}^{(1)}(\mathcal{H}_r) \otimes B_{\text{roots}}^{(0)}(V_{\Lambda}^{N,q})$ expresses a structural principle: on lattice VOAs, the *modular axis* (genus tower, curvature, $\hat{A}$ -genus) and the *braiding axis* (R -matrix, cocycle, ordering cycles) are *orthogonal*. The modular axis sees only the rank; the braiding axis sees only the cocycle. This separation may fail for the Yangian (Conjecture O.2.17), where the R -matrix residue $-\hbar P$ could contribute to the genus-1 curvature directly.

COROLLARY B.14.4 (*Lattice shadow obstruction tower: termination at weight 2;*). The shadow obstruction tower (Definition 13.22.46) of a quantum lattice VOA $V_{\Lambda}^{N,q}$ terminates at weight 2: $\Theta_{V_{\Lambda}}^{\leq r} = \kappa \cdot \eta \otimes \Lambda$ for all $r \geq 2$, with $o_{r+1}(V_{\Lambda}) = 0$ for all $r \geq 2$. The lattice tower is Gaussian/formal: curvature-braiding orthogonality (Theorem B.14.2) ensures that the cocycle twist does not generate higher shadow corrections, so the tower terminates at the same level as the Heisenberg tower but by formality of the deformation algebra rather than by vanishing of higher operations.

Proof. The L_{∞} -algebra $\text{Def}_{\infty}^{\text{mod}}(V_{\Lambda})$ is formal: by Theorem B.14.2, the curvature and braiding decouple, so the transferred L_{∞} brackets ℓ_k^{tr} are all coboundaries for $k \geq 2$. The shadow algebra V_{Λ}^{sh} therefore reduces to $\mathbb{Q}[\kappa]$ with $\kappa = \text{rank}(\Lambda)$. Since all higher obstruction classes o_{r+1} lie in the image of the coboundary map, they vanish in the shadow algebra for $r \geq 2$. $\square$

Remark B.14.5 (Completion kinematics of lattice VOAs). The lattice VOA V_{Λ} of rank $r = \text{rank}(\Lambda)$ has vacuum character $\chi_{V_{\Lambda}}(q) = \theta_{\Lambda}(q)/\eta(q)^r$, where θ_{Λ} is the lattice theta function. At generic lattice, the primitive generating series is $G_{V_{\Lambda}}(t) = r t/(1 - t)$: one primitive per derivative per basis vector, exactly as for rank- r Heisenberg. The Koszul radius is $\rho_K = 1/(r + 1)$ and the completion entropy $h_K(V_{\Lambda}) = \log(r + 1)$. The primitive defect $\Delta_{V_{\Lambda}}(t) = 0$: the lattice twist does not create new quasi-primary cumulants (by curvature-braiding orthogonality, Theorem B.14.2).

All lattice VOAs are *exact Euler-Koszul*: $W(V_{\Lambda}) = \{1^r\}$ (vertex operators have conformal weight 1), so $\text{ek}(V_{\Lambda}) = 0$ and $S_{V_{\Lambda}}(u) = r \cdot \zeta(u)\zeta(u+1)$ (Definition K.7.1). The sewing reproducing kernel is a pure product of zeta functions, independent of the lattice structure. The depth decomposition $d(V_{\Lambda}) = 1 + d_{\text{arith}}$ with $d_{\text{alg}} = 0$ (Theorem S.9.1): the shadow obstruction tower detects only the Hecke eigenform content of Θ_{Λ} , with no homotopy defect.

The reduced-weight windows $K_q(V_\Lambda)$ have dimension $\sim (r+1)^q$, growing with the number of Heisenberg modes at each level. The cocycle phase $\varepsilon_{N,q}$ enters the differential on each window but does not change the window dimensions; this is the kinematic reflection of curvature-braiding orthogonality.

Remark B.14.6 (Lattice shadow connection). For lattice vertex algebras V_Λ : $\kappa = \text{rank}(\Lambda)$, $\alpha = 0$, $S_4 = 0$, $\Delta = 0$. The shadow metric $Q_{V_\Lambda} = (2\kappa)^2$ is *constant*, the connection form $\omega = Q'/(2Q) = 0$ is trivial, and the parallel transport $\Phi(t) = 1$ is the identity. The shadow obstruction tower terminates at $r_{\max} = 2$: the lattice is the archetype of the Gaussian class **G**. The arithmetic shadow depth (from Hecke eigenforms in the partition function) is an independent invariant, governed by the Epstein zeta function rather than the shadow metric.

B.14.3 E_1 CHIRAL HOCHSCHILD COHOMOLOGY FOR QUANTUM LATTICE VOAs

The E_∞ chiral Hochschild cohomology of lattice VOAs decomposes by lattice sector (Theorem B.8.1). The curvature-braiding orthogonality theorem (Theorem B.14.2) suggests the same decomposition persists in the E_1 setting, with the cocycle $\varepsilon_{N,q}$ introducing phase factors sector by sector.

Conjecture B.14.7 (E_1 lattice chiral Hochschild cohomology;). For a quantum lattice algebra $V_\Lambda^{N,q}$:

- (i) The E_1 -chiral Hochschild cohomology decomposes by lattice sector: $CH_{E_1}^n(V_\Lambda^{N,q}) = \bigoplus_{\alpha \in \Lambda} CH_{E_1}^n(V_\Lambda^{N,q})^\alpha$.
- (ii) In the Cartan sector ($\alpha = 0$), the E_1 and E_∞ chiral Hochschild cohomologies are isomorphic (the Cartan generators are E_∞ regardless of the cocycle).
- (iii) In non-zero sectors ($\alpha \neq 0$), the cocycle braiding $c_{N,q}(\alpha_i, \alpha_j) = (-1)^{\langle \alpha_i, \alpha_j \rangle} \zeta_N^{2q(\alpha_i, \alpha_j)}$ introduces phase twists in the chiral Hochschild differential, changing cohomology dimensions relative to the E_∞ case.
- (iv) The N -torsion of the braiding creates $\mathbb{Z}/N\mathbb{Z}$ periodicity in the sector-by-sector chiral Hochschild computation: sectors α and $\alpha + N\beta$ have isomorphic chiral Hochschild contributions.

Evidence. Part (i) follows from the lattice grading. Part (ii) follows from Theorem B.14.2: the Cartan sector is E_∞ . Part (iii) is the E_1 content: the ordering cycles in the bar complex (which control chiral Hochschild via bar-cobar) carry the cocycle phases. Part (iv) is structural (the braiding matrix has N -torsion by Theorem B.11.13).

B.15 LATTICE SHADOW OBSTRUCTION TOWER: INTEGRABLE SPIN CHAINS AND THE TRANSFER MATRIX DICTIONARY

The lattice shadow obstruction tower connects the modular Koszul duality engine to the most concrete physical systems in condensed matter physics: integrable spin chains. The continuum limits of XXX, XXZ, and XYZ chains are affine Kac–Moody or Virasoro algebras, and the shadow tower data controls finite-size corrections to the ground state energy through the Cardy formula and its higher-order analogues.

B.15.1 XXX SPIN CHAIN: THE $V_1(\mathfrak{sl}_2)$ SHADOW

PROPOSITION B.15.1 (*XXX shadow data;*). The isotropic Heisenberg antiferromagnet $H = -J \sum_i \vec{S}_i \cdot \vec{S}_{i+1}$ has continuum limit $V_1(\mathfrak{sl}_2)$ (SU(2) WZW at level $k = 1$) with central charge $c = 1$. The shadow data decomposes into two channels:

Channel	κ	α	S_4	Class
Current line (J^a directions)	9/4	1	0	L
T -line (Sugawara)	1/2	2	10/27	M

On the current line, $\kappa = \dim(\mathfrak{sl}_2)(k + h^\vee)/(2h^\vee) = 3 \cdot 3/4 = 9/4$ (not $c/2 = 1/2$; cf. Table K.7.1), and the Jacobi identity kills the quartic, giving class L with $r_{\max} = 3$. On the T -line, the Sugawara tensor has the Virasoro shadow at $c = 1$, class M with infinite shadow depth.

Proof. The current-line data follows from the affine $\mathfrak{sl}_2$ shadow theorem (Chapter G, Theorem G.16.2): $\dim = 3$, $h^\vee = 2$, $k = 1$, so $\kappa = 3 \cdot 3/4 = 9/4$, $\alpha = 1$ (from the Lie bracket $f^{ab}{}_c J^c$), $S_4 = 0$ (Jacobi identity). The T -line data: $\kappa_T = c/2 = 1/2$, $\alpha_T = 2$ (universal for Virasoro), $S_4 = 10/(c(5c + 22)) = 10/27$. $\square$

PROPOSITION B.15.2 (*Transfer matrix–shadow dictionary*;). For the XXX chain with Yang’s rational R -matrix $R(u) = u \cdot \text{Id} + P$ (where P is the permutation operator), the conserved charges I_n generated by $\log T(u) = \sum_n I_n u^{n-1}/(n-1)!$ correspond to shadow obstruction tower coefficients on the current line:

Transfer matrix	Shadow obstruction tower
I_1 (momentum)	Translation on $\text{Ran}(X)$
I_2 (Hamiltonian)	$\kappa = 9/4$ (modular characteristic)
I_3 (third charge)	$\alpha = 1$ (cubic shadow, Lie bracket)
$I_n, n \geq 4$ (higher charges)	$S_n = 0$ for $n \geq 4$ (class L: shadow terminates)

The classical r -matrix is $r(z) = k\Omega/z$ (simple pole, one order below the OPE double pole by $d \log$ extraction).

Proof. The correspondence is structural: the leading conserved charges of the integrable hierarchy are moments of the transfer matrix, while the shadow obstruction tower coefficients are moments of the shadow generating function. The shadow obstruction tower terminates at degree 3 because the Jacobi identity kills the quartic shadow coefficient ($S_4 = 0$). The higher conserved charges I_n for $n \geq 4$ are nonzero (generating the Yangian $Y(\mathfrak{sl}_2)$), but they lie outside the shadow obstruction tower: they contribute to the full L_∞ -algebra $\text{Def}_\infty^{\text{mod}}(V_1(\mathfrak{sl}_2))$, not to the scalar shadow projections S_n . The r -matrix identification $r(z) = k\Omega/z$ follows from the collision residue computation: the OPE $J^a(z)J^b(w) \sim k\kappa^{ab}/(z-w)^2 + f^{ab}{}_c J^c(w)/(z-w)$ yields, after $d \log$ extraction, $r(z) = k\Omega/z$: the double pole $k\kappa^{ab}/(z-w)^2$ shifts to $k\kappa^{ab}/(z-w)$ and the simple pole becomes regular and drops. Here $\Omega = \sum_a I^a \otimes I_a$ is the quadratic Casimir. $\square$

B.15.2 XXZ SPIN CHAIN: THE MINIMAL MODEL SHADOW

PROPOSITION B.15.3 (*XXZ shadow data*;). The anisotropic Heisenberg chain $H = -\sum_i (S_i^x S_{i+1}^x + S_i^y S_{i+1}^y + \Delta_{\text{anis}} S_i^z S_{i+1}^z)$ with $\Delta_{\text{anis}} = \cos(\pi\nu)$, $0 < \nu < 1$, has continuum limit a compactified boson with $c = 1 - 6(1-\nu)^2/\nu$. At the rational coupling $\nu = p/(p+1)$, the continuum limit is the unitary minimal model $\mathcal{M}(p, p+1)$ with shadow data on the Virasoro T -line:

p	c	Model	$\kappa = c/2$	ρ
3	1/2	Ising	1/4	≈ 12.5
4	7/10	Tricritical Ising	7/20	≈ 8.9
5	4/5	3-state Potts	2/5	≈ 7.8
6	6/7	–	3/7	≈ 7.3

All have class M on the T -line, with shadow growth rate ρ decreasing monotonically as c increases toward 1.

Proof. At $v = p/(p+1)$: $c = 1 - 6(1 - p/(p+1))^2/(p/(p+1)) = 1 - 6/(p(p+1))$ (the standard Kac formula). The shadow data on the T -line is the universal Virasoro shadow at this value of c : $\kappa = c/2$, $\alpha = 2$, $S_4 = 10/[c(5c+22)]$. The growth rate ρ is computed from $\rho^2 = (9\alpha^2 + 2\Delta)/(4\kappa^2)$ with $\Delta = 8\kappa S_4 = 40/(5c+22)$. $\square$

B.15.3 XYZ SPIN CHAIN: QUASI-MODULAR SHADOW

Remark B.15.4 (Quasi-modular structure of the XYZ shadow). The fully anisotropic XYZ chain $H = \sum_i (J_x S_i^x S_{i+1}^x + J_y S_i^y S_{i+1}^y + J_z S_i^z S_{i+1}^z)$ has a central charge determined by the elliptic modular parameter $\tau = iK'/K$ (where K, K' are complete elliptic integrals). The genus-1 shadow amplitudes involve the quasi-modular Eisenstein series $E_2^*(\tau)$: the propagator of the genus-1 bar complex is $\partial_z \log \theta_1(z|\tau) = E_2^*(\tau) \cdot z + \dots$, and graph sums produce quasi-modular polynomials in $\{E_2^*, E_4, E_6\}$, *not* holomorphic modular forms. The shadow obstruction tower of the XYZ chain is therefore a function on the upper half-plane taking values in the ring of quasi-modular forms, a structure that reduces to the trigonometric (XXZ) and rational (XXX) shadows in the appropriate limits $\tau \rightarrow i\infty$ and $\tau \rightarrow 0$.

B.15.4 FINITE-SIZE CORRECTIONS AND THE SHADOW HIERARCHY

PROPOSITION B.15.5 (*Shadow hierarchy and Cardy corrections*;). For a critical spin chain of length L with continuum limit a chiral algebra $\mathcal{A}$, the finite-size energy eigenvalues are:

$$E_n(L) = e_\infty \cdot L + \frac{2\pi v_F}{L} \left(x_n - \frac{c}{24} \right) + O(1/L^2),$$

where x_n is the scaling dimension, v_F is the Fermi velocity, and the $O(1/L^2)$ corrections encode the shadow obstruction tower data. The genus-1 free energy $F_1(\mathcal{A}) = \kappa(\mathcal{A})/24$ determines the leading finite-size correction to the extensive ground state energy, and the higher shadow coefficients S_r for $r \geq 3$ control subleading corrections involving the higher conserved charges.

Proof. The Cardy formula $E_n(L) = e_\infty L + 2\pi v_F (x_n - c/24)/L + \dots$ is standard (Blöte–Cardy–Nightingale 1986, Affleck 1986). The identification of $F_1 = \kappa/24$ with the first subleading correction is the genus-1 shadow amplitude at the scalar level (Theorem D). The higher-degree corrections at genus 1 involve $S_3, S_4, \dots$ through the planted-forest formula. $\square$

Appendix C

The moonshine module

The moonshine module $V^\natural$ is the unique holomorphic vertex algebra at $c = 24$ with $\dim V_1^\natural = 0$ (Frenkel–Lepowsky–Meurman [175]). The twenty-four Niemeier lattice VOAs share $c = 24$ and $\kappa(V_\Lambda) = \text{rank}(\Lambda) = 24$; the moonshine module has $\kappa(V^\natural) = c/2 = 12$, and the modular characteristic separates it from all twenty-four lattice VOAs at the first shadow level.

Table C.1: Five-theorem verification for the moonshine module $V^\natural$.

Theorem	Statement for $V^\natural$	Status	Reference
A (adjunction)	Koszul dual: Virasoro sector gives Vir_2 ; full dual involves Griess algebra	Open [†]	Rem C.3.1
B (inversion)	$\Omega(\overline{B}(V^\natural)) \xrightarrow{\sim} V^\natural$	Proved	Thm 8.6.1
C (complementarity)	$\kappa(V^\natural) + \kappa(\text{Vir}_2) = 13$	Proved [‡]	Thm K.7.1
D (modular char.)	$\kappa(V^\natural) = 12$	Proved	Prop C.1.1
H (chiral Hochschild)	$\text{ChirHoch}^*(V^\natural)$ polynomial	Proved	Thm 14.4.12

[†]The full Koszul dual of $V^\natural$ as a VOA requires the weight-2 Griess algebra and is not a standard-family object (Remark C.3.1). The Virasoro-sector partner Vir_2 captures the scalar complementarity. [‡]The complementarity sum $\kappa + \kappa' = 13$ is the Virasoro-sector value.

C.1 THE MODULAR CHARACTERISTIC

PROPOSITION C.1.1 ($\kappa(V^\natural) = 12$;). The modular characteristic of the moonshine module is

$$\kappa(V^\natural) = \frac{c}{2} = 12.$$

Proof. Three independent verifications.

Path 1 (bar complex first principles). The genus-1 fiberwise curvature $d_{\text{fib}}^2 = \kappa \cdot \omega_1$ is sourced additively by each independent curvature channel. Weight-1 currents contribute $\kappa = 1$ per boson (Theorem 2.7.2); the Virasoro sector contributes $\kappa = c/2$ (Theorem 13.8.13). Since $\dim V_1^\natural = 0$, no Heisenberg channel exists. The weight-2 Griess algebra generators are conformal primaries: they enter the bar differential at degree ≥ 2 (the shadow coefficients $S_3, S_4, \dots$) but do not source the scalar genus-1 curvature (the degree-0 vacuum diagram has no external insertions). Therefore $\kappa(V^\natural) = c/2 = 12$.

Table C.2: Shadow archetype data for the moonshine module.

Invariant	Value
Class	M (mixed/infinite shadow depth)
Shadow depth $r_{\max}$	∞
$\kappa(V^{\natural})$	12
S_4	5/1704
Critical discriminant Δ	$20/71 \neq 0$
F_1	$1/2$
F_2	$7/480$
r -matrix $r(z)$	$(c/2)/z^3 + 2T/z$ (Virasoro, pole order 3)
Koszul dual (Virasoro sector)	Vir_2
Complementarity sum	$\kappa + \kappa' = 13$
L_{∞} -formality	Non-formal ($\Delta \neq 0$)

Path 2 (orbifold from the Leech lattice). The FLM construction realizes $V^{\natural} = V_{\Lambda_{24}}^{\mathbb{Z}/2}$, where $\mathbb{Z}/2$ acts by the Leech involution $v \mapsto -v$ combined with the canonical automorphism. The Leech lattice VOA has $\kappa(V_{\Lambda_{24}}) = \text{rank}(\Lambda_{24}) = 24$ (Theorem B.14.2). The involution kills all 24 weight-1 currents, removing the Heisenberg contribution $\kappa_{\text{Heis}} = 24 - 12 = 12$. What survives is the Virasoro contribution: $\kappa(V^{\natural}) = 12$.

Path 3 (Niemeier discrimination). If $\kappa(V^{\natural}) = 24$, then $V^{\natural}$ and all Niemeier lattice VOAs would share the same genus-1 free energy $F_1 = \kappa/24 = 1$. The shadow obstruction tower would fail to distinguish them at the first level, contradicting $F_1(V^{\natural}) = 1/2 \neq 1 = F_1(V_{\Lambda_{24}})$. $\square$

Remark C.1.2 (Why $\kappa = c/2$, not $\kappa = 24$). The lattice formula $\kappa = \text{rank}(\Lambda)$ applies to lattice VOAs because each weight-1 Heisenberg boson contributes $\kappa = 1$ to the genus-1 obstruction. Lattice VOAs at $c = 24$ have $\text{rank} = 24 = c$; this numerical coincidence is an accident of rank-24 lattices, not a general identity. The Monster module is not a lattice VOA: $\dim V_1^{\natural} = 0$ eliminates the Heisenberg sector, and the stress tensor T is a genuine weight-2 generator (not the Sugawara composite $\frac{1}{2} \sum j_a j_a$ of weight-1 currents). The formula $\kappa = c/2$ applies because the Virasoro sector alone sources the genus-1 bar curvature.

C.2 SHADOW DEPTH AND THE SINGLE-LINE DICHOTOMY

On the T -line (the single primary line of conformal weight 2), the shadow metric is

$$Q_T(t) = (2\kappa + 3\alpha t)^2 + 2\Delta t^2 = (24 + 6t)^2 + \frac{40}{71} t^2,$$

with $\alpha = 2$ (universal for Virasoro), $S_4 = 10/(c(5c+22)) = 5/1704$, and critical discriminant

$$\Delta = 8\kappa S_4 = 8 \cdot 12 \cdot \frac{5}{1704} = \frac{20}{71} \neq 0.$$

The single-line dichotomy (Theorem 13.22.160) forces infinite shadow depth: $r_{\max}(V^{\natural}) = \infty$, placing $V^{\natural}$ in class M alongside Virasoro and $\mathcal{W}_N$. The shadow obstruction tower does not terminate; the quartic and all higher shadows are generically nonzero.

Remark C.2.1 (Niemeier discrimination at same central charge). The triple $(\kappa, \text{class}, \Delta)$ separates $V^{\natural}$ from all twenty-four Niemeier lattice VOAs at the shadow level. The Niemeier lattice VOAs share $(\kappa, \text{class}, \Delta) = (24, \mathbf{G}, 0)$: the shadow obstruction tower terminates at degree 2 (Theorem B.9.4). The Leech lattice VOA $V_{\Lambda_{24}}$ is indistinguishable from the other twenty-three Niemeier lattice VOAs at the shadow level; it is distinguished by its theta series (zero roots), not by the shadow tower. The moonshine module has $(\kappa, \text{class}, \Delta) = (12, \mathbf{M}, 20/71)$: a different shadow profile, separated already by κ .

The genus-1 free energies reflect the separation:

$$F_1(V^{\natural}) = \frac{\kappa}{24} = \frac{1}{2}, \quad F_1(V_{\Lambda_{24}}) = \frac{24}{24} = 1.$$

At genus 2: $F_2(V^{\natural}) = 7\kappa/5760 = 7/480$, while $F_2(V_{\Lambda_{24}}) = 7 \cdot 24/5760 = 7/240$. The ratio $F_g(V^{\natural})/F_g(V_{\Lambda}) = 1/2$ persists at all genera on the scalar lane ($V^{\natural}$ is uniform-weight with a single generator T).

C.3 THE KOSZUL DUAL AND COMPLEMENTARITY

Remark C.3.1 (The Koszul dual of $V^{\natural}$). The Virasoro Koszul duality $\text{Vir}_c^! \simeq \text{Vir}_{26-c}$ (Proposition H.6.7) specializes at $c = 24$ to a Virasoro-sector partner Vir_2 . The full Koszul dual $(V^{\natural})^!$ as a VOA involves the weight-2 Griess algebra (the 196883-dimensional space of weight-2 primaries under the Monster group $\mathbf{M}$) and is not a standard-family object. The Griess algebra structure constants are known explicitly (Conway 1985, Griess 1982), but the bar cohomology $H^*(\overline{B}(V^{\natural}))$ beyond the Virasoro sector has not been computed: the 196884 weight-2 states generate a Koszul dual whose algebraic structure encodes moonshine at the bar-complex level. This is a genuine open problem (cf. Remark B.9.7).

The Virasoro-sector complementarity gives

$$\kappa(V^{\natural}) + \kappa(\text{Vir}_2) = 12 + 1 = 13,$$

the universal Virasoro complementarity sum $+\kappa(\text{Vir}_{26-c}) = c/2 + (26 - c)/2 = 13$, not 0).

C.4 MOONSHINE AND THE SHADOW OBSTRUCTION TOWER

Remark C.4.1 (The j -function and the shadow tower). The partition function of $V^{\natural}$ is the Hauptmodul $J(\tau) = j(\tau) - 744 = q^{-1} + 196884q + 21493760q^2 + \dots$, whose coefficients decompose into Monster representations (Conway–Norton monstrous moonshine, proved by Borcherds [61]).

The shadow obstruction tower at the scalar level sees $\kappa = 12$ and the Virasoro shadow coefficients S_r at $c = 24$; it does not directly encode the j -function coefficients 196884, 21493760, $\dots$. The moonshine data lives in the *equivariant* shadow tower: the Monster group $\mathbf{M}$ acts on each bar-cohomology group $H^*(\overline{B}(V^{\natural}))$, and the graded traces of $g \in \mathbf{M}$ recover the McKay–Thompson series $T_g(\tau)$. The Rademacher exact formula (the genus-0 Hauptmodul property: J is determined by its polar part q^{-1}) translates to a modular bootstrap constraint: the degree-2 component of $\Theta_{V^{\natural}}$ determines the full genus-0 partition function.

Remark C.4.2 (The orbifold and shadow class transition). The $\mathbb{Z}/2$ orbifold $V_{\Lambda_{24}} \longrightarrow V^{\natural}$ simultaneously transforms:

- (i) $\dim V_1$: from 24 to 0 (all weight-1 currents killed);

- (ii) κ : from 24 to 12 (Heisenberg contribution removed);
- (iii) shadow class: from **G** to **M** (finite shadow depth to infinite shadow depth);
- (iv) Δ : from 0 to $20/71$ (irreducible shadow metric);
- (v) V_2 structure: $\dim V_2 = 196884$ for both $V_{\Lambda_{24}}$ and $V^{\natural}$, but the decomposition changes from 324 Heisenberg descendants + 196560 lattice states to 1 Virasoro descendant + 196883 Griess primaries carrying the Monster action.

This is the only instance in the standard landscape where a finite orbifold changes the shadow class. The mechanism: killing the Heisenberg generators removes the lattice contribution to κ , halving it from 24 to 12; the surviving Virasoro sector with $S_4 = 5/1704 \neq 0$ produces $\Delta = 20/71 \neq 0$, which the single-line dichotomy converts to infinite shadow depth.

Appendix D

The level-1 bridge

At level 1, two independently constructed bar complexes produce identical cohomology by the Frenkel–Kac–Segal theorem (Theorem B.4.1). The affine Kac–Moody algebra $\widehat{\mathfrak{g}}_1$ at level 1 and the lattice vertex algebra $V_{\Lambda_{\mathfrak{g}}}$ on the root lattice of a simply-laced $\mathfrak{g}$ are the same algebra in two presentations: the current presentation (with $\dim \mathfrak{g}$ generating fields $J^a(z)$) and the lattice presentation (with $\text{rank}(\mathfrak{g})$ Heisenberg fields and vertex operators $E_\alpha(z) = Y(e^\alpha, z)$). The bar constructions built from these two descriptions must agree, and the comparison reveals a structural phenomenon: the modular characteristic κ undergoes a *level-1 reduction* from the generic-level Kac–Moody value to the lattice rank.

Table D.1: Five-theorem verification for $\widehat{\mathfrak{g}}_1 \cong V_{\Lambda_{\mathfrak{g}}}$ (simply-laced).

Theorem	Statement	Status	Reference
A (adjunction)	$(\widehat{\mathfrak{g}}_1)^\dagger = \text{CE}^{\text{ch}}(\widehat{\mathfrak{g}}_{-1-2h^\vee}); \text{equiv. } (V_{\Lambda_{\mathfrak{g}}}^\varepsilon)^\dagger = (V_{\Lambda_{\mathfrak{g}}}^{\varepsilon^{-1}})^c$	Proved	Thms G.7.1, B.6.2
B (inversion)	$\Omega(\overline{B}(\widehat{\mathfrak{g}}_1)) \xrightarrow{\sim} \widehat{\mathfrak{g}}_1$	Proved	Thm G.12.3
C (complementarity)	$\mathcal{Q}_{\mathfrak{g}}(\widehat{\mathfrak{g}}_1) \oplus \mathcal{Q}_{\mathfrak{g}}(\widehat{\mathfrak{g}}_{-1-2h^\vee}) = H^*(\overline{\mathcal{M}}_{\mathfrak{g}}, Z)$	Proved	Thm G.12.5
D (modular char.)	$\kappa(\widehat{\mathfrak{g}}_1) = \text{rank}(\mathfrak{g})$ (Prop. D.2.1)	Proved	§D.2
H (chiral Hochschild)	$\text{ChirHoch}^*(\widehat{\mathfrak{g}}_1)$ polynomial	Proved	Thms 14.4.10, 14.4.12

D.1 THE FRENKEL–KAC–SEGAL ISOMORPHISM AT THE CHAIN LEVEL

The Frenkel–Kac–Segal theorem (Theorem B.4.1; [174, 372]) establishes a vertex algebra isomorphism

$$\varphi_{\text{FKS}}: L(\widehat{\mathfrak{g}}, 1) \xrightarrow{\cong} V_{\Lambda_{\mathfrak{g}}}^\varepsilon$$

for every simply-laced simple Lie algebra $\mathfrak{g}$. At level 1 simply-laced, the universal vacuum module $V_1(\mathfrak{g})$ is simple (no null vectors in the vacuum Verma module), so $V_1(\mathfrak{g}) = L(\widehat{\mathfrak{g}}, 1) = V_{\Lambda_{\mathfrak{g}}}$.

The isomorphism φ_{FKS} sends each Cartan current $H_i(z)$ to the Heisenberg field $Y(\alpha_{i,-1}|0\rangle, z)$ and each root current $E_\alpha(z)$ to the vertex operator $Y(e^\alpha, z)$. In particular, the $\dim \mathfrak{g}$ generators of the current presentation are not independent at the lattice level: the $\dim \mathfrak{g} - \text{rank}(\mathfrak{g})$ root currents are vertex operators of Heisenberg composites e^α .

Table D.2: Shadow archetype data for $\widehat{\mathfrak{g}}_1 \cong V_{\Lambda_{\mathfrak{g}}}$.

Invariant	Value
Class	G (Gaussian); reduced from L at $k = 1$
Shadow depth $r_{\max}$	2
κ	$\text{rank}(\mathfrak{g})$
Cubic shadow $\mathfrak{C}$	0 (Jacobi + null-vector exactness)
r -matrix $r(z)$	$\Omega / ((1+h^\vee)z)$ (KZ normalisation at $k = 1$; cf. Remark G.5.7)
Koszul dual	$\text{CE}^{\text{ch}}(\widehat{\mathfrak{g}}_{-1-2h^\vee}) = (V_{\Lambda_{\mathfrak{g}}}^{\varepsilon^{-1}})^c$
Complementarity	$\kappa + \kappa' = 0$ (affine KM)
L_∞ -formality	Strictly formal (depth 2, all shadows vanish for $r \geq 3$)

Remark D.1.1 (Two generating sets, one algebra). The current algebra $\widehat{\mathfrak{g}}_1$ is freely strongly generated by $\dim \mathfrak{g}$ fields of weight 1: the Cartan currents $\{H_i\}_{i=1}^r$ and the root currents $\{E_\alpha\}_{\alpha \in \Phi}$. The lattice VOA $V_{\Lambda_{\mathfrak{g}}}$ is freely strongly generated by $r = \text{rank}(\mathfrak{g})$ Heisenberg fields $\{h_i\}_{i=1}^r$, with the vertex operators $E_\alpha(z)$ arising as normally ordered exponentials of the h_i . The bar complex is an invariant of the algebra, not of a presentation: the two generating sets produce quasi-isomorphic bar complexes. The comparison of the resulting bar-level invariants is the content of this chapter.

D.2 THE MODULAR CHARACTERISTIC AT LEVEL 1

At generic level $k \neq -h^\vee$, the modular characteristic of the affine Kac–Moody algebra is (equation (G.13)):

$$\kappa(\widehat{\mathfrak{g}}_k) = \frac{\dim(\mathfrak{g})(k + h^\vee)}{2h^\vee}. \quad (\text{D.1})$$

The lattice curvature-braiding orthogonality theorem (Theorem B.14.2) gives:

$$\kappa(V_{\Lambda_{\mathfrak{g}}}) = \text{rank}(\Lambda_{\mathfrak{g}}) = \text{rank}(\mathfrak{g}).$$

At $k = 1$ simply-laced, both formulas apply to the same algebra. Their values are:

$\mathfrak{g}$	$\kappa^{\text{KM}} = \frac{\dim \mathfrak{g}(1+h^\vee)}{2h^\vee}$	$\kappa^{\text{lat}} = \text{rank}(\mathfrak{g})$	$c = \frac{\dim \mathfrak{g}}{1+h^\vee}$
$\mathfrak{sl}_2$	9/4	1	1
$\mathfrak{sl}_3$	$8 \cdot 4/6 = 16/3$	2	2
D_4	$28 \cdot 7/12 = 49/3$	4	4
E_6	$78 \cdot 13/24 = 169/4$	6	6
E_7	$133 \cdot 19/36 = 2527/36$	7	7
E_8	$248 \cdot 31/60 = 1922/15$	8	8

The two columns disagree. The lattice value $\kappa^{\text{lat}} = \text{rank}(\mathfrak{g})$ is correct; the Kac–Moody formula (D.1) overcounts because its derivation treats all $\dim \mathfrak{g}$ currents as *independent* generators of the bar complex.

PROPOSITION D.2.1 (*Level-1 κ reduction*;). For $\mathfrak{g}$ simply-laced simple and $k = 1$:

$$\kappa(\widehat{\mathfrak{g}}_1) = \text{rank}(\mathfrak{g}),$$

and not $\dim(\mathfrak{g})(1 + h^\vee)/(2h^\vee)$. The generic-level formula (D.1) applies to the universal vacuum module $V_k(\mathfrak{g})$ with $\dim \mathfrak{g}$ independent weight-1 generators; at $k = 1$, the lattice realization identifies the root currents as composites of the $\text{rank}(\mathfrak{g})$ Heisenberg generators, reducing the effective generator count and thereby the modular characteristic.

Proof. By the Frenkel–Kac–Segal isomorphism $\varphi_{\text{FKS}}: V_1(\mathfrak{g}) \xrightarrow{\cong} V_{\Lambda_{\mathfrak{g}}}$, the modular characteristic κ is computed from either presentation. The lattice computation (Theorem B.14.2) decomposes the genus-1 bar complex into Cartan and root sectors. The Cartan sector (zero lattice charge) has $d_{\text{fib}}^2 = \text{rank}(\mathfrak{g}) \cdot \omega_1$, contributed by $\text{rank}(\mathfrak{g})$ independent Heisenberg bosons. Each root sector (lattice charge $\gamma = \alpha_i + \alpha_j$ with $\langle \alpha_i, \alpha_j \rangle = -1$) has $d_{\text{fib}}^2 = 0$: the simple-pole residue is unchanged at genus 1 (Proposition B.14.1), and the root-sector bar differential is identical to its genus-0 value. The total curvature is the Cartan contribution alone: $\kappa = \text{rank}(\mathfrak{g})$.

The discrepancy with the generic-level formula arises because $\kappa^{\text{KM}} = \dim(\mathfrak{g})(k + h^\vee)/(2h^\vee)$ is derived from the OPE of $\dim \mathfrak{g}$ currents treated as *independent* generators (equation (G.12)). This derivation includes a simple-pole contribution $\kappa_{\text{sp}} = \dim(\mathfrak{g})/2$ from the structure constants f^{abc} . At generic level, this contribution is a genuine part of the bar curvature because the root currents are algebraically independent of the Cartan currents. At $k = 1$ simply-laced, the FKS isomorphism identifies each root current $E_\alpha(z) = Y(e^\alpha, z)$ as a vertex operator built from the Heisenberg fields. These vertex operators are composites, not independent generators: the bar complex of $V_{\Lambda_{\mathfrak{g}}}$ factors through the lattice weight filtration, and the root-sector curvature $d_{\text{fib}}^2|_{\gamma \neq 0} = 0$ by the curvature-braiding orthogonality theorem. The simple-pole contribution κ_{sp} that appears in the universal-level derivation is killed at $k = 1$ by the lattice structure. $\square$

Remark D.2.2 (The central charge coincidence). At level 1 simply-laced, the central charge satisfies $c = k \dim \mathfrak{g}/(k + h^\vee) = \dim \mathfrak{g}/(1 + h^\vee) = \text{rank}(\mathfrak{g})$. Thus $\kappa = c = \text{rank}(\mathfrak{g})$ at $k = 1$. This is a coincidence specific to level 1: at generic k , $\kappa \neq c$ and $\kappa \neq c/2$ for affine Kac–Moody algebras (the discriminant $(k + h^\vee)^2 - kh^\vee > 0$ has no real solutions; see equation (G.13) step 4(x)). The identity $\kappa = c$ at $k = 1$ is an independent confirmation: it follows from $\kappa = \text{rank}(\mathfrak{g})$ (this proposition) and $c = \text{rank}(\mathfrak{g})$ (the Sugawara formula at $k = 1$).

D.3 SHADOW CLASS REDUCTION: FROM L TO G

At generic level, the affine Kac–Moody algebra $\widehat{\mathfrak{g}}_k$ is class L (Lie/tree, $r_{\text{max}} = 3$): the Lie bracket $[J^a, J^b] = f_c^{ab} J^c$ produces a nonzero cubic shadow $\mathfrak{C}$, and the Jacobi identity kills the quartic obstruction $o_4 = 0$ (Table G.2). At $k = 1$ simply-laced, a stronger vanishing holds.

PROPOSITION D.3.1 (*Cubic shadow vanishing at level 1*;). For $\mathfrak{g}$ simply-laced and $k = 1$:

$$\mathfrak{C}(\widehat{\mathfrak{g}}_1) = 0.$$

The shadow obstruction tower terminates at degree 2, and $\widehat{\mathfrak{g}}_1 \cong V_{\Lambda_{\mathfrak{g}}}$ is class G (Gaussian).

Proof. By Theorem B.14.2(ii), every root sector of the genus-1 bar complex has $d_{\text{fib}}^2 = 0$. The cubic shadow is the degree-3 component of the MC element Θ_A in the modular convolution algebra; it receives contributions from the bar differential acting on 3-fold tensor products of generators. In the lattice presentation, the generating fields are the $\text{rank}(\mathfrak{g})$ Heisenberg currents $h_i(z)$, which have only double-pole OPEs $h_i(z) h_j(w) \sim A_{ij}/(z-w)^2$. Since the cubic shadow requires a simple pole (the Lie bracket), and Heisenberg generators have no simple poles, the degree-3 component vanishes identically: $\mathfrak{C}(V_{\Lambda_{\mathfrak{g}}}) = 0$.

In the current presentation, the same vanishing holds by the FKS isomorphism: the cubic shadow of $\widehat{\mathfrak{g}}_1$ computed from the J^a currents must agree with the cubic shadow of $V_{\Lambda_{\mathfrak{g}}}$ computed from the h_i fields (since κ and the full shadow tower are intrinsic to the algebra). The mechanism is that the level-1 null vectors force the Lie bracket contributions to become exact in the bar complex: the structure constant f^{abc} contributions to the degree-3 MC equation, which are nonzero at generic k , degenerate into coboundaries at $k = 1$ via the lattice relations $E_\alpha = Y(e^\alpha, z)$. $\square$

Remark D.3.2 (Classification transition at $k = 1$). The shadow class of $\widehat{\mathfrak{g}}_k$ undergoes a transition at $k = 1$:

Level	Class	r_{max}
Generic $k \neq -h^\vee$	L (Lie/tree)	3
$k = 1$ (simply-laced)	G (Gaussian)	2
$k = -h^\vee$ (critical)	uncurved ($\kappa = 0$)	2

At generic level, the Lie bracket is the source of the cubic shadow. At the two exceptional levels, the cubic shadow vanishes for different reasons: at $k = -h^\vee$ the entire curvature vanishes ($\kappa = 0$); at $k = 1$ simply-laced, the lattice realization makes the Lie bracket contributions exact.

D.4 EXPLICIT VERIFICATION: $\mathfrak{sl}_2$ AT LEVEL 1

For $\mathfrak{g} = \mathfrak{sl}_2$: $\dim \mathfrak{g} = 3$, $h^\vee = 2$, $\text{rank} = 1$, root lattice $\Lambda = A_1 = \mathbb{Z}\alpha$ with $\langle \alpha, \alpha \rangle = 2$.

Central charge. $c = 3 \cdot 1/(1+2) = 1 = \text{rank}(A_1)$.

Modular characteristic. The generic formula gives $\kappa^{\text{KM}} = 3 \cdot 3/(2 \cdot 2) = 9/4$. The lattice formula gives $\kappa^{\text{lat}} = 1$. By Proposition D.2.1, $\kappa(\widehat{\mathfrak{sl}}_{2,1}) = 1$.

Genus-1 free energy. $F_1 = \kappa/24 = 1/24$, the free energy of a single free boson.

Bar complex. In the lattice presentation, V_{A_1} has a single Heisenberg generator $h(z)$ of weight 1. The bar complex is the Heisenberg bar complex $\overline{B}(\mathcal{H}_1)$ with $\kappa = 1$. The genus-1 curvature is $d_{\text{fib}}^2 = \omega_1$ from the single Cartan boson. No root-sector curvature arises because $\langle n\alpha, m\alpha \rangle = -1$ has no integer solutions (Computation B.5.3): the lattice bar differential vanishes on pure lattice-vector elements.

In the current presentation, the three generators $e(z)$, $h(z)$, $f(z)$ produce a bar complex with 3 generators in bar degree 1, but the FKS relations $e = Y(e^\alpha, z)$, $f = Y(e^{-\alpha}, z)$ identify two of these with vertex operators of the third, and the resulting quasi-isomorphism reduces the effective bar complex to the rank-1 Heisenberg model.

D.5 THE ADE FAMILY

COMPUTATION D.5.1 (*Level-1 bridge data for the simply-laced series;*).

$\mathfrak{g}$	rank	$\dim \mathfrak{g}$	$c = \text{rank}$	$\kappa = \text{rank}$	$ \Phi $
A_1	1	3	1	1	2
A_2	2	8	2	2	6
A_3	3	15	3	3	12
D_4	4	28	4	4	24
D_5	5	45	5	5	40
E_6	6	78	6	6	72
E_7	7	133	7	7	126
E_8	8	248	8	8	240

In every case: $\kappa = c = \text{rank}(\mathfrak{g}) = \text{rank}(\Lambda_{\mathfrak{g}})$, agreeing with the lattice formula. The number of roots $|\Phi| = \dim \mathfrak{g} - \text{rank}(\mathfrak{g})$ counts the root currents that become composites under FKS; these contribute zero to the genus-1 bar curvature by Theorem B.14.2(ii).

Remark D.5.2 (Non-simply-laced types). For non-simply-laced $\mathfrak{g}$ (types B_n, C_n, F_4, G_2), the Frenkel–Kac–Segal theorem does not apply directly: the root lattice contains roots of different lengths with $\langle \alpha, \alpha \rangle \neq 2$ (Remark B.4.3). The level-1 algebra $\widehat{\mathfrak{g}}_1$ is not a lattice VOA. At level 1 for non-simply-laced types, $\kappa = \dim(\mathfrak{g})(1 + h^\vee)/(2h^\vee)$ is the full generic-level formula (no reduction occurs), and $\widehat{\mathfrak{g}}_1$ remains class L. The class reduction $L \rightarrow G$ at $k = 1$ is a specifically simply-laced phenomenon, controlled by the lattice realization.

Remark D.5.3 (Unimodularity and self-duality at $k = 1$). Among the ADE root lattices, only E_8 is unimodular ($\Lambda_{E_8} = \Lambda_{E_8}^*$). By Proposition B.10.1, V_{E_8} is the unique Koszul self-dual lattice VOA in the ADE series: $(V_{E_8})^\dagger \cong V_{E_8}$. This self-duality is visible in the complementarity data: $\kappa(\widehat{E}_{8,1}) = 8, \kappa' = \kappa(\widehat{E}_{8,-61}) = -8$ (by the Feigin–Frenkel involution $k \mapsto -1 - 2h^\vee = -61$), so $\kappa + \kappa' = 0$ (as required for affine KM by Proposition G.17.9). For non-unimodular root lattices (A_n, D_n, E_6, E_7), the Koszul dual involves the inverse cocycle (Theorem B.6.2), and the FKS bridge identifies this with the Feigin–Frenkel dual $\widehat{\mathfrak{g}}_{-1-2h^\vee}$ (Theorem G.7.1).

Appendix E

Free field archetypes

The Heisenberg algebra has one generator. Its shadow tower terminates at degree 2, its r -matrix vanishes after d log absorption, and every higher bracket on the convolution algebra is zero: the archetype is Gaussian (class G). What changes with two?

The answer depends on how the second generator is coupled. A free fermion adjoined by an antisymmetric OPE $\psi(z)\psi(w) \sim 1/(z-w)$ leaves the tower Gaussian: the antisymmetry kills the would-be contact shadow before it can propagate, and the second generator contributes nothing beyond degree 2. A second boson coupled through a symplectic pairing produces the $\beta\gamma$ system (Chapter F); here the simple-pole OPE $\beta(z)\gamma(w) \sim 1/(z-w)$ survives d log absorption as a quartic contact interaction, and the shadow tower extends to degree 4 (class C). A fermion-boson pair with a simple-pole OPE gives the bc ghost system, Koszul dual to $\beta\gamma$ with matching shadow invariants in the opposite statistical sector. The dichotomy is sharp: one generator forces class G; two generators forces class G or class C according to the statistics of the pairing, and no finer gradation exists within the free-field regime. The r -matrix profile is uniform across all three cases after d log absorption: $r(z) = 0$. What distinguishes the classes is the degree 4 contact stratum, not the binary shadow data.

The modular Koszul triples (Definition H.26.56) of the free-field archetypes are:

$$\mathfrak{T}_{\mathcal{F}} = (\mathcal{F}, \text{Sym}^{\text{ch}}(\gamma), r(z) = 0),$$

$$\mathfrak{T}_{\beta\gamma} = (\beta\gamma_{\lambda}, bc_{\lambda}, r(z) = 0), \quad \mathfrak{T}_{bc} = (bc_{\lambda}, \beta\gamma_{\lambda}, r(z) = 0).$$

The free fermion r -matrix vanishes: the simple pole in the OPE $\psi(z)\psi(w) \sim 1/(z-w)$ is absorbed by d log extraction (Remark E.5.1). The $\beta\gamma$ - bc pair also has vanishing r -matrix: their OPE $\beta(z)\gamma(w) \sim 1/(z-w)$ has a simple pole, which is absorbed by d log extraction, leaving $r(z) = 0$. The quartic contact shadow, not the r -matrix, carries the leading nontrivial interaction data for class C algebras.

Remark E.0.1 (Shadow obstruction tower for free fields: the Gaussian base case). Each free-field archetype specializes the universal MC element $\Theta_{\mathcal{A}} \in \text{MC}(\mathfrak{g}_{\mathcal{A}}^{\text{mod}})$ (Theorem 13.21.69). The Gaussian archetype is characterized by maximal truncation: the shadow obstruction tower terminates at degree 2, so that $\Theta_{\mathcal{A}}^{\leq 2} = \kappa \cdot \eta \otimes \Lambda$ and all higher projections $\Theta_{\mathcal{A}}^{\leq r} = \Theta_{\mathcal{A}}^{\leq 2}$ for $r \geq 3$. Equivalently, the convolution algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ has trivial higher brackets: the modular deformation complex $\text{Def}_{\infty}^{\text{mod}}(\mathcal{A})$ is formal.

The free fermion is Gaussian with $\kappa \neq 0$; the $\beta\gamma$ and bc systems break out of the Gaussian class because $\Theta^{\leq 4} \neq \Theta^{\leq 2}$ (quartic contact shadow nontrivial on the charged stratum), even though $\Theta_{\beta\gamma|_{\text{w.c.}}}^{\leq 2} = 0$ on the weight-changing line (the global modular characteristic $\kappa(\beta\gamma) = c/2$ is generically nonzero). Both two-generator free-field systems ($\beta\gamma$ and bc) are class C ($r_{\max} = 4$) by the same stratum separation

mechanism; the single-generator free fermion is class G ($r_{\max} = 2$) by fermionic antisymmetry. The free-field periodic table therefore exhibits the transition from the Gaussian to the contact/quartic archetype within the shadow depth classification (Table K.7.1).

Remark E.o.2 (Three-pillar interpretation: free-field archetypes). In the three-pillar architecture (§K.7.1): (i) free bosons produce a *strict* homotopy chiral algebra (Gaussian archetype, all secondary Borchers operations $j'_n = 0$ for $n \geq 3$; Definition 16.9.7, cf. Example 8.10.13). The $\beta\gamma$ - bc pairs are non-strict: they carry $j'_3 \neq 0$ from the cubic OPE, but the quartic contact invariant vanishes ($\mu_{\beta\gamma} = 0$, Corollary 18.5.16), so the Čech homotopy chiral algebra (Theorem 8.10.5) terminates at degree 3; (ii) the convolution sL_∞ -algebra (Theorem 3.1.24) is *formal* for all free-field archetypes: the transferred higher brackets $\ell_k^{\text{tr}} = 0$ for $k \geq 3$ on free bosons and fermions, and ℓ_4^{tr} is a coboundary for $\beta\gamma$ - bc . The shadow algebra is $\mathbb{Q}[\kappa]$ (bosonic) or $\mathbb{Q}[\kappa, \mu]$ with $\mu = 0$ ($\beta\gamma$ - bc); (iii) the log-FM tropicalization (Theorem 13.22.402) reduces to the classical FM compactification for free fields: no nodal divisor insertions are needed because the OPE has at most simple poles, so the planted-forest coefficient algebra $\mathcal{G}_{\text{pf}}$ contributes no corrections beyond depth 1. Free-field archetypes are the unique family where Pillar B is formal and Pillar C is classical simultaneously.

Remark E.o.3 (Free-field bar complex: the polynomial growth baseline). The bar cohomology of the free-field archetypes fixes the polynomial growth baseline for all subsequent families. At genus 0, $\dim H^n(\bar{\mathbf{B}}(\mathcal{A}))$ grows as follows:

Family	$n=0$	1	2	3	4	5	6	GF
Free fermion $\mathcal{F}$	1	0	0	0	0	0	0	1
Heisenberg $\mathcal{H}_k$	1	0	1	0	0	0	0	$1 + x^2$
$\beta\gamma$	1	2	4	10	26	70	192	$\sqrt{(1+x)/(1-3x)}$
bc ghosts	1	2	4	10	26	70	192	$\sqrt{(1+x)/(1-3x)}$

The free fermion and Heisenberg bar complexes are finite-dimensional; $\beta\gamma$ and bc share the discriminant $\Delta(x) = (1-3x)(1+x)$ with $\widehat{\mathfrak{sl}}_2$ and the Virasoro algebra (Theorem K.7.1). Among free-field archetypes, only those whose OPE has a simple pole produce infinite bar cohomology. The polynomial growth ($\sim 3^{n/2}$) calibrates the exponential growth of interacting theories (Kac–Moody, $\mathcal{W}$ -algebras).

E.1 FREE-FIELD ARCHETYPES: SETUP AND OPE STRUCTURE

The four free-field archetypes (the free fermion, the $\beta\gamma$ system, the bc ghost system, and the single-generator fermion–boson pair) are defined below with their OPE structure and relations. Each definition specifies input data for the universal construction $\Theta_{\mathcal{A}} := D_{\mathcal{A}} - d_0 \in \text{MC}(\mathfrak{g}_{\mathcal{A}}^{\text{mod}})$ (Theorem 13.21.69). The bar complex, Koszul dual, genus tower, and shadow invariants computed below are all *outputs* of that single MC element, projected to the relevant degree and genus. For free-field archetypes, the projection is maximally simple: the Gaussian archetype (free fermion) has $\Theta_{\mathcal{A}} = \Theta_{\mathcal{A}}^{\leq 2}$, and the contact/quartic archetype ($\beta\gamma$, bc) terminates at $\Theta_{\mathcal{A}}^{\leq 4}$.

E.1.1 FREE FERMION

Remark E.1.1 (Shadow archetype: Gaussian). Shadow depth $r_{\max} = 2$ (class G). Modular characteristic $\kappa(\mathcal{F}) = c/2 = 1/4$. Central charge $c = 1/2$. The shadow obstruction tower is purely scalar: $\Theta_{\mathcal{F}}^{\leq r} =$

$\Theta_{\mathcal{F}}^{\leq 2} = \kappa \cdot \eta \otimes \Lambda$ for all $r \geq 2$. No cubic or higher shadows. Koszul dual: $\mathcal{F}^! = \text{Sym}^{\text{ch}}(\gamma)$ (one bosonic generator, Theorem E.1.21).

The free fermion replaces the Heisenberg double pole with a fermionic simple pole; the bar complex collapses.

Definition E.1.2 (Free fermion chiral algebra). The free fermion chiral algebra $\mathcal{F}$ is generated by a single fermionic field $\psi(z)$ of conformal weight $h = \frac{1}{2}$ with OPE:

$$\psi(z)\psi(w) = \frac{1}{z-w} + \text{regular}$$

The quadratic relation enforcing fermionic statistics is:

$$R_{\text{ferm}} = \{\psi(z_1) \otimes \psi(z_2) + \psi(z_2) \otimes \psi(z_1)\} \subset j_* j^*(\mathcal{F} \boxtimes \mathcal{F})$$

Remark E.1.3 (Fermionic sign). The antisymmetry $\psi(z)\psi(w) = -\psi(w)\psi(z)$ away from the diagonal forces many components of the bar complex to vanish.

E.1.1.1 Shadow obstruction tower of the free fermion

The free fermion is the Gaussian archetype in its purest form. The Heisenberg algebra achieves class G through *commutativity*: the double pole generates only symmetric bar elements, and the absence of a simple pole kills the cubic shadow. The free fermion achieves class G through *antisymmetry*: the simple pole would produce a cubic shadow in a bosonic algebra, but fermionic statistics force $S_3 = 0$ because cyclic permutations on three-point configuration space forms act by cube roots of unity (proof: Theorem E.2.1, degree 2). The two mechanisms are complementary, and both produce the same outcome: the shadow obstruction tower terminates at degree 2.

PROPOSITION E.1.4 (*Shadow invariants of the free fermion*;). The shadow obstruction tower of the free fermion $\mathcal{F}$ is given by:

1. Modular characteristic: $\kappa(\mathcal{F}) = c/2 = 1/4$.
2. Cubic shadow: $S_3(\mathcal{F}) = 0$. (Fermionic antisymmetry forces the cubic coupling to vanish.)
3. Quartic shadow: $S_4(\mathcal{F}) = 0$. (Consequence of $S_3 = 0$: no quartic contact term survives in the deformation complex.)
4. Critical discriminant: $\Delta(\mathcal{F}) = 8\kappa S_4 = 0$.
5. Shadow class: G (Gaussian), $r_{\text{max}} = 2$.
6. Tower termination: $\Theta_{\mathcal{F}}^{\leq r} = \Theta_{\mathcal{F}}^{\leq 2} = \frac{1}{4} \cdot \eta \otimes \Lambda$ for all $r \geq 2$.

Proof. (1): The free fermion has central charge $c = 1/2$ (a single real fermion of weight $h = 1/2$; standard from the Virasoro commutation relations). Then $\kappa = c/2 = 1/4$ by the universal formula $\kappa = c \cdot \rho$ with $\rho = 1/2$ for single-generator algebras (Theorem 13.21.44).

(2): The cubic shadow S_3 is the degree-3 projection of $\Theta_{\mathcal{F}}$ in the modular convolution algebra. A degree-3 element requires three fermion insertions on a three-point configuration space. By fermionic antisymmetry, $\psi_1 \otimes \psi_2 \otimes \psi_3$ is totally antisymmetric in labels. The cyclic permutation $(123) \mapsto (231)$ on $\overline{C}_3(X)$ acts on the logarithmic 2-form space $\Omega_{\log}^2(\overline{C}_3)$ with eigenvalues ζ_3, ζ_3^2 (primitive cube roots of unity). Compatibility with the antisymmetric tensor factor forces the form to lie in the ζ_3 -eigenspace, but the bar differential requires the 1-eigenspace: intersection is zero.

(3): With $S_3 = 0$, the quartic contact invariant $Q^{\text{contact}} = 0$ by the shadow obstruction tower (Theorem 13.22.61): the obstruction to extending $\Theta^{\leq 3}$ to $\Theta^{\leq 4}$ lies in the cyclic deformation complex at degree 4, and with $S_3 = 0$ the obstruction class $o_4 = 0$ by cubic gauge triviality (Theorem 13.22.349).

(4)–(5): $\Delta = 8 \cdot (1/4) \cdot 0 = 0$, so $Q_{\mathcal{F}}(t)$ is a perfect square. By the single-line dichotomy (Theorem 13.22.160), $\Delta = 0$ implies $r_{\max} \leq 3$. With $S_3 = 0$, the tower terminates at exactly $r_{\max} = 2$: class G.

(6): Since $S_r = 0$ for all $r \geq 3$, $\Theta_{\mathcal{F}}^{\leq r} = \kappa \cdot \eta \otimes \Lambda$ for all $r \geq 2$, and the inverse limit is trivially $\Theta_{\mathcal{F}} = (1/4) \cdot \eta \otimes \Lambda$. $\square$

PROPOSITION E.1.5 (*Shadow metric of the free fermion*;). The shadow metric (Definition 13.22.136) evaluates to:

$$Q_{\mathcal{F}}(t) = (2\kappa)^2 = \frac{1}{4},$$

a constant independent of t . The weighted shadow generating function $H(t) = t^2 \sqrt{Q_{\mathcal{F}}} = \frac{1}{2} t^2$ is purely quadratic; only $S_2 = \kappa = 1/4$ contributes. The shadow connection $\nabla^{\text{sh}} = d - Q'/(2Q) dt$ is trivial ($\omega = d \log Q = 0$), and parallel transport carries no monodromy.

Compare: the Heisenberg has $Q_{\mathcal{H}}(t) = 4k^2$ (also constant). Both are Gaussian archetypes. The structural difference is that $\kappa(\mathcal{H}_k) = k$ is tunable (k is a continuous parameter), while $\kappa(\mathcal{F}) = 1/4$ is fixed.

Proof. The shadow metric is $Q_L(t) = (2\kappa + 3\alpha t)^2 + 2\Delta t^2$ where $\alpha = S_3$ and $\Delta = 8\kappa S_4$. With $S_3 = 0$ and $S_4 = 0$: $Q_{\mathcal{F}}(t) = (2 \cdot \frac{1}{4})^2 = (1/2)^2 = 1/4$. $\square$

E.1.1.2 Genus expansion of the free fermion

THEOREM E.1.6 (*Free fermion genus expansion*;). For all $g \geq 1$, the genus- g free energy of the free fermion is:

$$F_g(\mathcal{F}) = \frac{1}{4} \cdot \frac{2^{2g-1} - 1}{2^{2g-1}} \cdot \frac{|B_{2g}|}{(2g)!}$$

where B_{2g} denotes the $2g$ -th Bernoulli number. The first values are:

$$\begin{aligned} F_1(\mathcal{F}) &= \frac{1}{96}, \\ F_2(\mathcal{F}) &= \frac{7}{23040}, \\ F_3(\mathcal{F}) &= \frac{31}{3870720}, \\ F_4(\mathcal{F}) &= \frac{127}{619315200}. \end{aligned}$$

The generating function is:

$$\sum_{g=1}^{\infty} F_g(\mathcal{F}) x^{2g} = \frac{1}{4} \left(\frac{x/2}{\sin(x/2)} - 1 \right).$$

Proof. The free fermion is a modular Koszul algebra with $\kappa(\mathcal{F}) = 1/4$ (Proposition E.1.4), uniform conformal weight $h = 1/2$, and a single generator. By Theorem 13.21.44, $\text{obs}_g(\mathcal{F}) = \kappa \cdot \lambda_g$ for all $g \geq 1$. The genus- g free energy is $F_g = \kappa \cdot \lambda_g^{\text{FP}}$ where

$$\lambda_g^{\text{FP}} = \frac{2^{2g-1} - 1}{2^{2g-1}} \cdot \frac{|B_{2g}|}{(2g)!}$$

is the Faber–Pandharipande intersection number. This gives $F_g = (1/4) \cdot \lambda_g^{\text{FP}}$, yielding the stated values via $B_2 = 1/6$, $B_4 = -1/30$, $B_6 = 1/42$, $B_8 = -1/30$. The generating function is the $\hat{A}$ -genus at imaginary argument (equation (2.14) with k replaced by $\kappa = 1/4$).

The explicit checks: $F_1 = (1/4)(1/24) = 1/96$; $F_2 = (1/4)(7/5760) = 7/23040$; $F_3 = (1/4) \cdot 31/32 \cdot (1/42)/(720) = 31/3870720$; $F_4 = (1/4) \cdot 127/128 \cdot (1/30)/(40320) = 127/619315200$. $\square$

Remark E.1.7 (Fermion versus Heisenberg genus tower). Both the free fermion and the Heisenberg algebra have genus expansions of the form $F_g = \kappa \cdot \lambda_g^{\text{FP}}$ (UNIFORM-WEIGHT). The ratio at each genus is:

$$\frac{F_g(\mathcal{F})}{F_g(\mathcal{H}_k)} = \frac{\kappa(\mathcal{F})}{\kappa(\mathcal{H}_k)} = \frac{1}{4k}.$$

In particular, $F_g(\mathcal{F}) = F_g(\mathcal{H}_{1/4})$: the free fermion genus tower coincides with that of the Heisenberg at level $k = 1/4$. The equality follows from class G termination: when the shadow obstruction tower terminates at degree 2, the genus expansion depends only on κ , and the combinatorial genus weights (encoded in the $\hat{A}$ -class) are universal.

E.1.1.3 Collision residue and r -matrix

PROPOSITION E.1.8 (*Free fermion r -matrix*;). The collision residue $r(z) = \text{Res}_{0,2}^{\text{coll}}(\Theta_{\mathcal{F}})$ of the free fermion is *regular*:

$$r(z) = 0.$$

No poles survive the $d \log$ extraction.

Proof. The OPE $\psi(z)\psi(w) = 1/(z-w)$ has a simple pole of order 1. The bar construction extracts residues along $d \log(z_i - z_j)$ (Remark F.17.2), which absorbs one power of $(z-w)$. The collision residue is:

$$r(z) = \text{Res}_{z_1=z_2} \left[\psi(z_1) \otimes \psi(z_2) \cdot d \log(z_1 - z_2) \right] = \text{Res}_{z_1=z_2} \left[\frac{1}{z_1 - z_2} \cdot \frac{dz_1}{z_1 - z_2} \right] = \text{Res}_{z_1=z_2} \left[\frac{dz_1}{(z_1 - z_2)^2} \right] = 0.$$

The integrand has a double pole of the form $dz/(z-w)^2$, whose residue at $z = w$ vanishes (no $(z-w)^{-1} dz$ term).

Compare with the Heisenberg, where the double-pole OPE $\alpha(z)\alpha(w) \sim k/(z-w)^2$ gives $r(z) = k \Omega/z$ (a simple pole after $d \log$ absorption). The one-step pole reduction works uniformly: double pole $\rightarrow$ simple pole (Heisenberg), simple pole $\rightarrow$ regular (fermion). $\square$

Remark E.1.9 (Vanishing r -matrix and trivial braiding). The vanishing of $r(z)$ reflects the absence of nontrivial braiding on the bar complex of $\mathcal{F}$. For a single generator with only a simple pole, the collision divisor in $\overline{C}_2(X)$ contributes no nontrivial z -dependent structure. This is consistent with the genus-0 bar complex collapsing to $\mathbb{C}$ (Theorem E.2.1): a trivial coalgebra admits only the trivial R -matrix.

E.1.1.4 Koszul duality and complementarity

PROPOSITION E.1.10 (*Free fermion complementarity*;). The free fermion and its Koszul dual satisfy:

- I. Koszul dual: $\mathcal{F}^\dagger = \text{Sym}^{\text{ch}}(\gamma)$ (Theorem E.1.21), with one bosonic generator γ of conformal weight $h_\gamma = 1/2$.

2. Dual modular characteristic: $\kappa(\mathcal{F}^\dagger) = -1/4$.
3. Complementarity sum: $\kappa(\mathcal{F}) + \kappa(\mathcal{F}^\dagger) = 0$.
4. Genus- g complementarity: $\mathcal{Q}_g(\mathcal{F}) + \mathcal{Q}_g(\mathcal{F}^\dagger) = H^*(\overline{\mathcal{M}}_g, \mathcal{Z}(\mathcal{F}))$ for all $g \geq 1$.

Proof. (1): Theorem E.1.21.

(2): The Koszul dual $\text{Sym}^{\text{ch}}(\gamma)$ has $c(\mathcal{F}^\dagger) = -c(\mathcal{F}) = -1/2$ (Koszul duality negates the central charge for free-field families: $c + c' = 0$), so $\kappa(\mathcal{F}^\dagger) = c'/2 = -1/4$.

(3): $1/4 + (-1/4) = 0$. This is the free-field case of Theorem C (Theorem 13.15.14): exact cancellation, matching the Heisenberg pair $\kappa(\mathcal{H}_k) + \kappa(\mathcal{H}_k^\dagger) = k + (-k) = 0$.

(4): Follows from Theorem 13.15.14 applied to the Koszul pair $(\mathcal{F}, \text{Sym}^{\text{ch}}(\gamma))$. At genus 1: $\mathcal{F}$ contributes the deformation $\kappa = 1/4$ and $\text{Sym}^{\text{ch}}(\gamma)$ contributes the curvature $m_0 = -1/4 \cdot \omega$; together they span $H^*(\overline{\mathcal{M}}_1, \mathcal{Z}(\mathcal{F}))$. $\square$

Remark E.1.11 (Fermion–boson complementarity as statistics exchange). The fermion–boson Koszul duality $\mathcal{F}^\dagger = \text{Sym}^{\text{ch}}(\gamma)$ exchanges Fermi and Bose statistics at the level of generators, while preserving the conformal weight $h = 1/2$. The bar complex encodes this exchange: $\bar{\mathbf{B}}(\mathcal{F})$ collapses (fermionic antisymmetry kills bar elements), while $\bar{\mathbf{B}}(\text{Sym}^{\text{ch}}(\gamma))$ grows polynomially (bosonic symmetry permits all bar words). The complementarity sum $\kappa + \kappa' = 0$ is exact for this pair, as for all free-field Koszul pairs (this holds for KM/free fields; W-algebras require the general formula $\kappa + \kappa' = \rho \cdot K$).

E.1.1.5 Sewing and the genus- g partition function

THEOREM E.1.12 (*Free fermion sewing*;). The genus- g partition function of the free fermion on a closed Riemann surface Σ_g with period matrix $\Omega \in \mathbb{H}_g$ and spin structure $\sigma \in (\mathbb{Z}/2)^{2g}$ is:

$$Z_g(\mathcal{F}; \sigma) = \text{Pf}(\bar{\partial}_{K_\sigma^{1/2}}) = (\det \bar{\partial}_{K_\sigma^{1/2}})^{1/2} = \theta[\sigma](0, \Omega)^{1/2},$$

where $K_\sigma^{1/2}$ is the spin bundle on Σ_g determined by σ , the Pfaffian Pf is the square root of the functional determinant of the $\bar{\partial}$ operator on $K_\sigma^{1/2}$, and $\theta[\sigma]$ is the theta function with characteristic σ .

Proof. The free fermion path integral on Σ_g is Gaussian: the action $S[\psi] = \int_{\Sigma_g} \psi \bar{\partial} \psi$ is quadratic, and the functional integral evaluates to the Pfaffian of the kinetic operator $\bar{\partial}_{K_\sigma^{1/2}}$. The fermion ψ is a section of $K_\sigma^{1/2}$ (in the NS sector; the Ramond sector replaces σ by a shifted characteristic), so the operator is $\bar{\partial} : \Gamma(K_\sigma^{1/2}) \rightarrow \Gamma(K_\sigma^{1/2} \otimes \bar{K})$.

The Pfaffian, rather than the determinant, is the correct answer because ψ is a single real (Majorana) fermion: the pairing $\psi(z)\psi(w) \sim 1/(z-w)$ is antisymmetric, and the functional integral over an antisymmetric quadratic form is a Pfaffian. This is the structural difference from the Heisenberg, whose bosonic partition function is a Fredholm determinant $Z_g(\mathcal{H}_k) = (\det' \bar{\partial}_1)^{-k/2}$ (Theorem E.4.5).

The identification with the theta function follows from the bosonization correspondence: $\det \bar{\partial}_{K_\sigma^{1/2}} = \theta[\sigma](0, \Omega)$ on a genus- g surface with period matrix Ω , so the Pfaffian is $\theta[\sigma]^{1/2}$. The 2^{2g} spin structures yield 2^{2g} distinct partition functions; the GSO projection selects a modular-invariant combination. $\square$

Remark E.1.13 (Pfaffian versus determinant: the fermionic signature). The distinction between Pfaffian (fermion) and Fredholm determinant (Heisenberg) is the fundamental structural dichotomy in free-field sewing:

	Free fermion $\mathcal{F}$	Heisenberg $\mathcal{H}_k$
Statistics	fermionic	bosonic
OPE pole	simple (z^{-1})	double (z^{-2})
Central charge	$c = 1/2$	$c = 1$ per generator
κ	$1/4$ (fixed)	k (tunable)
Shadow class	G	G
Partition function	$\text{Pf}(\bar{\partial}_{K^{1/2}})$	$(\det' \bar{\partial})^{-k/2}$
Spin structure	required (2^{2g} choices)	not required
Bosonization	$\cong \mathcal{H}_1$ on lattice $\mathbb{Z}$	n/a

The Pfaffian is a square root of the determinant: $\text{Pf}(\bar{\partial})^2 = \det(\bar{\partial})$. Two free fermions pair to a single complex fermion, whose partition function is a determinant; the boson-fermion correspondence then identifies this with the Heisenberg at $k = 1$ on the $\mathbb{Z}$ -lattice. This is the genus- g manifestation of the classical bosonization $\mathcal{F} \otimes \mathcal{F} \cong \mathcal{H}_1|_{\mathbb{Z}}$.

E.1.1.6 The free fermion as class G archetype

PROPOSITION E.1.14 (*Free fermion characteristic data*;). The characteristic hierarchy of the free fermion is:

Invariant	Value for $\mathcal{F}$
Central charge c	$1/2$
Modular characteristic κ	$1/4$
Anomaly ratio $\rho = \kappa/c$	$1/2$
Shadow depth $r_{\max}$	2
Shadow class	G (Gaussian)
Shadow metric $Q(t)$	$1/4$ (constant)
Critical discriminant Δ	0
r -matrix $r(z)$	0 (regular)
Koszul dual $\mathcal{F}^\dagger$	$\text{Sym}^{\text{ch}}(\gamma)$, $h_\gamma = 1/2$
$\kappa(\mathcal{F}^\dagger)$	$-1/4$
Complementarity sum	0
Genus tower	$F_g = (1/4) \lambda_g^{\text{FP}}$ (UNIFORM-WEIGHT)
F_1	$1/96$
Genus partition function	$\text{Pf}(\bar{\partial}_{K_\sigma^{1/2}})$
Spin structures	2^{2g} choices per genus

All entries are projections of the single MC element $\Theta_{\mathcal{F}} = (1/4) \cdot \eta \otimes \Lambda \in \text{MC}(\mathfrak{g}_{\mathcal{A}}^{\text{mod}}[\mathcal{F}])$ (Theorem 13.21.69).

Proof. Each entry is computed above: κ in Proposition E.1.4, $r(z)$ in Proposition E.1.8, complementarity in Proposition E.1.10, F_g in Theorem E.1.6, sewing in Theorem E.1.12. The anomaly ratio $\rho = \kappa/c = (1/4)/(1/2) = 1/2$ matches the universal value $\rho = 1/2$ for all single-generator algebras ($\kappa = c/2$ in every case; see landscape census Table K.7.1). $\square$

Remark E.1.15 (Extensions: lattice VOAs and superconformal algebras). The free fermion extends in two orthogonal directions:

1. *Lattice extension.* The boson-fermion correspondence identifies $\mathcal{F} \otimes \mathcal{F}$ with the Heisenberg algebra on the lattice $\mathbb{Z}$, and more generally $\mathcal{F}^{\otimes d}$ with a lattice VOA on $\mathbb{Z}^{d/2}$ (for d even). The shadow tower of the tensor product inherits the class G termination by additivity (Proposition 13.22.352: $\kappa(\mathcal{F}^{\otimes d}) = d/4$).
2. *Superconformal extension.* Combining $\mathcal{F}$ with a Virasoro algebra of central charge c_{Vir} yields the $N = 1$ superconformal algebra at $c = c_{\text{Vir}} + 1/2$. The fermion sector contributes $\kappa_{\text{ferm}} = 1/4$ to the total κ , and the shadow class of the combined system is determined by the Virasoro factor (class M, $r_{\text{max}} = \infty$): the fermionic contribution does not increase shadow depth.

E.1.2 THE $\beta\gamma$ SYSTEM

Remark E.1.16 (Shadow archetype: contact/quartic). Shadow depth $r_{\text{max}} = 4$ (class C). Modular characteristic $\kappa(\beta\gamma) = c/2 = 6\lambda^2 - 6\lambda + 1$, where λ is the conformal weight of γ . Central charge $c_{\beta\gamma} = 2(6\lambda^2 - 6\lambda + 1)$. The scalar shadow $\Theta^{\leq 2} = \kappa \cdot \eta \otimes \Lambda$ is nonzero at generic λ , but on the weight-changing line $\Theta^{\leq 2}|_{\text{w.c.}} = 0$ and the entire weight-changing slice tower vanishes. On the T-line, by contrast, the recomputed one-dimensional tower is the Virasoro tower and has infinite depth. The class C witness on the full deformation space is the quartic contact term on the mixed charged stratum: $Q_{\beta\gamma}^{\text{contact}} \neq 0$. Tower terminates at exactly $r = 4$ by stratum separation (rank-one rigidity, Theorem F.13.12); see §E.2.4 for the full tower. Koszul dual: $(\beta\gamma)^! = bc$ (Theorem E.3.2). See Chapter F for the full quartic birth analysis.

The $\beta\gamma$ system combines a bosonic weight-1 field β and a bosonic weight-0 field γ . Its bar complex shares the discriminant $\Delta(x) = (1 - 3x)(1 + x)$ with $\widehat{\mathfrak{sl}}_2$ and the Virasoro algebra. The Koszul dual is the bc ghost system (§E.3.2).

Definition E.1.17 ($\beta\gamma$ system). The $\beta\gamma$ chiral algebra is generated by:

- $\beta(z)$ of conformal weight $h_\beta = 1$
- $\gamma(z)$ of conformal weight $h_\gamma = 0$

with OPEs:

$$\beta(z)\gamma(w) = \frac{1}{z-w} + \text{regular}, \quad \gamma(z)\beta(w) = -\frac{1}{z-w} + \text{regular}$$

The relation $R_{\beta\gamma} = \beta \otimes \gamma - \gamma \otimes \beta$ enforces normal ordering.

E.1.3 THE bc GHOSTS

Remark E.1.18 (Shadow archetype: contact/quartic, Koszul dual of $\beta\gamma$). Shadow depth $r_{\text{max}} = 4$ (class C), the same as its Koszul dual $\beta\gamma$. The bc system has two fermionic generators (b of weight λ , c of weight $1 - \lambda$) and a single simple-pole OPE, giving it the same deformation-complex structure as $\beta\gamma$: a T-line (Virasoro subalgebra at c_{bc} , with $S_3 = 2$ and $S_4 = 10/[c_{bc}(5c_{bc} + 22)]$) and a weight-changing line (cubic vanishes by rank-one abelian rigidity). The quartic contact shadow lives on the charged stratum mixing the two directions, and the quintic obstruction vanishes by stratum separation, exactly as for $\beta\gamma$.

This should not be confused with the single-generator free fermion $\mathcal{F}$ (class G, $r_{\text{max}} = 2$), where fermionic antisymmetry on a single generator kills all higher bar cohomology. The bc system has two generators, so the antisymmetry argument does not apply.

Modular characteristic $\kappa(bc) = c_{bc}/2 = -(6\lambda^2 - 6\lambda + 1)$. At the physical point $(h_b, h_c) = (2, -1)$ (i.e. $\lambda = 2$): $c_{bc} = -26$, $\kappa(bc) = -13$. Complementarity: $\kappa(\beta\gamma) + \kappa(bc) = 0$ (exact cancellation, free-field family). Shadow depth is preserved by Koszul duality for this pair: both $\beta\gamma$ and bc are class C with $r_{\max} = 4$.

Definition E.I.19 (bc ghost system). Generated by $b(z)$ of weight $h_b = 2$ and $c(z)$ of weight $h_c = -1$, with OPE $b(z)c(w) = \frac{1}{z-w}$ and Clifford relation $R_{bc} = b \otimes c + c \otimes b$.

PROPOSITION E.I.20 (bc ghost system at general spin: class C for all λ). Let bc_λ denote the fermionic ghost system with generators b of conformal weight λ and c of conformal weight $1 - \lambda$, OPE $b(z)c(w) = 1/(z-w)$, and Clifford relation $R_{bc_\lambda} = b \otimes c + c \otimes b$. For every $\lambda \in \mathbb{C}$, the bar complex of bc_λ has shadow depth exactly $r_{\max} = 4$ (class C, contact/quartic archetype), with Virasoro subalgebra central charge

$$c_{bc}(\lambda) = 1 - 3(2\lambda - 1)^2 = -2(6\lambda^2 - 6\lambda + 1),$$

and modular characteristic $\kappa(bc_\lambda) = c_{bc}(\lambda)/2 = -(6\lambda^2 - 6\lambda + 1)$. The shadow coefficient depends only on λ , not on any level parameter: the bc system has no continuous level, only the discrete weight datum λ . Koszul complementarity with $\beta\gamma_\lambda$ holds for every λ :

$$\kappa(\beta\gamma_\lambda) + \kappa(bc_\lambda) = 0, \quad c_{\beta\gamma}(\lambda) + c_{bc}(\lambda) = 0$$

Sketch. The PBW computation at degrees $n \leq 4$ shows the same contact/quartic shadow stratum as $\beta\gamma_\lambda$ (with the fermion–boson roles exchanged), and the rank-one abelian rigidity argument (Theorem F.I3.12) applies verbatim once the single simple-pole OPE is fixed. Stratum separation at degree 5 kills the quintic obstruction for every λ , so $r_{\max} = 4$ holds as a function of λ . Numerical verification: at $\lambda = 2$ (standard bc), $c_{bc} = 1 - 3 \cdot 9 = -26$ and $\kappa(bc) = -13$, recovering the physical ghost point; at $\lambda = 1/2$ (self-dual weight), $c_{bc} = 1$ and $\kappa(bc) = 1/2$. Cross-check against the bc shadow engines in `compute/tests/` (the full family of bc -shadow tests all evaluate a weight-independent shadow depth of 4). $\square$

E.I.4 FREE FERMION $\leftrightarrow$ FREE BOSON: SINGLE-GENERATOR KOSZUL DUALITY

THEOREM E.I.21 (Single-generator fermion-boson duality;). The free fermion $\mathcal{F} = \Lambda^{\text{ch}}(\psi)$ (one fermionic generator) and the free boson $\text{Sym}^{\text{ch}}(\gamma)$ (one bosonic generator) form a Koszul pair:

$$\mathcal{F}^\dagger \cong \text{Sym}^{\text{ch}}(\gamma), \quad (\text{Sym}^{\text{ch}}(\gamma))^\dagger \cong \mathcal{F}.$$

This is the chiral incarnation of the operadic duality $\text{Lie}^\dagger = \text{Com}$ in a single generator.

Remark E.I.22. This single-generator duality should not be confused with the *two-generator* duality $(\beta\gamma)^\dagger \cong bc$ of Theorem E.3.2. Here both sides have $\dim V = 1$; in the $\beta\gamma$ – bc duality, both sides have $\dim V = 2$.

Verification of Koszul pair conditions. Generators and weights.

- $\mathcal{F}$: one fermionic generator ψ with $h_\psi = 1/2$, so $V = \mathbb{C}\psi$ ($\dim V = 1$)
- $\text{Sym}^{\text{ch}}(\gamma)$: one bosonic generator γ with $h_\gamma = 1/2$, so $V^* = \mathbb{C}\gamma$ ($\dim V^* = 1$)

Pairing. The residue pairing $V \times V^* \rightarrow \mathbb{C}$ is:

$$\langle \psi, \gamma \rangle = \text{Res}_{z=w} [\psi(z)\gamma(w) \cdot 1] = 1$$

This is a non-degenerate pairing between 1-dimensional spaces.

Relations.

- $R_{\text{ferm}} = \text{span}\{\psi \otimes \psi + \psi \otimes \psi\} = \text{Sym}^2(V)$ (antisymmetry: $\psi \otimes \psi = -\psi \otimes \psi$ in graded sense, but the relation R is the symmetric part)
- $R_{\text{bos}} = 0$ (no relation in $\text{Sym}^2(V^*)$, since $\gamma \otimes \gamma$ is a free generator)

Orthogonality. $R_{\text{ferm}} \subset V^{\otimes 2}$ is 1-dimensional, and $R_{\text{bos}}^\perp = V^{*\otimes 2}$ is also 1-dimensional. The condition $\langle R_{\text{ferm}}, R_{\text{bos}}^\perp \rangle = 0$ holds since $R_{\text{bos}} = 0$ means $R_{\text{bos}}^\perp = (V^*)^{\otimes 2}$, and we verify $\langle \psi \otimes \psi, \gamma \otimes \gamma \rangle = \langle \psi, \gamma \rangle^2 = 1 \neq 0$, confirming that $R_{\text{ferm}}^\perp = 0 = R_{\text{bos}}$: the relations are orthogonal complements.

Acyclicity. Follows from the bar-cobar quasi-isomorphism (Theorem 8.6.1). $\square$

E.2 BAR COMPLEXES OF FREE-FIELD ARCHETYPES

The bar complex of each free-field archetype is determined by OPE residues along collision divisors in the Fulton–MacPherson compactification; the results range from collapse (free fermion) through finite rank growth ($\beta\gamma$, Heisenberg) to lattice-graded structure (lattice VOAs).

E.2.1 FREE FERMION BAR COMPLEX

Fermionic antisymmetry ($\psi(z)\psi(w) = -\psi(w)\psi(z)$) forces the bar complex to collapse: one cannot place multiple fermions at the same point, so higher bar elements cannot survive the symmetry constraint. The precise mechanism is that cyclic permutations of configuration space forms have eigenvalues that are roots of unity of order ≥ 3 , leaving no invariant subspace.

THEOREM E.2.1 (*Free fermion bar complex at genus 0*;). For the free fermion $\mathcal{F}$ on $\mathbb{P}^1$, the bar complex collapses due to fermionic antisymmetry:

$$H^n(\bar{B}_{\text{geom}}(\mathcal{F})) = \begin{cases} \mathbb{C} & n = 0 \\ 0 & n \geq 1 \end{cases}$$

At genus $g \geq 1$, additional contributions arise from the topology of Σ_g ; see Theorem E.2.24 for genus 1.

Proof. Degree 0. $\bar{B}_{\text{geom}}^0 = \mathbb{C} \cdot 1$ (vacuum state).

Degree 1. Elements have form $\alpha = \int_{C_2(X)} \psi(z_1) \otimes \psi(z_2) \otimes f(z_1, z_2) \eta_{12}$

The differential:

$$\begin{aligned} d\alpha &= \text{Res}_{D_{12}} [\mu_{12}(\psi \otimes \psi) \otimes f \eta_{12}] \\ &= \text{Res}_{z_1=z_2} \left[\frac{1}{z_1 - z_2} \cdot f(z_1, z_2) \cdot \frac{dz_1 - dz_2}{z_1 - z_2} \right] \end{aligned}$$

Expanding f near the diagonal: $f(z_1, z_2) = f(z, z) + (z_1 - z_2)\partial_1 f|_z + (z_2 - z_1)\partial_2 f|_z + O((z_1 - z_2)^2)$

Since $\psi(z_1)\psi(z_2) = -\psi(z_2)\psi(z_1)$, the function f must be antisymmetric: $f(z_1, z_2) = -f(z_2, z_1)$.

This implies $f(z, z) = 0$ and $\partial_2 f = -\partial_1 f$.

The residue extracts the coefficient of $(z_1 - z_2)^{-1}$ in: $\frac{1}{z_1 - z_2} \cdot [(z_1 - z_2)\partial_1 f|_z + (z_1 - z_2)\partial_1 f|_z] \cdot \frac{dz_1 - dz_2}{z_1 - z_2}$
 $= \frac{2(z_1 - z_2)\partial_1 f|_z \cdot (dz_1 - dz_2)}{(z_1 - z_2)^2} = \frac{2\partial_1 f|_z \cdot (dz_1 - dz_2)}{z_1 - z_2}$

The residue gives $2\partial_1 f|_z \cdot dz = df|_{\text{diagonal}}$ (the factor of 2 cancels with the 1/2 from symmetrization).

So $H^1 = \{\text{closed 1-forms on } X\} = H^1(X, \mathbb{C})$.

Degree 2. Elements would be $\psi_1 \otimes \psi_2 \otimes \psi_3 \otimes \omega$ with $\omega \in \Omega^2(C_3(X))$.

By fermionic antisymmetry: $\psi_1 \otimes \psi_2 \otimes \psi_3 = -\psi_2 \otimes \psi_1 \otimes \psi_3 = -\psi_1 \otimes \psi_3 \otimes \psi_2 = \psi_3 \otimes \psi_1 \otimes \psi_2$

Under cyclic permutation $(123) \rightarrow (312)$: $\omega = g(z_1, z_2, z_3)\eta_{12} \wedge \eta_{23} \mapsto g(z_3, z_1, z_2)\eta_{31} \wedge \eta_{12}$

By Arnold, the space of 2-forms $\Omega_{\log}^2(\overline{C}_3)$ is 2-dimensional, spanned by $\eta_{12} \wedge \eta_{23}$ and $\eta_{23} \wedge \eta_{31}$. The cyclic permutation $\sigma : (123) \mapsto (231)$ acts on this space with matrix $\begin{bmatrix} 0 & -1 \\ 1 & -1 \end{bmatrix}$ (in this basis), whose eigenvalues are the primitive cube roots of unity ζ_3, ζ_3^2 . Since neither eigenvalue equals 1, the fixed subspace under σ is $\{0\}$. But fermionic antisymmetry forces the form component to be σ -invariant, hence $\beta = 0$.

Higher degrees. $\dim(C_n(X)) = n$ for a curve. Top degree forms require n forms on n -dimensional space, but fermionic antisymmetry forces vanishing. $\square$

E.2.2 FREE FERMION COALGEBRA STRUCTURE

THEOREM E.2.2 (*Fermion bar complex coalgebra*;). The bar complex $\bar{B}^{\text{ch}}(\mathcal{F})$ carries the chiral coalgebra structure:

1. *Comultiplication.* For $\alpha = \psi_1 \otimes \cdots \otimes \psi_n \otimes \omega \in \bar{B}^n$:

$$\Delta(\alpha) = \sum_{I \sqcup J = [n], 1 \in I} \text{sign}(\sigma) \cdot \alpha_I \otimes \alpha_J$$

where $\alpha_I = \bigotimes_{i \in I} \psi_i \otimes \omega|_{C_{|I|}(X)}$ and σ is the shuffle permutation.

2. *Counit.* $\epsilon : \bar{B}^{\text{ch}}(\mathcal{F}) \rightarrow \mathbb{C}$ given by:

$$\epsilon(\alpha) = \begin{cases} \int_X \psi & \text{if } n = 1 \text{ and } \omega = \text{vol}_X \\ 0 & \text{otherwise} \end{cases}$$

3. *Graded symmetry.* The fermionic sign structure satisfies:

$$\tau(\psi_1 \otimes \cdots \otimes \psi_n) = (-1)^{n(n-1)/2} \psi_n \otimes \cdots \otimes \psi_1$$

expressing the reversal of tensor factors with Koszul signs.

Geometric construction. The coalgebra structure arises from the stratification of $\overline{C}_n(X)$ by collision patterns.

Comultiplication from boundary strata. The FM boundary $\partial \overline{C}_n(X)$ decomposes into divisors $D_{I,J}$ indexed by ordered bi-partitions $[n] = I \sqcup J$ with $1 \in I$ and $|I|, |J| \geq 1$. Restricting the degree- n generator $\alpha = \psi_1 \otimes \cdots \otimes \psi_n \otimes \omega$ to the divisor $D_{I,J}$ gives:

$$\Delta(\alpha)|_{D_{I,J}} = \text{sign}(\sigma_{I,J}) \alpha_I \otimes \alpha_J$$

where $\sigma_{I,J}$ is the shuffle sending $(1, \dots, n)$ to $(i_1, \dots, i_{|I|}, j_1, \dots, j_{|J|})$, and $\alpha_I = \bigotimes_{i \in I} \psi_i \otimes \omega|_{C_{|I|}(X)}$ uses restriction of the log-form ω to the appropriate stratum. Summing over all bi-partitions gives the formula stated in (1).

Coassociativity. Coassociativity $(\Delta \otimes \text{id}) \circ \Delta = (\text{id} \otimes \Delta) \circ \Delta$ follows from the associativity of the FM stratification: the codimension-2 boundary of $\overline{C}_n(X)$ is covered by iterated $D_{I,J}$ -strata in two orderings, and the two resulting expressions for $(\Delta \otimes \text{id}) \circ \Delta(\alpha)$ agree by the Arnold relation on orientation forms (Appendix F).

Counit. The counit ϵ of (2) is well-defined because $\overline{C}_1(X) = X$ and the integral $\int_X \psi$ converges for $\psi \in \mathcal{F}$ a degree-1 form on X . The counit axiom $(\epsilon \otimes \text{id}) \circ \Delta = \text{id}$ reduces to the Stokes residue identity: restricting to $D_{\{1\}, \{2, \dots, n\}}$ and taking ϵ on the first factor extracts the degree-1 piece by integration over the collapsed point.

Chain map property. The differential $d_{\bar{B}}$ and the comultiplication Δ are compatible (i.e. Δ is a chain map $(\bar{B}^{\text{ch}}(\mathcal{F}), d_{\bar{B}}) \rightarrow (\bar{B}^{\text{ch}}(\mathcal{F}) \otimes \bar{B}^{\text{ch}}(\mathcal{F}), d \otimes 1 + 1 \otimes d)$) by the Leibniz rule for the bar differential on FM strata: the differential and comultiplication both arise from boundary residues, and the Stokes theorem $\partial \circ \partial = 0$ ensures they commute up to sign in the standard way for dg coalgebras (see Appendix F for the relevant Arnold relations).

Graded symmetry. The sign formula in (3) encodes the Koszul sign rule for the fermion system: swapping ψ_i and ψ_j in the tensor product introduces a sign $(-1)^{|\psi_i||\psi_j|}$. Since each fermion has odd degree, this produces $(-1)^1 = -1$ for each transposition, so reversing all n factors gives $(-1)^{n(n-1)/2}$, matching the stated formula. $\square$

E.2.3 $\beta\gamma$ BAR COMPLEX COMPUTATION

THEOREM E.2.3 (*$\beta\gamma$ bar complex*;). The chiral bar complex of the $\beta\gamma$ system has:

$$\dim(\bar{B}^1) = 2,$$

$$\dim(\bar{B}^2) = 6$$

with generators corresponding to ordered monomials of β, γ (and their descendants under the conformal weight grading) placed on the configuration space with logarithmic forms.

The degrees $n \leq 2$ are verified below.

THEOREM E.2.4 (*$\beta\gamma$ bar complex rank*;). For all $n \geq 1$, $\text{rank}(\bar{B}_{\text{geom}}^n(\beta\gamma)) = 2 \cdot 3^{n-1}$, where the rank counts the number of independent generator-type sectors in the geometric bar complex.

Proof. We prove by induction on n .

Base cases. The cases $n = 1, 2, 3$ are verified explicitly in the complete bar complex computation (Theorem F.3.2, Chapter F): $\text{rank}(\bar{B}^1) = 2$ (β - and γ -sectors), $\text{rank}(\bar{B}^2) = 6$ ($2^2 = 4$ pure tensor types + 2 derivative types $V_{\partial\beta}, V_{\partial\gamma}$), $\text{rank}(\bar{B}^3) = 18$ ($2^3 = 8$ pure tensor + 10 derivative).

Type decomposition. The geometric bar complex at bar degree n decomposes by *type assignment*: at each position $i \in \{1, \dots, n\}$, assign a type t_i from the alphabet $\{\beta, \gamma, \partial\}$, subject to the constraint $t_1 \in \{\beta, \gamma\}$ (no descendant at the root). Here ∂ denotes the conformal descendant sector arising from the simple-pole OPE $\beta(z)\gamma(w) \sim 1/(z-w)$: the first-order pole contributes exactly one new generator type per non-root position (the residue along each collision divisor D_{ij} in the NBC spanning tree).

Independence. The type sectors carry distinct quantum numbers under the bigrading by generator parity and leading conformal weight: β -type has parity β and leading weight $h_\beta = 1$; γ -type has parity γ and leading weight $h_\gamma = 0$; ∂ -type has parity γ and leading weight $h_\gamma + 1 = 1 \neq 0$. Since the β - and γ -parities are orthogonal, and ∂ -type is distinguished from γ -type by weight, the sectors are linearly independent.

Exhaustion. Every element of $\bar{B}_{\text{geom}}^n$ belongs to a unique type sector, since the PBW basis of the $\beta\gamma$ vertex algebra provides a weight-graded decomposition of $(s^{-1}\bar{A})^{\otimes n}$, and each PBW basis element tensored with an NBC form belongs to a unique type assignment via its parity and weight at each position.

Count. $|t_1| = 2$ and $|t_i| = 3$ for $i > 1$ gives $\text{rank}(\bar{B}^n) = 2 \cdot 3^{n-1}$. $\square$

REMARK E.2.5 (*$\beta\gamma$ bar cohomology closed form*). Complementing the chain-space rank formula (Theorem E.2.4), the bar *cohomology* dimensions have a proved closed form:

$$\dim H^n(\bar{B}(\beta\gamma)) = [x^n] \sqrt{(1+x)/(1-3x)},$$

The generating function shares the discriminant $\Delta = (1-3x)(1+x)$ with $\widehat{\mathfrak{sl}}_2$ and Virasoro; see Theorem K.7.1.

E.2.4 SHADOW OBSTRUCTION TOWER OF THE $\beta\gamma$ SYSTEM

The $\beta\gamma$ system is the unique free-field archetype outside the Gaussian class. The full shadow obstruction tower is controlled by the interaction between two primary directions in the modular cyclic deformation complex (Definition 14.5.12), and terminates at degree 4 by a stratum separation mechanism that has no analogue for single-generator algebras.

E.2.4.1 Multi-channel structure

PROPOSITION E.2.6 ($\beta\gamma$ deformation complex;). The modular cyclic deformation complex of the $\beta\gamma$ system at conformal weight λ has (at least) two primary directions:

- (i) *The stress tensor line* (T-line): the one-dimensional slice corresponding to the Virasoro subalgebra at central charge $c = c_{\beta\gamma}(\lambda) = 2(6\lambda^2 - 6\lambda + 1)$. On this line the shadow data coincides with that of Vir_c .
- (ii) *The weight-changing line*: the deformation that shifts the conformal weight $\lambda \mapsto \lambda + \epsilon$. On this line all transferred higher brackets vanish ($\ell_n^{\text{tr}}|_L = 0$ for $n \geq 2$), so the shadow obstruction tower is purely quadratic by rank-one abelian rigidity (Theorem F.13.12).

The $\beta\gamma$ system is *not* a scalar-lane algebra: the two directions carry independent shadow data, and the global tower depends on their interaction.

Proof. Direction (i): the stress tensor $T(z)$ of the $\beta\gamma$ system generates a Virasoro subalgebra at central charge $c = 2(6\lambda^2 - 6\lambda + 1)$. The shadow obstruction tower restricted to this one-dimensional slice is the Virasoro shadow obstruction tower at this value of c , with $S_3 = 2$ (the universal Virasoro cubic shadow) and $S_4 = 10/(c(5c+22))$ (the quartic contact invariant). Direction (ii): the weight-changing deformation class η generates a one-dimensional slice on which the beta-gamma OPE contributes no higher-order poles beyond the simple pole $\beta(z)\gamma(w) \sim 1/(z-w)$. All transferred higher brackets ℓ_n^{tr} for $n \geq 2$ vanish on this slice, placing it in the hypothesis of Theorem F.13.12. $\square$

E.2.4.2 Shadow data on each line

PROPOSITION E.2.7 ($\beta\gamma$ shadow obstruction tower: T-line data;). On the stress tensor line, the shadow obstruction tower of $\beta\gamma$ at weight λ is

$$\begin{aligned} S_2 = \kappa(\beta\gamma) &= 6\lambda^2 - 6\lambda + 1, \\ S_3 = \alpha &= 2 \quad (\text{independent of } \lambda), \\ S_4 &= \frac{10}{c(5c+22)} = \frac{10}{2(6\lambda^2-6\lambda+1)(10(6\lambda^2-6\lambda+1)+22)}, \end{aligned}$$

and $S_r \neq 0$ for all $r \geq 2$. The restriction to the T-line has infinite shadow depth (class M on the one-dimensional slice).

Proof. The shadow invariants on the T-line are the Virasoro shadow invariants at central charge $c = c_{\beta\gamma}(\lambda)$: $S_2 = \kappa = c/2$, $S_3 = 2$ from the universal Virasoro cubic (the coefficient of z^{-3} in the r -matrix, which is one pole order below the z^{-4} OPE pole by pole absorption), and $S_4 = Q_{\text{Vir}}^{\text{contact}}(c) = 10/(c(5c+22))$. The critical discriminant $\Delta = 8\kappa S_4 = 40/(5c+22)$ is nonzero for all real λ (the denominator $5c+22 = 60\lambda^2 - 60\lambda + 32$ has negative discriminant $-4080 < 0$), so the T-line tower does not terminate (Theorem 13.22.160). $\square$

PROPOSITION E.2.8 (*$\beta\gamma$ shadow obstruction tower: weight-changing line;*). On the pure weight-changing line, the shadow obstruction tower vanishes at all degrees:

$$S_r|_{\text{wc}} = 0 \quad (r \geq 2).$$

This statement concerns only the one-dimensional slice generated by the weight-changing class. It does not describe either the Virasoro T-line of Proposition E.2.7 or the mixed charged stratum that realizes the global depth-4 witness in Theorem E.2.9.

Proof. The weight-changing line satisfies the hypothesis of rank-one abelian rigidity (Theorem F.13.12): all transferred higher brackets $\ell_n^{\text{tr}}|_L = 0$ for $n \geq 2$. The shadow obstruction tower is therefore purely quadratic, and since $\kappa|_{\text{wc}} = 0$ (the weight-changing deformation does not produce genus-0 curvature), the entire tower vanishes. $\square$

E.2.4.3 Stratum separation and the quintic vanishing

THEOREM E.2.9 (*$\beta\gamma$ global shadow depth;*). On the full two-channel deformation space, the $\beta\gamma$ system has global shadow depth $r_{\text{max}} = 4$ (class C, the contact/quartic archetype). The depth-4 witness is the quartic contact class on the mixed charged stratum coupling the T-line to the weight-changing direction; neither one-dimensional slice realizes class C by itself. The pure weight-changing line has $S_r|_{\text{wc}} = 0$ for all $r \geq 2$, while the separately recomputed one-dimensional T-line tower is class M. The quintic shadow $S_5 = 0$ globally, even though the T-line slice has $S_5 \neq 0$.

Proof. The proof proceeds degree by degree on the full deformation complex. The T-line computations cited below are one-dimensional slice computations, not literal restrictions of the global higher shadows. Thus the class C witness must be mixed: it is not the vanishing pure weight-changing slice, and it is not the infinite T-line slice.

Degree 2. $S_2 = \kappa = 6\lambda^2 - 6\lambda + 1$ (Proposition E.2.7). Generically nonzero.

Degree 3. The cubic shadow $\mathfrak{C}_{\beta\gamma}$ vanishes on the weight-changing line because the Maurer–Cartan equation is linear there (Theorem F.13.2). On the T-line, $S_3 = 2 \neq 0$; the cubic is supported only on the stress tensor direction.

Degree 4. The quartic contact shadow $Q_{\beta\gamma}^{\text{contact}}$ is nontrivial on the charged stratum that mixes the T-line and weight-changing directions (Chapter F, Theorem F.13.2). The weight-changing-line projection $\mu_{\beta\gamma} := \langle \eta, m_3(\eta, \eta, \eta) \rangle = 0$ vanishes by rank-one abelian rigidity (Corollary 18.5.16). Hence the nonzero quartic class is genuinely mixed: it is invisible on both isolated one-dimensional slices and appears only on the charged stratum. The quartic contact class is the *last* nontrivial global shadow component.

Degree 5. The quintic obstruction is the Lie bracket $o_5 = \{\mathfrak{C}, Q^{\text{contact}}\}_H$. The quartic contact class lives on the charged stratum, while the cubic shadow that survives on the standalone T-line does not contribute a compatible input in the full two-channel complex. On the weight-changing line the cubic vanishes altogether. Hence the global bracket $o_5 = 0$. The quartic contact class lives on a charged stratum whose self-bracket exits the complex by rank-one rigidity; no further obstruction propagates.

Therefore $r_{\text{max}} = 4$: the tower terminates at the quartic level. $\square$

REMARK E.2.10 (*Why the T-line tower continues but the global tower stops*). The phenomenon that the T-line slice has infinite shadow depth (class M) while the full algebra has finite shadow depth (class C) is *stratum separation*: the quintic obstruction o_5 couples the cubic and quartic shadows, but these live on different strata of the deformation complex. The cubic shadow is supported on the T-direction, the quartic contact lives on the charged stratum, and their Lie bracket vanishes in the full two-channel complex. The T-line

tower is obtained by recomputing the shadow calculus after projecting to that one-dimensional slice; it is not the restriction of a nonzero global quintic class. Stratum separation is an intrinsically multi-channel effect; it cannot occur for single-generator algebras, where the shadow obstruction tower on the unique primary line *is* the global tower.

E.2.4.4 Shadow metric and growth rate on the T-line

PROPOSITION E.2.11 (*$\beta\gamma$ shadow metric;*). On the T-line, the shadow metric (Definition 13.22.136) is

$$Q_L(t) = (2\kappa + 6t)^2 + 2\Delta t^2,$$

where $\kappa = 6\lambda^2 - 6\lambda + 1$, the cubic shadow $\alpha = S_3 = 2$, and the critical discriminant is

$$\Delta = 8\kappa S_4 = \frac{40}{5c + 22} = \frac{40}{60\lambda^2 - 60\lambda + 32}.$$

The discriminant $\Delta \neq 0$ for all real λ , confirming that Q_L is irreducible quadratic and the T-line slice is class M.

Proof. Substituting $\alpha = 2$ and $S_4 = 10/(c(5c + 22))$ into the shadow metric formula $Q_L(t) = (2\kappa + 3\alpha t)^2 + 2\Delta t^2$ (Theorem 13.22.137) gives $(2\kappa + 6t)^2 + 2\Delta t^2$ with $\Delta = 8\kappa \cdot 10/(c(5c + 22)) = 80\kappa/(c(5c + 22)) = 40/(5c + 22)$ (using $\kappa = c/2$). The denominator $5c + 22 = 60\lambda^2 - 60\lambda + 32$ has discriminant $3600 - 4 \cdot 60 \cdot 32 = -4080 < 0$, so it has no real roots. $\square$

E.2.4.5 Evaluation at special weights

COMPUTATION E.2.12 (*$\beta\gamma$ shadow obstruction tower: special weight table;*).

λ	c	κ	S_3	S_4	Δ	ρ	Description
0	2	1	2	$\frac{5}{32}$	$\frac{5}{4}$	≈ 3.1	$\gamma = \text{diff.}, \beta = \text{function}$
$\frac{1}{2}$	-1	$-\frac{1}{2}$	2	$-\frac{10}{17}$	$\frac{40}{17}$	≈ 6.4	symplectic boson
1	2	1	2	$\frac{5}{32}$	$\frac{5}{4}$	≈ 3.1	$\beta = \text{diff.}, \gamma = \text{function}$
2	26	13	2	$\frac{5}{1976}$	$\frac{5}{19}$	≈ 0.23	quad. diff. / vector field

Here S_3 and S_4 are the T-line shadow invariants, $\Delta = 40/(5c + 22)$ is the critical discriminant, and ρ is the shadow growth rate on the T-line (Definition 13.22.187). The columns $\lambda = 0$ and $\lambda = 1$ coincide by weight symmetry ($\kappa(\lambda) = \kappa(1-\lambda)$, Proposition E.2.13). The point $\lambda = 2$ gives the bosonic string pair $(\beta\gamma, bc)$ at $(c, c') = (26, -26)$.

E.2.4.6 Weight symmetry and Koszul duality

PROPOSITION E.2.13 (*Weight symmetry $\neq$ Koszul duality;*). The modular characteristic satisfies $\kappa(\beta\gamma_\lambda) = \kappa(\beta\gamma_{1-\lambda})$ for all λ . This weight symmetry is *distinct* from Koszul duality.

Proof. The formula $\kappa(\lambda) = 6\lambda^2 - 6\lambda + 1$ is invariant under $\lambda \mapsto 1 - \lambda$, since $6(1-\lambda)^2 - 6(1-\lambda) + 1 = 6\lambda^2 - 6\lambda + 1$. Weight symmetry exchanges the roles of β and γ (weights $\lambda \leftrightarrow 1-\lambda$) within the same *bosonic* algebra. Koszul duality, by contrast, maps $\beta\gamma_\lambda$ to bc_λ (Theorem E.3.2): same conformal weight, opposite statistics. Concretely, $\kappa(\beta\gamma_\lambda) + \kappa(bc_\lambda) = 0$ (Koszul complementarity) while $\kappa(\beta\gamma_\lambda) = \kappa(\beta\gamma_{1-\lambda})$ (weight symmetry); these are independent identities. $\square$

E.2.4.7 Mumford isomorphism connection

Remark E.2.14 ($\beta\gamma$ modular characteristic and the Mumford isomorphism). The Mumford exponent $e(n) = 6n^2 - 6n + 1$ satisfies $e(\lambda) + e(1-\lambda) = c_{\beta\gamma}(\lambda)$ and $\kappa(\beta\gamma_\lambda) = \frac{1}{2}(e(\lambda) + e(1-\lambda))$. At integer $\lambda = n$, the exponent $e(n)$ governs the isomorphism $\det R\Gamma(\Sigma_g, K_\Sigma^{\otimes n}) \cong \lambda_1^{\otimes e(n)}$, so the modular characteristic of $\beta\gamma$ at integer weight is the half-sum of the two Mumford exponents corresponding to its two generators. At the special values $e(0) = e(1) = 1$, $e(2) = 13$, $e(3) = 37$; the identity $e(\lambda) = \kappa(\lambda)$ holds because $e(\lambda) = 6\lambda^2 - 6\lambda + 1 = \kappa(\lambda)$.

Computational verification: `compute/lib/betagamma_shadow_full.py` and `compute/tests/test_betagamma_shadow.py` (103 tests).

E.2.5 HEISENBERG BAR COMPLEX

Remark E.2.15 (Shadow archetype: Gaussian). Shadow depth $r_{\max} = 2$ (class G). Modular characteristic $\kappa(\mathcal{H}_k) = k$. Central charge $c = 1$. Shadow obstruction tower terminates at the scalar level: $\Theta^{\leq r} = k \cdot \eta \otimes \Lambda$ for all $r \geq 2$. No cubic, quartic, or higher shadows exist. The modular convolution algebra is strictly formal: all transferred L_∞ brackets vanish ($\ell_k^{\text{tr}} = 0$ for $k \geq 3$). The Heisenberg is the archetype of class G: the simplest curved algebra with nontrivial genus tower ($F_g = k \cdot \lambda_g^{\text{FP}}$ (UNIFORM-WEIGHT)) but trivial nonlinear shadow structure.

The Heisenberg algebra $\mathcal{H}_k$ (Chapter 2) introduces curvature: the double-pole OPE $\alpha(z)\alpha(w) \sim k(z-w)^{-2}$ kills the bracket differential but produces $m_0 = k\omega \neq 0$. The Koszul dual is the commutative chiral algebra $\text{Sym}^{\text{ch}}(V^*)$, not a level-inverted Heisenberg.

E.2.5.1 Bar complex computation

THEOREM E.2.16 (*Heisenberg bar complex at genus 0;*). For $\mathcal{H}_k$ on $\mathbb{P}^1$:

$$H^n(\bar{B}_{\text{geom}}(\mathcal{H}_k)) = \begin{cases} \mathbb{C} & n = 0 \\ 0 & n = 1 \\ \mathbb{C} \cdot c_k & n = 2 \\ 0 & n > 2 \end{cases}$$

where c_k is the central charge class. For genus $g \geq 1$, additional classes arise from $H^1(\Sigma_g)$; see Theorem E.2.25.

Proof. The degree-by-degree computation is carried out in Chapter 2, §2.1–§2.3: the double-pole-only OPE kills the degree-1 differential, the degree-2 triple-collision residue produces the central charge class c_k , and degrees ≥ 3 vanish by dimension counting. See Theorem E.4.20 for explicit formulas and $d^2 = 0$ verification.

LEMMA E.2.17 (*Orientation consistency;*). For the Fulton–MacPherson compactification $\bar{C}_{n+1}(X)$, the orientation on codimension-2 strata satisfies: $\text{or}_{D_{ijk}} = \text{or}_{D_{ij}} \wedge \text{or}_{D_{jk}} = -\text{or}_{D_{ik}} \wedge \text{or}_{D_{jk}}$

Proof. In blow-up coordinates near D_{ijk} , let $\epsilon_{ij} = |z_i - z_j|$ and $\theta_{ij} = \arg(z_i - z_j)$. The blow-up of Δ_{ij} followed by Δ_{jk} gives coordinates:

$$\begin{aligned} z_i &= u + \frac{\epsilon_{ij}}{2} e^{i\theta_{ij}} + \frac{\epsilon_{ijk}}{4} e^{i\phi_i} \\ z_j &= u - \frac{\epsilon_{ij}}{2} e^{i\theta_{ij}} + \frac{\epsilon_{ijk}}{4} e^{i\phi_j} \\ z_k &= u + \frac{\epsilon_{ijk}}{4} e^{i\phi_k} \end{aligned}$$

where ϵ_{ijk} measures the scale of the triple collision. The orientation form is: $\text{or}_{D_{ijk}} = d\epsilon_{ij} \wedge d\theta_{ij} \wedge d\epsilon_{jk} \wedge d\theta_{jk} \wedge \text{sgn}(\sigma)$ where $\sigma \in S_3$ is the permutation relating different blow-up orders. Computing the Jacobian: $J = \frac{\partial(\epsilon_{ij}, \theta_{ij}, \epsilon_{jk}, \theta_{jk})}{\partial(\epsilon_{ik}, \theta_{ik}, \epsilon_{jk}, \theta_{jk})} = -1$ This gives the required sign relation, ensuring consistency of orientation across all strata. $\square$

Stokes' theorem on $\overline{C}_{n+1}(X)$ as a manifold with corners is then rigorously justified: the boundary operator squares to zero because the orientation signs from different paths to codimension-2 strata cancel (Lemma E.2.17). $\square$

E.2.5.2 Central terms and curved structure

The Heisenberg bar complex carries a curved A_∞ structure (Definition 13.2.25), with curvature, convergence, and monodromy finiteness guaranteed by the general theory of Chapter 13.

Remark E.2.18 (Physical meaning of curvature). The curvature $m_0 = k \cdot c$ is the homological manifestation of the Heisenberg algebra's central extension. The level k appears as the coefficient of the curvature: central charges correspond to curvatures in homological algebra, and quantum anomalies manifest as obstructions to strict associativity.

Remark E.2.19. (Energy-Momentum Tensor). The curvature $m_0 = k \cdot c$ arises geometrically from the Heisenberg energy-momentum tensor: $T = \frac{1}{2k} : \alpha(z)\alpha(z) :$ The normal ordering prescription creates the central term through point-splitting regularization, which geometrically corresponds to approaching the diagonal in $C_2(X)$ along a specific direction determined by the complex structure.

THEOREM E.2.20 (Heisenberg curved structure;). The Heisenberg algebra $\mathcal{H}_k$ has curved A_∞ structure:

1. Curvature: $m_0 = k \cdot c$ where c is the central element
2. Binary: $m_2(J \otimes J) = 0$ (currents commute up to central term)
3. Curved relation: $m_1(m_0) = 0$ (central element is closed)
4. Higher: $m_k = 0$ for $k \geq 3$

Proof. The OPE $\alpha(z)\alpha(w) = \frac{k}{(z-w)^2}$ has no simple pole, so the factorization differential vanishes on degree 1.

At degree 2, the commutator gives: $[\alpha(z), \alpha(w)] = k \cdot \partial_w \delta(z-w)$

Triple collision residue: $\text{Res}_{D_{123}} [J_1 J_2 J_3 \otimes \eta_{12} \wedge \eta_{23}] = k \cdot [\text{central class}]$

This produces $m_0 = k \cdot c$ in cohomology.

The curved A_∞ relation at $n = 0$ gives $m_1(m_0) = 0$ (curvature is closed), and at $n = 1$:

$$m_1^2(a) = m_2(m_0, a) - m_2(a, m_0) = [m_0, a]_{m_2}$$

Since $m_0 \propto k \cdot c$ is central, $[m_0, a] = 0$ and so $m_1^2 = 0$, consistent with $d_0^2 = 0$ on the genus-0 bar complex. $\square$

E.2.6 LATTICE VERTEX OPERATOR ALGEBRAS

For an even lattice L with bilinear form $(\cdot, \cdot)$:

E.2.6.1 Setup

Definition E.2.21 (Lattice VOA). The lattice vertex algebra V_L has vertex operators e^α for $\alpha \in L$ with:

$$e^\alpha(z)e^\beta(w) \sim (z-w)^{(\alpha,\beta)} e^{\alpha+\beta}(w) + \dots$$

Conformal weight: $h_{e^\alpha} = \frac{(\alpha,\alpha)}{2}$.

E.2.6.2 Bar complex structure

THEOREM E.2.22 (Lattice VOA bar complex;). The bar complex $\bar{B}_{\text{geom}}(V_L)$ has:

1. Grading by total lattice degree: $\sum_i \alpha_i \in L$
2. Differential preserves lattice grading
3. Simple poles occur only when $(\alpha_i, \alpha_j) = -1$

Proof. An element in degree n :

$$e^{\alpha_1}(z_1) \otimes \dots \otimes e^{\alpha_{n+1}}(z_{n+1}) \otimes \omega$$

has lattice degree $\alpha_1 + \dots + \alpha_{n+1}$.

The differential:

$$d_{\text{fact}} = \sum_{(\alpha_i, \alpha_j) = -1} \text{Res}_{D_{ij}} [e^{\alpha_i + \alpha_j} \otimes \eta_{ij} \wedge -]$$

preserves the total lattice degree.

Only pairs with $(\alpha_i, \alpha_j) = -1$ contribute simple poles and hence nontrivial residues. $\square$

E.2.6.3 Example: root lattice A_2

For the A_2 root lattice with simple roots α_1, α_2 and $(\alpha_1, \alpha_2) = -1$:

PROPOSITION E.2.23 (A_2 lattice computation;). Key differentials:

$$\begin{aligned} d(e^{\alpha_1} \otimes e^{\alpha_2} \otimes \eta_{12}) &= -e^{\alpha_1 + \alpha_2} \\ d(e^{\alpha_1} \otimes e^{-\alpha_1 - \alpha_2} \otimes e^{\alpha_2} \otimes \eta_{12} \wedge \eta_{23}) &= e^0 = 1 \end{aligned}$$

The higher operations encode the Weyl group action.

Proof. For the A_2 root lattice, $(\alpha_1, \alpha_1) = (\alpha_2, \alpha_2) = 2$ and $(\alpha_1, \alpha_2) = -1$.

First differential. The bar complex element $e^{\alpha_1} \otimes e^{\alpha_2} \otimes \eta_{12}$ lives in bar degree 1 (two tensor factors, one form). The differential extracts the OPE residue:

$$d(e^{\alpha_1} \otimes e^{\alpha_2} \otimes \eta_{12}) = \text{Res}_{z_1=z_2} [e^{\alpha_1}(z_1)e^{\alpha_2}(z_2)].$$

The lattice VOA OPE gives $e^{\alpha_1}(z)e^{\alpha_2}(w) = \epsilon(\alpha_1, \alpha_2)(z-w)^{(\alpha_1, \alpha_2)} e^{\alpha_1 + \alpha_2}(w) + \dots = \epsilon(\alpha_1, \alpha_2)(z-w)^{-1} e^{\alpha_1 + \alpha_2}(w) + \dots$ where $\epsilon(\alpha_1, \alpha_2) = -1$ is the 2-cocycle sign (for the standard bimultiplicative choice on A_2). Taking the residue of the simple pole gives $d = -e^{\alpha_1 + \alpha_2}$.

Second differential. The element $e^{\alpha_1} \otimes e^{-\alpha_1 - \alpha_2} \otimes e^{\alpha_2} \otimes \eta_{12} \wedge \eta_{23}$ lives in bar degree 2. The differential is the sum of residues at the two collision divisors D_{12} and D_{23} . For D_{12} : $(\alpha_1, -\alpha_1 - \alpha_2) = -2 + 1 = -1$, so $e^{\alpha_1}(z_1)e^{-\alpha_1 - \alpha_2}(z_2) \sim \epsilon \cdot (z_1 - z_2)^{-1} e^{-\alpha_2}(z_2)$. Taking this residue and composing with the remaining e^{α_2} factor: $\text{Res}_{D_{23}}[e^{-\alpha_2}(z_2)e^{\alpha_2}(z_3)] = (-\alpha_2, \alpha_2) \cdot e^0 = -2 \cdot 1$. For D_{23} : $(-\alpha_1 - \alpha_2, \alpha_2) = -(\alpha_1, \alpha_2) - (\alpha_2, \alpha_2) = 1 - 2 = -1$, yielding a similar contribution. After accounting for signs from form orientations and the cocycle, the total differential gives $e^0 = 1$.

Weyl group action. The Weyl group $W(A_2) \cong S_3$ acts on the lattice, permuting the roots $\{\alpha_1, \alpha_2, -\alpha_1 - \alpha_2\}$. The bar complex is W -equivariant: the simple reflections s_1, s_2 act on bar complex elements by permuting lattice labels and adjusting cocycle signs. The higher A_∞ operations m_k for $k \geq 3$ arise from residues at higher collision strata and encode the relations in the Weyl group presentation $\langle s_1, s_2 \mid s_i^2 = 1, (s_1 s_2)^3 = 1 \rangle$. $\square$

E.2.7 GENUS 1 EXAMPLES: ELLIPTIC BAR COMPLEXES

E.2.7.1 Free fermion on the torus

THEOREM E.2.24 (*Elliptic free fermion bar complex*;). For the free fermion $\mathcal{F}$ on an elliptic curve E_τ :

$$H^n(\bar{B}_{\text{elliptic}}(\mathcal{F})) = \begin{cases} \mathbb{C} & n = 0 \\ \mathbb{C}^2 \oplus \mathbb{C}[\text{spin}] & n = 1 \\ \mathbb{C} \cdot \hat{c} & n = 2 \\ 0 & n > 2 \end{cases}$$

where $\mathbb{C}[\text{spin}]$ depends on the choice of spin structure.

Proof. The differential on genus 1 has additional terms from theta functions:

Degree 1. Elements have form

$$\alpha = \int_{C_2(E_\tau)} \psi(z_1) \otimes \psi(z_2) \otimes f(z_1, z_2; \tau) \eta_{12}^{(1)}$$

The differential includes the elliptic propagator:

$$d^{(1)}\alpha = \text{Res}_{D_{12}} \left[\frac{\theta_1'(0)}{\theta_1(z_{12})} \cdot f \cdot \eta_{12}^{(1)} \right]$$

The theta function zeros contribute additional cohomology classes corresponding to the 2^{2g} spin structures.

Degree 2. The central extension appears from the modular anomaly:

$$\hat{c} = \frac{c - \tilde{c}}{24} \omega_{\mathcal{M}_1}$$

where $\omega_{\mathcal{M}_1}$ is the Kähler form on the moduli space of elliptic curves. $\square$

E.2.7.2 Heisenberg algebra on higher genus

THEOREM E.2.25 (*Higher genus Heisenberg*;). For $\mathcal{H}_k$ on Σ_g ($g \geq 1$), the geometric bar complex cohomology is:

$$H^n(\bar{B}_{\text{geom}}^{(g)}(\mathcal{H}_k)) = \begin{cases} \mathbb{C} & n = 0 \\ \mathbb{C}^{2g} & n = 1 \\ \mathbb{C} \oplus \mathbb{C} \cdot c_k^{(g)} & n = 2 \\ 0 & n > 2 \end{cases}$$

Here $H^1 \cong H^1(\Sigma_g, \mathbb{C})$ reflects the $2g$ first-cohomology classes of Σ_g (realized as zero modes of the current $\alpha(z)$), H^2 contains the fundamental class $[\Sigma_g]$ and an additional class $c_k^{(g)}$ arising from the central extension, measuring the obstruction to trivializing the Heisenberg bundle over $\mathcal{M}_g$.

Proof. The proof uses the truncation of cohomology forced by $\dim_{\mathbb{R}} \Sigma_g = 2$.

Degree 0. The bar complex $\bar{B}^0 = \mathbb{C}$ (vacuum), and $d^0 = 0$, so $H^0 = \mathbb{C}$.

Degree 1. The degree-1 bar complex is:

$$\bar{B}^1 = \Gamma(\bar{C}_2(\Sigma_g), V \boxtimes V \otimes \Omega_{\log}^1)$$

where V is the weight-1 space spanned by the current $\alpha(z)$. On the closed surface Σ_g , the zero modes of $\alpha(z)$, i.e., the elements of $\ker(d : \bar{B}^1 \rightarrow \bar{B}^0)$ modulo $\text{im}(d : \bar{B}^2 \rightarrow \bar{B}^1)$, are classified by $H^1(\Sigma_g, \mathbb{C})$.

Concretely, the current $\alpha(z) = \partial\phi(z)$ on Σ_g has zero modes $\oint_{A_i} \alpha(z) dz$ and $\oint_{B_j} \alpha(z) dz$ for the A - and B -cycles of Σ_g ($i, j = 1, \dots, g$). By Hodge theory, these span a $2g$ -dimensional space isomorphic to $H^1(\Sigma_g, \mathbb{C}) \cong H^{1,0}(\Sigma_g) \oplus H^{0,1}(\Sigma_g)$.

Degree 2. The degree-2 bar differential involves the collision residue:

$$d(\alpha(z_1) \otimes \alpha(z_2) \cdot \eta_{12}) = \text{Res}_{z_1=z_2} \left[\frac{k}{(z_1 - z_2)^2} \eta_{12} \right] = k \cdot 1$$

On Σ_g , this residue maps to $H^2(\Sigma_g, \mathbb{C}) \cong \mathbb{C}$ (the fundamental class $[\Sigma_g]$). The class $c_k^{(g)} \in H^2$ arises as follows: the Heisenberg algebra at level k defines a line bundle $\mathcal{L}_k$ on $\mathcal{M}_g$ whose first Chern class is $c_1(\mathcal{L}_k) = k \cdot \lambda$, where λ is the Hodge class. The class $c_k^{(g)}$ is the image of this Chern class in the bar complex cohomology, and it is nonzero whenever $k \neq 0$.

Degree $n > 2$. Since Σ_g is a compact Riemann surface, $H^n(\Sigma_g, \mathbb{C}) = 0$ for $n > 2$. The geometric bar complex at degree n involves sections over the configuration space $\bar{C}_{n+1}(\Sigma_g)$ with logarithmic n -forms. The residue differential contracts pairs of points, and the resulting cohomology is controlled by the cohomology of Σ_g itself through the Leray spectral sequence for the forgetful map $\bar{C}_{n+1}(\Sigma_g) \rightarrow \Sigma_g^{n+1}$. For the single-generator Heisenberg algebra (rank 1), the Lie algebra cohomology of a finite-dimensional abelian Lie algebra is computed via the bar complex.

More precisely, the Lie algebra cohomology is classified by the bar complex of the rank-1 Heisenberg algebra: it computes $H_{\text{Lie}}^*(\mathfrak{h}_g, \mathbb{C}_k)$ of the abelian Lie algebra $\mathfrak{h}_g = H^0(\Sigma_g, \Omega^1) \oplus H^1(\Sigma_g, \mathcal{O})$ (dimension $2g$) with coefficients in the 1-dimensional representation determined by the level k central extension. For a 1-dimensional central extension of an abelian Lie algebra, the Chevalley–Eilenberg differential d_{CE} on $\Lambda^*(\mathfrak{h}_g^*)$ satisfies $d_{\text{CE}}(\xi) = k \cdot \omega(\xi, -)$ where ω is the symplectic form from the intersection pairing. The resulting cohomology is concentrated in degrees ≤ 2 : since $k \neq 0$, the map $d_{\text{CE}} : \Lambda^1 \rightarrow \Lambda^2$ is surjective onto the ω -multiples, and by induction the higher cohomology groups $H^n = 0$ for $n > 2$. $\square$

E.3 KOSZUL DUALITY FOR FREE FIELDS

Having computed the bar complexes, the Koszul duals are extracted next. The algebra-level dualities exchange statistics (bosonic $\leftrightarrow$ fermionic) and invert the propagator. Later in this section we record the specific module-theoretic and twisted-sector comparisons that are separately proved for the free-field families.

E.3.1 $\beta\gamma$ - bc ORTHOGONALITY AND DUALITY

PROPOSITION E.3.1 (*bc - $\beta\gamma$ orthogonality*). The relations $R_{bc} \perp R_{\beta\gamma}$ under the residue pairing: the Clifford relation of the bc system is orthogonal to the Weyl relation of the $\beta\gamma$ system.

Proof. The generators pair via the residue pairing $\langle b, \beta \rangle = 1$, $\langle c, \gamma \rangle = 1$, $\langle b, \gamma \rangle = 0$, $\langle c, \beta \rangle = 0$ (dual bases).

The quadratic relations are $R_{bc} = b \otimes c + c \otimes b$ (Clifford/symmetric) and $R_{\beta\gamma} = \beta \otimes \gamma - \gamma \otimes \beta$ (Weyl/antisymmetric).

Computing:

$$\begin{aligned} \langle R_{bc}, R_{\beta\gamma} \rangle &= \langle b \otimes c + c \otimes b, \beta \otimes \gamma - \gamma \otimes \beta \rangle \\ &= \langle b, \beta \rangle \langle c, \gamma \rangle - \langle b, \gamma \rangle \langle c, \beta \rangle \\ &\quad + \langle c, \beta \rangle \langle b, \gamma \rangle - \langle c, \gamma \rangle \langle b, \beta \rangle \\ &= (1)(1) - (0)(0) + (0)(0) - (1)(1) = 0. \end{aligned}$$

The cancellation is exact: the symmetric relation (+) and antisymmetric relation (−) are orthogonal complements under the residue pairing. This is the quadratic data underlying the Koszul duality $(\beta\gamma)^\dagger \cong bc$. $\square$

E.3.2 $\beta\gamma$ - bc KOSZUL DUALITY

THEOREM E.3.2 (*$\beta\gamma$ - bc Koszul duality*). The $\beta\gamma$ system (two bosonic generators with antisymmetric relation) and the bc ghost system (two fermionic generators with symmetric relation) are Koszul dual:

$$(\beta\gamma)^\dagger \cong bc \quad \text{and} \quad (bc)^\dagger \cong \beta\gamma.$$

At the level of bar complexes:

$$H^*(\bar{B}_{\text{geom}}(bc)) \cong \text{Sym}^{\text{ch}}(\beta, \gamma), \quad H^*(\bar{B}_{\text{geom}}(\beta\gamma)) \cong \Lambda^{\text{ch}}(b, c).$$

Remark E.3.3. This is a *two-generator* duality: $\beta\gamma$ has $\dim V = 2$ (bosonic) and bc has $\dim V^* = 2$ (fermionic). It should not be confused with the *single-generator* duality $\Lambda^{\text{ch}}(\psi) \leftrightarrow \text{Sym}^{\text{ch}}(\gamma)$ between one free fermion and one free boson.

Proof. The key computation uses the Gui–Li–Zeng quadratic duality framework. The quadratic datum for $\beta\gamma$ has generators $N = \mathbb{C}\beta \oplus \mathbb{C}\gamma$ ($\dim N = 2$, bosonic) and relation $P = \text{span}\{\beta \otimes \gamma - \gamma \otimes \beta\} \subset \Lambda^2(N)$ (antisymmetric).

The dual datum $(s^{-1}N^\vee \omega^{-1}, P^\perp)$ is computed via the residue pairing:

$$\langle P \otimes \omega_{X^2}, P^\perp \otimes s^2 \omega_{X^2} \rangle = 0$$

Under this pairing, the antisymmetric relation dualizes to:

$$P^\perp = \text{span}\{b \otimes c + c \otimes b\} \subset \text{Sym}^2(N^*)$$

which is the anticommutation relation for the bc ghost system (two fermionic generators $b = \beta^*$, $c = \gamma^*$).

Therefore $\mathcal{A}(s^{-1}N^\vee\omega^{-1}, P^\perp) = bc$, establishing $(\beta\gamma)^\dagger = bc$.

The geometric manifestation is that Verdier duality on configuration spaces exchanges symplectic pairings with Clifford pairings. Here “symplectic” means antisymmetric ($\beta\gamma - \gamma\beta = 1$), while “Clifford” means anticommuting ($bc + cb = 1$). See Section F.4.3 for the full NAP perspective. $\square$

Remark E.3.4 (The twisting morphism for free-field dualities). The Koszul duality $(\beta\gamma)^\dagger \cong bc$ is mediated by the universal twisting morphism $\tau: \bar{B}(\beta\gamma) \rightarrow \beta\gamma$, which takes a concrete form for free fields.

For the $\beta\gamma$ system, τ acts on a single-insertion bar element by returning the corresponding current: $\tau([\beta^*]) = \beta$, $\tau([\gamma^*]) = \gamma$. The Maurer–Cartan equation $d\tau + \tau \star \tau = 0$ encodes the free-field OPE: the convolution $(\tau \star \tau)([\beta^* \otimes \gamma^* \otimes \eta_{12}]) = \text{Res}_{z_1=z_2} [\beta(z_1) \gamma(z_2) \eta_{12}] = 1$ recovers the contraction $\beta(z)\gamma(w) \sim 1/(z-w)$, and the MC equation states that this is the *only* obstruction to exactness of the bar complex.

Dually, the twisting morphism for the bc system $\tau_{bc}: \bar{B}(bc) \rightarrow bc$ satisfies the *same* MC equation with the Clifford OPE $b(z)c(w) \sim 1/(z-w)$. Verdier duality on $\bar{C}_2(X)$ exchanges the two: the propagator $\eta_{12} = d \log(z_1 - z_2)$ is Verdier self-dual, so $\mathbb{D}_{\text{Ran}}(\tau_{\beta\gamma}) = \tau_{bc}$ (Theorem II.1.84, Theorem A₂). The Koszul duality $(\beta\gamma)^\dagger \cong bc$ is the *statement that Verdier duality intertwines the two twisting morphisms*. Acyclicity of the twisted tensor product $K(\tau) = \beta\gamma \otimes_\tau \bar{B}(\beta\gamma)$ follows from the quadratic Koszulness of the antisymmetric relation $\beta\gamma - \gamma\beta = 1$, confirming the Koszul property via the fundamental theorem (Theorem II.1.9).

E.3.3 DERIVED COMPLETION AND EXTENDED DUALITY

Definition E.3.5 (Derived $\beta\gamma$ - bc system). The *derived $\beta\gamma$ - bc system* arises from considering the BRST complex:

$$\mathcal{B}^\bullet = \cdots \xrightarrow{\mathcal{Q}} \beta\gamma \xrightarrow{\mathcal{Q}} bc \xrightarrow{\mathcal{Q}} \beta'\gamma' \xrightarrow{\mathcal{Q}} \cdots$$

where each arrow represents a BRST-type differential that shifts ghost number and conformal weight.

Remark E.3.6 (Geometric origin). This complex arises from the geometry of holomorphic vector bundles on curves. The $\beta\gamma$ system describes sections of $\mathcal{O} \oplus K$, while bc describes sections of $K^{-1} \oplus K^2$. The BRST differential geometrically corresponds to the $\bar{\partial}$ -operator in a twisted complex.

Conjecture E.3.7 (Extended fermion-ghost duality;). There exists a *derived fermionic system* $\mathcal{F}^\bullet$ with generators:

- $\psi^{(0)}$ of weight $h = 1/2$ (standard fermion)
- $\psi^{(1)}$ of weight $h = 3/2$ (weight-1 descendant)
- $\psi^{(-1)}$ of weight $h = -1/2$ (weight-(-1) ancestor)

satisfying anticommutation relations:

$$\psi^{(i)}(z)\psi^{(j)}(w) = \frac{\delta_{i+j,0}}{z-w} + \text{regular}$$

This forms a Koszul dual to the derived $\beta\gamma$ - bc system. (Contributing to the derived/super extension flank adjoining Conjecture ??, not to the standard W_∞ /Yangian packet.)

Evidence: Sketch of proposed argument. Consider the configuration space $\overline{C}_n(X)$ with its natural stratification by collision types. The derived structure arises from the entire stratified space and its perverse sheaf structure.

Step 1. The derived fermion lives in the jet bundle $J^\infty(\Pi E)$ where $E \rightarrow X$ is the spinor bundle and Π denotes parity reversal. The components $\psi^{(k)}$ correspond to the k -th jet components:

$$\psi^{(k)}(z) = \sum_n \psi_n^{(k)} z^{-n-h_k}$$

Step 2. On $\overline{C}_n(X)$, we have forms:

$$\omega_{\text{derived}} = \sum_{k=-1}^1 \psi_1^{(k)} \otimes \cdots \otimes \psi_n^{(k_n)} \otimes \eta_{I_k}$$

where η_{I_k} are forms adapted to the weight grading.

Step 3. The Koszul pairing extends:

$$\begin{pmatrix} \langle \psi^{(0)}, \beta \rangle & \langle \psi^{(0)}, \gamma \rangle & \langle \psi^{(0)}, b \rangle & \langle \psi^{(0)}, c \rangle \\ \langle \psi^{(1)}, \beta \rangle & \langle \psi^{(1)}, \gamma \rangle & \langle \psi^{(1)}, b \rangle & \langle \psi^{(1)}, c \rangle \\ \langle \psi^{(-1)}, \beta \rangle & \langle \psi^{(-1)}, \gamma \rangle & \langle \psi^{(-1)}, b \rangle & \langle \psi^{(-1)}, c \rangle \end{pmatrix} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$$

The weight conditions ensure proper pole structure in the residue extraction.

Step 4. The derived structure carries a differential:

$$Q\psi^{(k)} = (k+1)\psi^{(k+1)} + \text{curvature terms}$$

compatible with the BRST differential on the $\beta\gamma$ - bc side.

Step 5. The residue pairing matrix of Step 3 is rank 3 (matching the 3 generators $\psi^{(-1)}, \psi^{(0)}, \psi^{(1)}$ paired against the 4 generators β, γ, b, c of the derived $\beta\gamma$ - bc system). The pairing $\langle \psi^{(i)}, - \rangle : \mathcal{B}^\bullet \rightarrow \mathbb{C}$ identifies $\mathcal{F}^\bullet$ with the linear dual of the cogenerators of $\bar{B}(\mathcal{B}^\bullet)$: the bar complex of the derived $\beta\gamma$ - bc system has cogenerators in bar degree 1 dual to $\psi^{(0)}, \psi^{(\pm 1)}$, with the bar differential $d_{\bar{B}}$ encoding the BRST differential Q of Step 4. The A_∞ structure on $\mathcal{F}^\bullet$ is then recovered from the Verdier dual $\mathbf{D}_{\text{Ran}}(\bar{B}(\mathcal{B}^\bullet))$, which is the homotopy Koszul-dual factorization algebra computed from the bar resolution (Theorem II.1.84). This identifies $\mathcal{F}^\bullet$ as the homotopy Koszul dual $(\mathcal{B}^\bullet)_\infty^!$. Note: the cobar functor $\Omega(\bar{B}(\mathcal{B}^\bullet)) \simeq \mathcal{B}^\bullet$ (bar-cobar inversion, Theorem B) recovers $\mathcal{B}^\bullet$ itself, not its Koszul dual.

Example E.3.8 (Physical interpretation). In string theory, this extended system describes:

- $\psi^{(0)}$: Matter fermions
- $\psi^{(1)}$: Faddeev–Popov ghosts for local supersymmetry
- $\psi^{(-1)}$: Ghosts for ghosts in higher string field theory

The derived Koszul duality becomes the field-antifield correspondence in the BV formalism.

Remark E.3.9 (Scope). A complete proof requires assembling the jet bundle structure, stratified residue pairing, and cobar reconstruction into a single functorial argument. This is a derived/super extension problem, not one of the standard MC4 finite-packet lanes; no analogue of $\mathcal{I}_N$ or $\Delta_{a,0}(N)$ is yet identified here.

E.3.4 MODULE KOSZUL DUALITY FOR $\beta\gamma$ - bc

The algebra-level duality $(\beta\gamma)^\dagger \cong bc$ (Theorem E.3.2) extends to module categories. Both systems have natural families of modules parameterized by their zero-mode eigenvalue.

Definition E.3.10 ($\beta\gamma$ and bc Fock modules). For $\lambda \in \mathbb{C}$:

- (i) The $\beta\gamma$ Fock module $M_\lambda^{\beta\gamma}$ is generated by $|\lambda\rangle$ with $\gamma_0|\lambda\rangle = \lambda|\lambda\rangle, \beta_n|\lambda\rangle = \gamma_n|\lambda\rangle = 0$ for $n > 0$. Character (with $q = e^{2\pi i\tau}, y = e^{2\pi iz}$):

$$\text{ch}(M_\lambda^{\beta\gamma})(\tau, z) = \frac{y^\lambda}{\prod_{n \geq 1} (1 - q^n)^2}.$$

- (ii) The bc Fock module M_q^{bc} at ghost number $q \in \mathbb{Z}$ is generated by $|q\rangle$ with ghost number $J_0^{\text{gh}}|q\rangle = q|q\rangle, b_n|q\rangle = c_n|q\rangle = 0$ for appropriate $n > 0$ (depending on ghost number vacuum). For general weights $(j, 1-j)$, the conformal weight is $h_q = -\frac{1}{2}q(q - (2j-1))$. For $(2, -1)$:

$$\text{ch}(M_q^{bc}) = q^{h_q} \prod_{n \geq 1} (1 + q^n)^2, \quad h_q = -\frac{1}{2}q(q - 3).$$

PROPOSITION E.3.11 (*Module Koszul duality for $\beta\gamma$ - bc*). Under the Koszul duality $(\beta\gamma)^\dagger \cong bc$, the module Koszul duality functor (Theorem 11.6.2) yields an equivalence

$$D(\text{Mod}_{\beta\gamma}^{\text{E}_1, \text{compl}}) \simeq D(\text{Mod}_{bc}^{\text{E}_1, \text{compl}}).$$

Under this equivalence:

- (i) The $\beta\gamma$ Fock module $M_\lambda^{\beta\gamma}$ maps to the bc Fock module $M_{q(\lambda)}^{bc}$ with $q(\lambda) = \lambda$ (ghost number = γ_0 -eigenvalue).
- (ii) The symplectic pairing $\beta(z)\gamma(w) \sim (z - w)^{-1}$ on the $\beta\gamma$ side corresponds to the Clifford pairing $b(z)c(w) \sim (z - w)^{-1}$ on the bc side: the symmetric/antisymmetric exchange of the algebra-level duality extends to modules.
- (iii) The spectral flow $\sigma_n^{\beta\gamma} : \beta_m \mapsto \beta_{m+n}, \gamma_m \mapsto \gamma_{m-n}$ dualizes to $\sigma_n^{bc} : b_m \mapsto b_{m+n}, c_m \mapsto c_{m-n}$, exchanging twist sectors.

Proof. Apply Theorem 11.6.2 to the Koszul pair $(\beta\gamma, bc)$. The hypotheses are satisfied: $\beta\gamma$ is Koszul (the bar spectral sequence collapses at E_2 by Theorem E.3.2), and both algebras have finite-type grading (finite-dimensional weight spaces), so the bar coalgebra is graded-dualizable.

For (i): the bar resolution of $M_\lambda^{\beta\gamma}$ has the form $\bar{B}_n(\beta\gamma, M_\lambda^{\beta\gamma}) = \Gamma(\bar{C}_{n+2}(X), j_* j^*(\beta\gamma \boxtimes \bar{\beta\gamma}^{\boxtimes n} \boxtimes M_\lambda^{\beta\gamma}) \otimes \Omega_{\log}^n)$. The γ_0 -eigenvalue λ is preserved by the bar differential (which acts on the $z_i \neq z_j$ locus and does not affect the zero mode). On the dual side, λ becomes the ghost number q .

For (ii): the exchange of symmetric/antisymmetric pairings is the quadratic duality of Proposition E.3.1, which extends to modules by functoriality of the bar construction.

For (iii): follows from Example E.3.30 and the functoriality of bar-cobar for algebra automorphisms. $\square$

Remark E.3.12 (BRST cohomology as module Koszul duality). In the string theory context, the matter sector is $\beta\gamma$ (or more precisely, the matter CFT) and the ghost sector is bc . The BRST cohomology $H_{\text{BRST}}^*(\mathcal{H}_{\text{matter}} \otimes bc)$ computes the physical states. From the Koszul duality perspective, the BRST differential is precisely the bar complex differential for the module Koszul duality: it resolves the matter module via bc ghosts, and the BRST cohomology is the derived Koszul dual module.

E.3.5 HEISENBERG KOSZUL DUAL: SYMMETRIC ALGEBRA

THEOREM E.3.13 (*Heisenberg Koszul dual*;). The Heisenberg chiral algebra $\mathcal{H}_k$ at level k has Koszul dual:

$$\mathcal{H}_k^! \simeq (\mathrm{Sym}^{\mathrm{ch}}(V^*), d = 0, m_0 = -k \cdot \omega)$$

where $\mathrm{Sym}^{\mathrm{ch}}(V^*)$ is the chiral symmetric (commutative) algebra on the dual generator space, and $\omega \in \mathrm{Sym}^2(V^*)$ is the element dual to the pairing $\langle \alpha, \alpha \rangle = k$. This is a *curved* commutative chiral algebra in the sense of Positselski: the curvature $m_0 = -k \cdot \omega$ encodes the level, and $m_0 = 0$ only at level $k = 0$.

More explicitly, the bar complex decomposes as:

$$\begin{aligned} \bar{B}^{\mathrm{ch}}(\mathcal{H}_k) &\simeq \mathrm{coLie}^{\mathrm{ch}}(V^*) \quad (\text{conilpotent chiral coalgebra}) \\ \Omega^{\mathrm{ch}}(\mathrm{coLie}^{\mathrm{ch}}(V^*)) &\simeq (\mathrm{Sym}^{\mathrm{ch}}(V^*), m_0 = -k \cdot \omega) \quad (\text{curved cobar}) \end{aligned}$$

Proof. Proof 1: Via factorization envelopes. The Heisenberg chiral algebra is the factorization envelope of the abelian Lie^* algebra $\mathfrak{h}_k = (\mathcal{O}_X, 0)$ with trivial bracket and pairing $\langle \alpha, \alpha \rangle = k$. This is a special case of Nishinaka's general construction [428] (see also Vicedo [429]): the enveloping vertex algebra $U_{\mathrm{vert}}(\mathfrak{h}_k)$ recovers $\mathcal{H}_k$. By the Francis–Gaitsgory theory of chiral $\mathrm{Lie} \leftrightarrow \mathrm{Com}$ duality [167], for an abelian chiral Lie algebra $\mathfrak{a}$:

$$\mathrm{Fact}(\mathfrak{a})^! \simeq C_{\mathrm{Lie}^*}^*(\mathfrak{a}) = \mathrm{Sym}^{\mathrm{ch}}(\mathfrak{a}^*[1])$$

Since $\mathfrak{h}_k$ is abelian, the Chevalley–Eilenberg complex is formal: $C_{\mathrm{Lie}^*}^*(\mathfrak{h}_k) = \mathrm{Sym}^{\mathrm{ch}}(\mathfrak{h}_k^*[1])$, which is the chiral symmetric algebra on the dual generators.

Proof 2: Explicit bar complex computation (Chapter 2, §2.1–§2.3). The double-pole-only OPE makes the coproduct on $\bar{B}^{\mathrm{ch}}(\mathcal{H}_k)$ cocommutative (the residue $\mathrm{Res}_{z_i=z_j}[\omega/(z_i - z_j)^2]$ is symmetric under $z_i \leftrightarrow z_j$). By Milnor–Moore, a conilpotent cocommutative coalgebra is a coLie coalgebra, whose cobar is $\mathrm{Sym}^{\mathrm{ch}}(V^*)$.

The level k determines the curvature of the Koszul dual: $m_0 = -k \cdot \omega \in \mathrm{Sym}^2(V^*)$. The bar differential satisfies $d^2 = 0$ (as it always does); the curvature manifests instead in the A_∞ relation $m_1^2(a) = [m_0, a]_{m_2}$ on the cobar side. $\square$

REMARK E.3.14 (*Level-shifting vs Koszul duality*). Two distinct phenomena must be distinguished. *Koszul duality*: the bar coalgebra $\bar{B}(\mathcal{H}_k)$, dualized, gives $\mathcal{H}_k^! = \mathrm{Sym}(V^*)$ (relating different algebras). *Level-shifting*: $\mathrm{Rep}(\mathcal{H}_k) \simeq \mathrm{Rep}(\mathcal{H}_{-k})$ (an equivalence of representation categories). The former is algebraic; the latter is representation-theoretic.

COROLLARY E.3.15 (*Heisenberg module-comodule equivalence*;). The bar–cobar adjunction restricts to an equivalence of derived categories between *complete* E_1 -chiral $\mathcal{H}_k$ -modules and *conilpotent* E_1 -chiral $\bar{B}^{\mathrm{ch}}(\mathcal{H}_k)$ -comodules:

$$D(\mathrm{Mod}_{\mathcal{H}_k}^{E_1, \mathrm{compl}}) \simeq D(\mathrm{CoMod}_{\bar{B}^{\mathrm{ch}}(\mathcal{H}_k)}^{E_1, \mathrm{conil}}).$$

Since $\mathcal{H}_k$ has finite-type grading (finite-dimensional weight spaces), the coalgebra $\bar{B}^{\mathrm{ch}}(\mathcal{H}_k)$ is graded-dualizable with linear dual $\mathcal{H}_k^! \simeq \mathrm{Sym}^{\mathrm{ch}}(V^*)$ (Theorem E.3.13). Under this dualization, conilpotent comodules correspond to complete modules, yielding:

$$D(\mathrm{Mod}_{\mathcal{H}_k}^{E_1, \mathrm{compl}}) \simeq D(\mathrm{Mod}_{\mathrm{Sym}^{\mathrm{ch}}(V^*)}^{E_1, \mathrm{compl}}).$$

Under this equivalence, Ext groups are exchanged: $\mathrm{Ext}_{\mathcal{H}_k}^i(L, M) \cong \mathrm{Ext}_{\mathrm{Sym}^{\mathrm{ch}}(V^*)}^i(\mathrm{Ind}(M), \mathrm{Ind}(L))$.

Since $\text{Sym}^{\text{ch}}(V^*)$ is commutative, its complete module theory is considerably more tractable than Heisenberg Fock module theory. This equivalence “linearizes” Heisenberg representation theory via Koszul duality.

Remark E.3.16. The equivalence is between *complete* module categories, *not* the full bounded derived categories D^b . The intermediate coalgebra step is essential: modules become comodules via bar resolution, and only under the finite-type dualizability of $\mathcal{H}_k$ do conilpotent comodules further correspond to complete modules over the dual algebra $\text{Sym}^{\text{ch}}(V^*)$.

Proof. Apply Theorem 11.6.2 (module Koszul duality) to $\mathcal{A} = \mathcal{H}_k$. The hypotheses are satisfied: $\mathcal{H}_k$ is Koszul (the bar spectral sequence collapses at E_2 by the computation above), and the bar coalgebra is $\bar{B}^{\text{ch}}(\mathcal{H}_k)$, whose cohomology coalgebra $\mathcal{H}_k^! = H^*(\bar{B}^{\text{ch}}(\mathcal{H}_k))$ is the dual coalgebra; its graded linear dual is $\mathcal{H}_k^! \simeq \text{Sym}^{\text{ch}}(V^*)$ by Theorem E.3.13. The passage from comodules to modules over the dual algebra uses the finite-type grading of $\mathcal{H}_k$ (finite-dimensional weight spaces ensure graded dualizability). $\square$

COMPUTATION E.3.17 (*Bar complex of the Koszul dual* $\text{Sym}^{\text{ch}}(V^*)$). We compute $\bar{B}^{\text{ch}}(\text{Sym}^{\text{ch}}(V^*))$ explicitly, verifying the Koszul duality inverse: $\Omega(\bar{B}(\text{Sym}^{\text{ch}}(V^*))) \simeq \text{Sym}^{\text{ch}}(V^*)$.

The bar complex. For a commutative chiral algebra $C = \text{Sym}^{\text{ch}}(W)$ generated by a vector space W , the operadic Koszul duality $\text{Com}^{\text{ch},!} = \text{Lie}^{\text{ch}}$ gives:

$$\bar{B}^{\text{ch}}(\text{Sym}^{\text{ch}}(W)) \simeq \text{coLie}^{\text{ch}}(s^{-1}\bar{W})$$

where $\bar{W} = W$ (no vacuum component in the augmentation ideal of a free algebra) and coLie^{ch} is the conilpotent Lie chiral coalgebra cogenerated by $s^{-1}W$.

Rank 1 case ($W = V^* \cong \mathbb{C}$). The free Lie algebra on one generator is abelian: $\text{Lie}(1) = \mathbb{C}$ and $\text{Lie}(n) = 0$ for $n \geq 2$ (there are no nontrivial brackets on a single element). Therefore:

$$\dim \bar{B}^n(\text{Sym}^{\text{ch}}(V^*)) = \begin{cases} 1 & n = 1, \\ 0 & n \geq 2. \end{cases}$$

The bar complex is concentrated in degree 1, with $\bar{B}^1 = s^{-1}V^*$. This is the bar complex of a *free* algebra; it detects only the generators and has no higher bar cohomology.

General rank ($W = V^* \cong \mathbb{C}^m$). For $\dim V^* = m \geq 2$, the free Lie algebra dimensions are given by the Witt formula (necklace counting):

$$\dim \bar{B}^n(\text{Sym}^{\text{ch}}(V^*)) = \ell(n, m) = \frac{1}{n} \sum_{d|n} \mu(d) m^{n/d}$$

where μ is the Möbius function. For $m = 2$ (the $\beta\gamma$ -system; see Theorem E.3.2):

$$\ell(1, 2) = 2, \quad \ell(2, 2) = 1, \quad \ell(3, 2) = 2, \quad \ell(4, 2) = 3, \quad \ell(5, 2) = 6.$$

These are the dimensions of the degree- n component of the free Lie algebra on two generators.

Koszul inversion check. Taking cobar of $\text{coLie}^{\text{ch}}(s^{-1}V^*)$ recovers $\text{Sym}^{\text{ch}}(V^*)$ by the bar-cobar inversion theorem (Theorem 8.6.1), confirming the Koszul pair $(\mathcal{H}_k, \text{Sym}^{\text{ch}}(V^*))$ is self-consistent.

E.3.6 HEISENBERG MODULE KOSZUL DUALITY

Definition E.3.18 (Fock module). For $\lambda \in \mathbb{C}$, the Fock module F_λ over $\mathcal{H}_k$ is generated by a vector $|\lambda\rangle$ with:

- $J_0|\lambda\rangle = \lambda|\lambda\rangle$, $J_n|\lambda\rangle = 0$ for $n > 0$;
- $F_\lambda \cong \mathbb{C}[J_{-1}, J_{-2}, \dots]$ as a vector space, with character $\text{ch}(F_\lambda) = q^{\lambda^2/2k} \prod_{n \geq 1} (1 - q^n)^{-1}$.

F_λ is simple for all $\lambda \in \mathbb{C}$ (no singular vectors exist because $\mathcal{H}_k$ is abelian).

PROPOSITION E.3.19 (Fock module bar resolution;). The geometric bar resolution (Theorem 15.3.4) of F_λ over $\mathcal{H}_k$ takes the form:

$$\bar{B}_n^{\text{ch}}(\mathcal{H}_k, F_\lambda) = \Gamma(\bar{C}_{n+2}(X), j_* j^*(\mathcal{H}_k \boxtimes \bar{\mathcal{H}}_k^{\boxtimes n} \boxtimes F_\lambda) \otimes \Omega_{\log}^n).$$

The bar differential $d_{\text{bar}} = \sum_{i < j} d_{ij}$ has the following structure:

- (i) Collisions $z_i = z_j$ between two algebra points ($1 \leq i < j \leq n$) produce the residue $k \cdot \text{Res}_{z_i=z_j} [\omega / (z_i - z_j)^2]$, which is *symmetric* in z_i, z_j (as in Theorem E.3.13);
- (ii) Collision of an algebra point z_i with the module point z_{n+1} produces the Heisenberg action $\text{Res}_{z_i=z_{n+1}} \alpha(z_i) \cdot F_\lambda$;
- (iii) Mixed terms vanish by the abelian OPE $\alpha(z)\alpha(w) \sim k/(z-w)^2$ (no simple pole).

Proof. The bar complex definition is Theorem 15.3.4 specialized to $\mathcal{A} = \mathcal{H}_k$, $\mathcal{M} = F_\lambda$. The structure of the bar differential follows from the Heisenberg OPE:

Algebra–algebra collisions. For $1 \leq i < j \leq n$, the OPE $\alpha(z_i)\alpha(z_j) \sim k/(z_i - z_j)^2$ contributes only a double pole. The residue $\text{Res}_{z_i=z_j} [\omega / (z_i - z_j)^2] = \partial_{z_i} \omega|_{z_i=z_j}$ is symmetric in z_i, z_j (as computed in Step 2–3 of the proof of Theorem E.3.13).

Algebra–module collisions. The OPE $\alpha(z_i) \cdot |\lambda\rangle$ produces the Heisenberg action: $J_0|\lambda\rangle = \lambda|\lambda\rangle$ from the residue of the simple pole, and $J_{-m}|\lambda\rangle$ from higher poles. This is the standard module action, realized geometrically by the residue along the collision divisor $D_{i,n+1} = \{z_i = z_{n+1}\}$.

No simple poles between algebra points. Since the Heisenberg OPE has no simple pole, there are no “mixed” contributions where an algebra collision produces a non-scalar result. Consequently the algebra part of the bar complex is purely cocommutative, and the module point interacts with algebra points only through the standard action. $\square$

PROPOSITION E.3.20 (Koszul dual module;). Under the module Koszul duality equivalence of Corollary E.3.15, the Fock module F_λ over $\mathcal{H}_k$ corresponds to a module $F_\lambda^!$ over $\mathcal{H}_k^! = \text{Sym}^{\text{ch}}(V^*)$ characterized by:

- (i) $F_\lambda^!$ is generated by a vector $|\lambda\rangle$ with $\alpha_0|\lambda\rangle = \lambda|\lambda\rangle$;
- (ii) as a graded vector space, $F_\lambda^! \cong \mathbb{C}[\alpha_{-1}, \alpha_{-2}, \dots] \cdot |\lambda\rangle$;
- (iii) the A_∞ module structure on $F_\lambda^!$ inherits the curvature $m_0 = -k \cdot \omega \in \text{Sym}^2(V^*)$ from the algebra level (Theorem E.3.13), so the strict differential satisfies $m_1^2 = [m_0, -]_{m_2} \neq 0$ when $k \neq 0$.

Proof. Apply the module Koszul duality functor of Theorem 11.6.2 to $\mathcal{M} = F_\lambda$. The bar complex $\bar{B}^{\text{ch}}(\mathcal{H}_k, F_\lambda)$ is a comodule over $\bar{B}^{\text{ch}}(\mathcal{H}_k)$, which is cocommutative (Proposition E.3.19(i)).

Under graded linear dualization (valid because $\mathcal{H}_k$ has finite-type grading), the comodule structure becomes a module structure over $\mathcal{H}_k^! = \text{Sym}^{\text{ch}}(V^*)$. The charge is preserved: the J_0 -eigenvalue λ of $|\lambda\rangle$

dualizes to the α_0 -eigenvalue λ on $F_\lambda^!$, because the Koszul pairing $\langle J, \alpha \rangle = 1$ identifies J_0 with α_0 at the Zhu algebra level ($A(\mathcal{H}_k) \cong \mathbb{C}[J_0] \cong \mathbb{C}[\alpha_0] \cong A(\text{Sym}^{\text{ch}}(V^*))$; see Example 15.2.26(iv)).

The curvature on $F_\lambda^!$ is inherited from the algebra-level curvature $m_0 = -k \cdot \omega$. The module action of m_0 on $F_\lambda^!$ is well-defined because m_0 lies in the center of $\text{Sym}^{\text{ch}}(V^*)$ (it is a quadratic element of a commutative algebra). $\square$

COROLLARY E.3.21 (*Fock module character from Koszul resolution*;). The character of F_λ can be derived from the Koszul resolution:

$$\text{ch}(F_\lambda) = \sum_{n \geq 0} (-1)^n \text{ch}(\mathcal{H}_k) \cdot \text{ch}((\mathcal{H}_k^!)_n) \cdot \text{ch}_{\text{naive}}(F_\lambda) = q^{\lambda^2/2k} \prod_{n \geq 1} \frac{1}{1 - q^n}.$$

Proof. By Theorem 15.4.2, the Koszul resolution of F_λ has terms $\mathcal{P}_n = \mathcal{H}_k \otimes (\mathcal{H}_k^!)_n \otimes F_\lambda$. The alternating character sum is:

$$\text{ch}(F_\lambda) = \text{ch}(\mathcal{H}_k) \cdot \text{ch}_{\text{naive}}(F_\lambda) \cdot \sum_{n \geq 0} (-1)^n \text{ch}((\mathcal{H}_k^!)_n) = \text{ch}(\mathcal{H}_k) \cdot \text{ch}_{\text{naive}}(F_\lambda) \cdot h_{\mathcal{H}_k^!}(-t).$$

The Koszul relation $h_{\mathcal{H}_k}(t) \cdot h_{\mathcal{H}_k^!}(-t) = 1$ (equivalent to Koszulity of $\mathcal{H}_k$; Theorem E.3.13) cancels $\text{ch}(\mathcal{H}_k)$, giving $\text{ch}(F_\lambda) = \text{ch}_{\text{naive}}(F_\lambda) = q^{\lambda^2/2k} \prod_{n \geq 1} (1 - q^n)^{-1}$.

The non-trivial content is the *exactness* of the resolution: the Koszul property of $\mathcal{H}_k$ (established by the spectral sequence collapse in Theorem E.3.13) guarantees that the resolution is acyclic. $\square$

PROPOSITION E.3.22 (*Ext groups between Fock modules*;). Let $\dim V = d$ and let F_λ, F_μ be Fock modules for $\mathcal{H}_k$ with J_0 -eigenvalues $\lambda, \mu \in V^*$.

- (i) If $\lambda \neq \mu$, then $\text{Ext}_{\mathcal{H}_k}^i(F_\lambda, F_\mu) = 0$ for all $i \geq 0$.
- (ii) If $\lambda = \mu$, the graded Ext algebra is an exterior algebra on countably many generators:

$$\sum_{i \geq 0} \sum_{j \geq 0} \dim \text{Ext}_{\mathcal{H}_k}^i(F_\lambda, F_\lambda)_j t^i q^j = \prod_{n=1}^{\infty} (1 + tq^n)^d.$$

In particular, $\dim \text{Ext}_{\mathcal{H}_k}^i(F_\lambda, F_\lambda)_j$ equals the number of d -coloured partitions of j into exactly i distinct parts.

Proof. Module Koszul duality (Corollary E.3.15) sends Fock modules (standard modules over $\mathcal{H}_k$) to simple modules over the Koszul dual $\text{Sym}^{\text{ch}}(V^*)$: the image of F_λ under the Koszul duality functor is the one-dimensional module $\mathbb{C}_\lambda$ on which α_0 acts by λ and all other modes act by 0. The Ext exchange gives

$$\text{Ext}_{\mathcal{H}_k}^i(F_\lambda, F_\mu) \cong \text{Ext}_{\text{Sym}^{\text{ch}}(V^*)}^i(\mathbb{C}_\mu, \mathbb{C}_\lambda),$$

with reversal of arguments (contravariant Koszul duality).

Part (i). The simple modules $\mathbb{C}_\lambda$ and $\mathbb{C}_\mu$ lie in different α_0 -eigenspaces. Since any projective resolution preserves the α_0 -eigenvalue, Hom between resolutions in distinct eigenspaces vanishes.

Part (ii). For $\lambda = \mu$, the simple module $\mathbb{C}_\lambda$ over $\text{Sym}^{\text{ch}}(V^*)$ admits a Koszul resolution by free modules:

$$\cdots \rightarrow \text{Sym}^{\text{ch}}(V^*) \otimes \Lambda^2(V_{<0}^*) \rightarrow \text{Sym}^{\text{ch}}(V^*) \otimes V_{<0}^* \rightarrow \text{Sym}^{\text{ch}}(V^*) \rightarrow \mathbb{C}_\lambda \rightarrow 0,$$

where $V_{<0}^* = \bigoplus_{n \geq 1} V^* \cdot z^n$ is the space of negative modes (with $\alpha_{-n}^{(a)}$ contributing conformal weight n for $a = 1, \dots, d$), and the Koszul differential is $d(s \otimes v_1 \wedge \dots \wedge v_{i+1}) = \sum_j (-1)^{j+1} s \cdot v_j \otimes v_1 \wedge \dots \wedge \widehat{v_j} \wedge \dots \wedge v_{i+1}$. Applying $\text{Hom}_{\text{Sym}^{\text{ch}}}(-, \mathbb{C}_\lambda)$:

$$\text{Hom}_{\text{Sym}^{\text{ch}}}(\text{Sym}^{\text{ch}} \otimes \Lambda^i(V_{<0}^*), \mathbb{C}_\lambda) \cong \Lambda^i(V_{<0}^*)^*$$

with induced differential $d^*(f) = f \circ d$. Since d involves multiplication by elements of $V_{<0}^* \subset \ker(\text{Sym}^{\text{ch}} \rightarrow \mathbb{C}_\lambda)$ (the augmentation ideal), the induced differential $d^* = 0$.

Therefore

$$\text{Ext}_{\text{Sym}^{\text{ch}}(V^*)}^i(\mathbb{C}_\lambda, \mathbb{C}_\lambda) \cong \Lambda^i(V_{<0}^*)^* \cong \Lambda^i(V_{<0}^*)$$

as graded vector spaces (the last isomorphism uses finite-dimensionality of each weight space). The generator $\alpha_{-n}^{(a)} \in V_{<0}^*$ contributes weight n , so the graded generating function is

$$\sum_{i,j} \dim \Lambda^i(V_{<0}^*)_j t^i q^j = \prod_{n=1}^{\infty} \prod_{a=1}^d (1 + tq^n) = \prod_{n=1}^{\infty} (1 + tq^n)^d. \quad \square$$

Remark E.3.23 (Ext Poincaré series and Jacobi functions). For $d = 1$, the Ext generating function $\prod_{n=1}^{\infty} (1 + tq^n)$ at $t = -1$ gives $\prod (1 - q^n) = q^{-1/24} \eta(\tau)$, recovering the Dedekind eta function. At $t = 1$, the series $\prod (1 + q^n) = q^{-1/24} \eta(2\tau)/\eta(\tau)$ counts the total dimension $\sum_i \dim \text{Ext}^i$ in each conformal weight. For general d , the specialization $t = -1$ gives $\eta(\tau)^d$, consistent with the Euler characteristic of the Ext algebra being the ratio of Heisenberg to dual characters.

Remark E.3.24 (Ext algebra and the genus universality invariant). The Euler characteristic $\chi(\text{Ext}^*) = \prod (1 - q^n)^d = q^{-d/24} \eta(\tau)^d$ satisfies $\chi(\text{Ext}^*) \cdot Z(\mathcal{H}_k) = 1$, where $Z = q^{d/24}/\eta(\tau)^d$ is the Heisenberg partition function. The conformal anomaly $q^{d/24}$ reflects $c = d$; the genus universality invariant $\kappa(\mathcal{H}_k) = k$ (Theorem 13.13.16) governs the genus- g obstruction $\text{obs}_g = k \cdot \lambda_g$ (UNIFORM-WEIGHT), with genus-1 value $F_1 = k/24 = c/24$. This is the “horizontal” (module Ext) manifestation of the “vertical” (genus) invariant $\kappa(\mathcal{H}_k)$.

E.3.7 TWISTED MODULES: RAMOND AND NEVEU–SCHWARZ SECTORS

The free fermion and Heisenberg algebras possess *twisted modules* arising from automorphisms of the chiral algebra. Module Koszul duality interacts non-trivially with these twisted sectors.

Definition E.3.25 (Ramond and Neveu–Schwarz sectors). Let $\mathcal{F}$ be the free fermion chiral algebra with generator $\psi(z)$ and automorphism $\sigma : \psi \mapsto -\psi$ (the fermion parity involution).

- (i) The *Neveu–Schwarz (NS) sector* is the untwisted vacuum module: modes ψ_r with $r \in \mathbb{Z} + \frac{1}{2}$, $\psi_r|0\rangle_{\text{NS}} = 0$ for $r > 0$. Character:

$$\text{ch}(\text{NS}) = q^{-1/48} \prod_{n \geq 1} (1 + q^{n-1/2}).$$

- (ii) The *Ramond (R) sector* is the σ -twisted module: modes ψ_n with $n \in \mathbb{Z}$, $\psi_n|0\rangle_{\text{R}} = 0$ for $n > 0$. The zero mode ψ_0 satisfies $\psi_0^2 = \frac{1}{2}$, so the ground states form a 1-dimensional Clifford module $(|+\rangle$ with $\psi_0|+\rangle = \frac{1}{\sqrt{2}}|+\rangle$ for a single fermion). Character:

$$\text{ch}(\text{R}) = q^{1/24} \prod_{n \geq 1} (1 + q^n).$$

The spectral flow automorphism U_θ with $\theta = 1/2$ interpolates between the two sectors: $U_{1/2} : \psi_r \mapsto \psi_{r+1/2}$, sending NS to R.

PROPOSITION E.3.26 (*Twisted module Koszul duality for fermions*;). Under the fermion–boson Koszul duality $\mathcal{F}^\dagger \simeq \text{Sym}^{\text{ch}}(\gamma)$:

- (i) The NS sector of $\mathcal{F}$ corresponds to the vacuum module of $\text{Sym}^{\text{ch}}(\gamma)$.
- (ii) The Ramond sector of $\mathcal{F}$ corresponds to the $\sigma^\dagger$ -twisted module of $\text{Sym}^{\text{ch}}(\gamma)$, where $\sigma^\dagger : \gamma \mapsto -\gamma$ is the dual involution.
- (iii) The spectral flow $U_{1/2}$ on $\mathcal{F}$ dualizes to a shift functor $\gamma_n \mapsto \gamma_{n+1/2}$ on $\text{Sym}^{\text{ch}}(\gamma)$ -modules.

Proof. The automorphism $\sigma : \psi \mapsto -\psi$ induces an automorphism $\sigma^\dagger$ of the Koszul dual via the bar-cobar functor. Since the bar construction is functorial for algebra automorphisms (Theorem 11.1.84), and since σ acts on the generator space $V = \text{Span}\{\psi\}$ by -1 , the induced automorphism $\sigma^\dagger = \bar{B}(\sigma)^\vee$ acts on $V^* = \text{Span}\{\gamma\}$ by -1 as well (the Koszul pairing $\langle \psi, \gamma \rangle = 1$ is preserved under the simultaneous sign change).

For (i): the NS sector is the vacuum module of $\mathcal{F}$, and module Koszul duality (Theorem 11.6.2) sends the vacuum module to the vacuum module.

For (ii): a σ -twisted module M of $\mathcal{F}$ is, by definition, a module where the monodromy around the insertion point acts by σ . Under the bar construction, the monodromy operator is the holonomy of the flat connection on $\bar{C}_{n+1}(X) \setminus D$; the twist by σ on the algebra side becomes a twist by $\sigma^\dagger$ on the dual side.

For (iii): spectral flow shifts the mode index by $1/2$. Since the Koszul pairing identifies ψ_r with γ_r (at the level of generator modes), the shift $\psi_r \mapsto \psi_{r+1/2}$ induces $\gamma_r \mapsto \gamma_{r+1/2}$. $\square$

Remark E.3.27 (*Character identity under twisted KD*). The Koszul character relation $h_{\mathcal{F}}(t) \cdot h_{\mathcal{F}^\dagger}(-t) = 1$ restricts to each twisted sector. For the Ramond sector:

$$\prod_{n \geq 1} (1 + q^n) \cdot \prod_{n \geq 1} (1 - q^n)^{-1} = \frac{1}{\prod_{n \geq 1} (1 - q^n)/(1 + q^n)} = \prod_{n \geq 1} \frac{1 + q^n}{1 - q^n},$$

which is the character of the $\sigma^\dagger$ -twisted module of $\text{Sym}^{\text{ch}}(\gamma)$ (the symmetric algebra on integer-moded generators).

Definition E.3.28 (*Heisenberg spectral flow*). The Heisenberg algebra $\mathcal{H}_k$ admits a one-parameter family of spectral flow automorphisms σ_λ for $\lambda \in \mathbb{C}$:

$$\sigma_\lambda(J_n) = J_n + k\lambda \delta_{n,0}, \quad \sigma_\lambda(L_n) = L_n + \lambda J_n + \frac{k\lambda^2}{2} \delta_{n,0}.$$

The spectral flow acts on Fock modules by charge shift: $\sigma_\lambda^*(F_\mu) \cong F_{\mu+k\lambda}$.

PROPOSITION E.3.29 (*Spectral flow under Koszul duality*;). Under the Heisenberg Koszul duality $\mathcal{H}_k^\dagger \simeq \text{Sym}^{\text{ch}}(V^*)$:

- (i) The spectral flow σ_λ on $\mathcal{H}_k$ dualizes to the translation automorphism $\tau_\lambda : \alpha_0 \mapsto \alpha_0 + \lambda$ on $\text{Sym}^{\text{ch}}(V^*)$.
- (ii) The Fock module correspondence (Proposition E.3.20) is equivariant: $\sigma_\lambda^*(F_\mu)^\dagger \cong \tau_\lambda^*(F_\mu^\dagger)$.
- (iii) The curvature $m_0 = -k \omega$ is invariant under spectral flow: $\sigma_\lambda^*(m_0) = m_0$.

Proof. For (i): the spectral flow shifts the zero mode $J_0 \mapsto J_0 + k\lambda$. Under the Zhu algebra isomorphism $A(\mathcal{H}_k) \cong \mathbb{C}[J_0] \cong \mathbb{C}[\alpha_0] \cong A(\text{Sym}^{\text{ch}}(V^*))$ (Example 15.2.26(iv)), this becomes the translation $\alpha_0 \mapsto \alpha_0 + \lambda$.

For (ii): $\sigma_\lambda^*(F_\mu) \cong F_{\mu+k\lambda}$ by Definition E.3.28, and $F_{\mu+k\lambda}^\dagger$ has α_0 -eigenvalue $\mu + k\lambda$ by Proposition E.3.20. On the dual side, $\tau_\lambda^*(F_\mu^\dagger)$ shifts $\alpha_0 \mapsto \alpha_0 + \lambda$, giving eigenvalue $\mu + \lambda$. Since the Koszul pairing scales by k (the J_0 -eigenvalue μ of F_μ maps to α_0 -eigenvalue μ under the identification), the spectral flow parameter matches.

For (iii): the curvature $m_0 = -k\omega$ lies in $\text{Sym}^2(V^*)$ and is independent of J_0 (it comes from the quadratic pole, not the zero mode). Since σ_λ shifts only J_0 , the curvature is invariant. $\square$

Example E.3.30 (bc system: twisted sectors and spectral flow). The bc ghost system (weights $(j, 1-j)$) has spectral flow $\sigma_n : b_m \mapsto b_{m+n}, c_m \mapsto c_{m-n}$, which shifts the ghost number vacuum by n units. Under the $bc \leftrightarrow \beta\gamma$ Koszul duality (Theorem E.3.2), this spectral flow dualizes to the corresponding $\beta\gamma$ spectral flow $\sigma_n^\dagger : \beta_m \mapsto \beta_{m+n}, \gamma_m \mapsto \gamma_{m-n}$.

At $j = 2$ (conformal ghosts), the Ramond-type twisted sector ($n = 1$) gives the “picture-changed” BRST complex of string theory: the picture-changing operator $X(z) = \{Q, \xi(z)\}$ is the bar complex differential in the spectrally flowed sector.

E.3.8 KOSZUL DUALITY SUMMARY TABLE

E.3.8.1 Koszul duality table

Algebra $\mathcal{A}$	Koszul Dual $\mathcal{A}^\dagger$	Type	Context	Status
Free fermion ψ	$\text{Sym}^{\text{ch}}(\gamma)$	Exact	Lie/Com	[171] a c d b
bc ghosts	$\beta\gamma$ system	Exact	D-branes	
Heisenberg $\mathcal{H}_k$	$\text{Sym}^{\text{ch}}(V^*)$ (curved)	Exact	Lie/Com	
Free boson $\partial\phi$	Symplectic bosons	Exact	Open-closed	
$\widehat{\mathfrak{g}}_k$	$\widehat{\mathfrak{g}}_{-k-2h^\vee}$	Filt./Curved	Feigin–Frenkel	
Virasoro _{c}	Vir_{26-c} (dynamic shadow)	Curved	$c \mapsto 26 - c$	
$\mathcal{W}_N$	$\mathcal{W}_N^\dagger$ (cumulant-enlarged)	Filt./Curved	Higher spin	
Super-Virasoro	Super- W_∞	Curved	AdS ₃ sugra	
$Y(\mathfrak{g})$	$Y_{R-1}(\mathfrak{g})$	Self-dual	Integrability	
Virasoro ₂₆	String vertex algebra	Classical	Genus-0 BRST/bar	
$W^{-h^\vee}(\mathfrak{g})$	Wakimoto	Classical	DS reduction $\leftrightarrow$ free field	
Lattice V_L	Lattice V_L^*	Classical	Form duality	

^a The Feigin–Frenkel isomorphism $\mathfrak{z}(\widehat{\mathfrak{g}}_{-h^\vee}) \cong \mathcal{W}(\widehat{\mathfrak{g}}^\vee)$ is a theorem of Feigin–Frenkel. The interpretation of the level involution $k \leftrightarrow -k - 2h^\vee$ as a Koszul duality in the chiral sense is proved in Chapter G: the low-degree bar calculation (Theorem G.5.3 for $\mathfrak{sl}_2$) together with the Serre-duality argument on configuration spaces (Theorem G.7.1) establishes the level shift.

^c The same-family shadow Vir_{26-c} is the *dynamic* Koszul dual at the M/S-level (Example 8.1.21). The full *kinematic* dual has infinitely many primitive cumulants ($\Delta_{\text{Vir}}(t) = t^3 + 2t^5 + \dots \neq 0$); the H-level identification with a $\mathcal{W}_\infty$ -type object is the residual MC₄ task (Theorem 8.1.27 provides the structural framework; the specific target identification is open).

^d The naive dual on generators L^*, W^* is insufficient: the composite field $\Lambda =: (TT) : -\frac{3}{10}\partial^2 T$ forces a cumulant cogenerator Λ^* with nonprimitive coproduct (Remark 12.12.12).

^b The Yangian E_1 -chiral Koszul duality $Y(\mathfrak{g})^\dagger \cong Y_{R^{-1}}(\mathfrak{g})$ is proved in Theorem O.2.2: the RTT presentation is quadratic in the E_1 -chiral sense, and the quadratic dual relations are the RTT relations with the inverse R -matrix $R^{-1}(u)$. At the classical level ($\hbar = 0$), this reduces to exact self-duality (Corollary O.2.3).

Remark E.3.31 (Status of Koszul duality identifications). The entries fall into two categories. *Proved:* the free-field and Heisenberg dualities (Chapter F.4, Theorem E.3.13); the Kac–Moody level shift $\widehat{\mathfrak{g}}_k \leftrightarrow \widehat{\mathfrak{g}}_{-k-2h^\vee}$ (Theorems G.5.3 and G.7.1). *H-level (MC4 closed on $\mathcal{W}_\infty$):* the infinite-generator identifications $\text{Virasoro} \rightsquigarrow W_\infty$, $\mathcal{W}_N \rightsquigarrow Y(\mathfrak{gl}_N)$, Super-Virasoro $\rightsquigarrow$ Super- W_∞ . The M-level theory (bar complex, inversion, Koszulness, complementarity) is proved for all principal $\mathcal{W}_N$ at generic level. On the $\mathcal{W}_\infty$ side, the finite-packet coefficient identities $C^{\text{res}} = C^{\text{DS}}$ on $\mathcal{I}_N$ are unconditionally closed at all stages via $\mathcal{W}_N$ rigidity (coefficient identification, Theorem 8.1.150) within the strong completion-tower framework (structural proof, Theorem 8.1.27). On the Yangian side, the evaluation-core comparison $K^{\text{line}} = K^{\text{RTT}}$ on $\Delta_{a,0}(N)$ is verified (249 tests); the remaining DK-5 categorical packet is still downstream of the post-core MC3 completion problem, which in type A is reduced to the compact-completion packet.

Remark E.3.32 (Scope: conjectural table entries). The three infinite-generator identifications each involve curved Koszul duality ($m_0 \neq 0$) with infinitely many generators. Two structural features: (1) non-quadratic OPE prevents the quadratic framework of Chapter II from applying directly; (2) the infinite-generator flank requires the coefficient-identification package, which is now unconditionally resolved on the $\mathcal{W}_\infty$ side via $\mathcal{W}_N$ rigidity (MC4 closed). Conditional on the DS/bar transport theorem (Theorem R.3.1), the same-family involution $\text{Vir}_c \leftrightarrow \text{Vir}_{26-c}$ gives the expected M/S-level shadow, while the H-level realization asks for an infinite-generator dual whose bar cohomology matches the semi-infinite growth (Motzkin numbers, Theorem II.1.21). The super row remains a separate extension flank adjoining Conjecture ??.

Remark E.3.33 (Heisenberg vs Yangian: self-duality contrast). The Heisenberg algebra is *not* self-dual: $\mathcal{H}^\dagger = \text{Sym}^{\text{ch}}(V^*) \not\cong \mathcal{H}$, since the central extension and non-commutative oscillator modes dualize to the commutative chiral algebra on the dual space ($\text{Lie} \leftrightarrow \text{Com}$ duality, not to be confused with the boson-fermion correspondence). By contrast, the Yangian satisfies $Y(\mathfrak{g})^\dagger \cong Y_{R^{-1}}(\mathfrak{g})$ (Theorem O.2.2): the RTT presentation is quadratic in the E_1 -chiral sense, the dual relations use the inverse R -matrix $R^{-1}(u)$, and at the classical level ($\hbar = 0$) this reduces to exact self-duality (Corollary O.2.3), visible in 3d mirror symmetry ($\text{Higgs} \leftrightarrow \text{Coulomb}$).

The Heisenberg OPE $\alpha(z)\alpha(w) \sim (z-w)^{-2}$ has a double pole that produces symmetric (bosonic) coproduct structure in the bar construction. By contrast, the Yangian’s RTT relations have built-in R -matrix self-duality that preserves the structure under bar-cobar.

Remark E.3.34 (Additional dualities). Some algebras in this table have *additional* duality structures beyond standard Koszul duality:

1. *Heisenberg.* Level inversion $\mathcal{H}_k \leftrightarrow \mathcal{H}_{-k}$ (curved duality, not Koszul).
2. *Affine Kac–Moody.* Langlands duality $\widehat{\mathfrak{g}}_k \leftrightarrow \widehat{\mathfrak{g}}_{k'}^\vee$ at critical/conformal levels.
3. *W-algebras.* At critical level, the external quantum-Langlands picture relates $\mathcal{W}^{-h^\vee}(\mathfrak{g}, f)$ to a Langlands-dual $\mathcal{W}$ -algebra, while the manuscript-internal proved statement is the critical fixed-point inversion package for the principal algebra. At general central charge: $\mathcal{W}_N^c \leftrightarrow \mathcal{W}_N^{c'}$ with $c + c' = 2(N-1)(2N^2 + 2N + 1)$.
4. *Virasoro.* Exceptional modular invariance at certain central charges.

These additional structures are typically curved or filtered Koszul dualities, operating in extended categories. They should not be confused with the standard Koszul duality listed in the main table column.

Remark E.3.35 (Completion kinematics of free-field archetypes). The free-field archetypes occupy the simplest corner of the completion phase diagram (Table K.7.1 in the landscape census):

Algebra	$G_{\mathcal{A}}(t)$	ρ_K	h_K	Class
Heisenberg $\mathcal{H}_k$	t	1	0	G
Free fermion ψ	t	1	0	G
$\beta\gamma$	$t/(1-t)$	1/2	$\log 2$	C
$\hat{\mathfrak{g}}_k$	$(\dim \mathfrak{g}) t/(1-t)$	$1/(\dim \mathfrak{g} + 1)$	$\log(\dim \mathfrak{g} + 1)$	L

All have $\Delta_{\mathcal{A}}(t) = 0$: the declared generators span the full primitive sector, with no cumulant enlargement needed. The G-class families (Heisenberg, free fermion) have $h_K = 0$, meaning the completed bar complex does not grow exponentially; the completion is trivial. The L- and C-class families have positive entropy controlled by the number of generator flavours.

The reduced-weight windows $K_q(\mathcal{A})$ (Definition 18.15.3) make the bar complex finite at each level: for Heisenberg, $\dim K_q = q$ (one bar word per reduced weight); for $\hat{\mathfrak{g}}_k$, $\dim K_q \sim (\dim \mathfrak{g} + 1)^q$. This is the kinematic underpinning of the finite-stage bar computations in the sections above.

E.3.8.2 Computing the Koszul dual via bar-cobar

Remark E.3.36 (Procedure). Given a chiral algebra $\mathcal{A}$ with generators $\{a_i\}$ and relations $\{R_j\}$, the Koszul dual $\mathcal{A}^!$ is computed as follows.

1. Write $\mathcal{A} = T(V)/(R)$ where $R \subset V^{\otimes 2}$.
2. Define the pairing $\langle \cdot, \cdot \rangle: V \otimes V^* \rightarrow \mathbb{C}$ and compute $R^\perp \subset (V^*)^{\otimes 2}$.
3. Set $\mathcal{A}^! = T(V^*)/(R^\perp)$.
4. Check Koszulity: if $\mathrm{Tor}_{\mathcal{A}}^{i,j}(\mathbb{C}, \mathbb{C}) = 0$ for $i \neq j$, then we have exact Koszul duality. Otherwise, compute the curvature $m_0 \neq 0$ to obtain curved Koszul duality.

E.3.8.3 Explicit example: $\beta\gamma \leftrightarrow$ free fermion calculation

This calculation is carried out in detail in Theorem E.3.2 above (see §E.3.2): the antisymmetric relation $\beta\gamma - \gamma\beta$ dualizes under the residue pairing to the Clifford relation $bc + cb$, establishing $(\beta\gamma)^! \cong bc$.

E.4 HEISENBERG HIGHER-GENUS AND FOURIER DUALITY

The Koszul dual $\mathcal{H}_k^! \simeq \mathrm{Sym}^{\mathrm{ch}}(V^*)$ was computed in Theorem E.3.13; see Chapter 2 for conventions. The bar complex $\bar{B}^{\mathrm{ch}}(\mathcal{H}_k) \simeq \mathrm{coLie}^{\mathrm{ch}}(V^*)$ is cocommutative because the double-pole OPE produces symmetric coproducts.

E.4.1 FAILURE OF SELF-DUALITY

THEOREM E.4.1 (*Heisenberg is not self-dual;*). For any level $k \neq 0$, the Heisenberg algebra $\mathcal{H}_k$ is not Koszul self-dual. Instead:

$$\mathrm{Koszul}(\mathcal{H}_k) = \mathrm{Sym}^{\mathrm{ch}}(V^*) \neq \mathcal{H}_k$$

The algebras have different structure:

Heisenberg $\mathcal{H}_k$	Symmetric $\text{Sym}^{\text{ch}}(V^*)$
Centrally extended	Free commutative
$\{J_\lambda J\} = k\lambda \neq 0$	$\{J_\lambda^* J^*\} = 0$
Double-pole OPE	Regular OPE
Curved ($\kappa = k$)	Curved ($m_0 = -k\omega$)
Nontrivial π_1	Trivial π_1

Proof. By Theorem E.2.16, the bar complex $\bar{B}^{\text{ch}}(\mathcal{H}_k)$ has cocommutative coproduct: the Heisenberg OPE $\alpha(z)\alpha(w) \sim k(z-w)^{-2}$ produces only the double-pole term, whose residue gives a symmetric (primitive) coproduct $\Delta(\alpha) = \alpha \otimes 1 + 1 \otimes \alpha$. Cocommutative coalgebras are Koszul dual to commutative algebras ($\text{Com}^! = \text{Lie}$, see [299], Theorem 7.6.5), so $\mathcal{H}_k^! = \text{Sym}^{\text{ch}}(V^*)$. This is commutative with regular OPE, while $\mathcal{H}_k$ is non-commutative with singular OPE, so $\mathcal{H}_k \not\cong \mathcal{H}_k^!$. $\square$

E.4.2 THREE DIFFERENT “DUALITIES” FOR HEISENBERG

Three separate mathematical structures govern Heisenberg, and confusing them is a reliable source of error.

1. *Koszul duality* (algebra $\rightarrow$ dual coalgebra $\rightarrow$ dual algebra).

$$\mathcal{H}_k \xrightarrow{\bar{B}} \bar{B}^{\text{ch}}(\mathcal{H}_k) \xrightarrow{(-)^\vee} \text{Sym}^{\text{ch}}(V^*)$$

The first arrow is the bar construction: extraction of OPE residues along collision divisors in $\bar{C}_n(X)$ produces the Koszul dual *coalgebra* $\text{coLie}^{\text{ch}}(V^*)$, a conilpotent factorization coalgebra on $\text{Ran}(X)$. The second arrow is Verdier/linear duality, producing the Koszul dual *algebra* $\text{Sym}^{\text{ch}}(V^*)$. The cobar construction is *not involved*: $\Omega(\bar{B}(\mathcal{H}_k)) \simeq \mathcal{H}_k$ recovers the original algebra, not its dual (Theorem 8.6.1).

The distinction is mediated by the convolution Lie algebra $\text{Hom}(\bar{B}(\mathcal{H}_k), \mathcal{H}_k)$: the canonical twisting morphism $\tau: \text{coLie}^{\text{ch}}(V^*) \rightarrow \mathcal{H}_k$, $v^* \mapsto J_v$, is its Maurer–Cartan element. The convolution product $\tau \star \tau = 0$ because the cogenerator v^* is primitive ($\bar{\Delta}(v^*) = 0$), so the MC equation $\partial\tau + \tau \star \tau = 0$ holds on generators for degree reasons (cf. Remark 2.5.2).

Level behavior: k appears as curvature $m_0 \propto k$; it does not change the duality type.

Structure exchanged: Lie (non-commutative) $\leftrightarrow$ Com (commutative).

2. *Level-shifting/rank-level duality* (representation categories).

$$\text{Rep}(\mathcal{H}_k) \simeq \text{Rep}(\mathcal{H}_{-k})$$

Level behavior: $k \leftrightarrow -k$ (for Heisenberg, $h^\vee = 0$).

Structure exchanged: Representation categories (not algebras themselves).

3. *Boson-fermion correspondence* (categorical equivalence).

$$\text{Rep}(\mathcal{H}_k) \simeq \text{Rep}(\mathcal{F}^{\otimes 2})$$

where $\mathcal{F}$ is the free fermion algebra.

Level behavior: Relates Heisenberg to fermions, not to itself.

Structure exchanged: Module categories have equivalent structure.

Only (1) is the subject of this manuscript. The three dualities act on different mathematical categories: (1) on algebras and coalgebras (via the bar-cobar adjunction on $\text{Ran}(X)$), (2) on representation categories (via autoequivalences), (3) on module categories (via bosonization). The bar construction is the engine of (1); it has no direct role in (2) or (3).

E.4.3 COSTELLO–GWILLIAM’S CONSTRUCTION

THEOREM E.4.2 (*Heisenberg duality* [92];). The Heisenberg chiral algebra arises from:

- *Factorization algebra*. Lie algebra cochains $C^*(\mathcal{O}_X)$ on the abelian Lie algebra $\mathcal{O}_X$ of holomorphic functions.
- *Koszul dual*. Factorization envelope = Lie algebra chains $C_*(\mathcal{O}_X^c)$ on compactly supported sections.

Under the factorization homology $\int_X$:

$$\begin{aligned} C^*(\mathcal{O}_X) &\rightsquigarrow \mathcal{H}_k \quad (\text{Heisenberg}) \\ C_*(\mathcal{O}_X^c) &\rightsquigarrow \text{Sym}(\mathcal{O}_X) \quad (\text{Symmetric algebra}) \end{aligned}$$

The Koszul duality $C^* \leftrightarrow C_*$ for Lie algebra (co)homology induces:

$$\mathcal{H}_k^! \simeq \text{Sym}^{\text{ch}}(V^*)$$

E.4.4 BV QUANTIZATION AND THE BAR COMPLEX FOR FREE FIELDS

PROPOSITION E.4.3 (*Bar complex as BV complex*;). Let $\mathcal{A}$ be a free field chiral algebra (Heisenberg, free fermion, $\beta\gamma$, or bc ghost system). Then the reduced bar complex $\bar{B}^{\text{ch}}(\mathcal{A})$ is quasi-isomorphic, as a curved differential graded coalgebra, to the chain-level BV complex of the corresponding free bosonic or fermionic field theory on a Riemann surface X .

Proof. By the Prism Principle (Theorem II.1.84), the genus-0 bar complex is computed by configuration space integrals on $\bar{C}_n(X)$ with the Fulton–MacPherson propagator. For free fields, the only nonvanishing OPE poles are of order ≤ 2 (double poles for Heisenberg; simple poles for $\beta\gamma$, fermions, and bc ghosts), so the bar differential decomposes as $d = d_{\text{bracket}} + d_{\text{curvature}}$ (Proposition 6.1.24). Since the OPE data are quadratic (no cubic or higher terms), the resulting configuration space integrals are exactly those of Wick’s theorem for Gaussian path integrals, which compute the BV complex. $\square$

Remark E.4.4 (Curvature and one-loop determinants). The bar curvature m_0 is an element of the bar complex proportional to the central class: $m_0 = k \cdot c$ for $\mathcal{H}_k$ (Theorem E.2.20). Anomaly cancellation (Theorem K.7.1): $\bar{B}^{\text{ch}}(\mathcal{H}^{26} \otimes bc)$ is uncurved because the total central charge $c_{\text{eff}} = 26 \cdot 1 + (-26) = 0$ vanishes. This is an anomaly cancellation at the level of c , not κ : the modular characteristic $\kappa(\mathcal{H}_1) = 1$ differs from $c(\mathcal{H}_1)/2 = 1/2$.

E.4.5 HIGHER GENUS: QUANTUM COMPLEMENTARITY

THEOREM E.4.5 (*Quantum complementarity for Heisenberg*;). For the Heisenberg algebra at genus g on a Riemann surface Σ_g with period matrix $\Omega \in \mathbb{H}_g$ (Siegel upper half-space):

$$\bar{B}_g^{\text{ch}}(\mathcal{H}_k) \cong \text{CE}(\hat{\mathfrak{h}}_k) \otimes H^*(\text{Jac}(\Sigma_g), \mathcal{L}_k)$$

The Koszul duality intertwines with the modular action on period matrices:

1. *Modular transformation.* The symplectic transformation $\Omega \rightarrow -\Omega^{-1}$ (exchanging A - and B -cycles) exchanges levels: $k \leftrightarrow -k$
2. *Theta functions.* The level- k theta function is:

$$\Theta_k(\Omega) = \sum_{n \in \mathbb{Z}^g} e^{i\pi k n^T \Omega n}$$

(The level k scales the quadratic form, not the characteristic.) Under $\Omega \rightarrow -\Omega^{-1}$, Poisson summation gives:

$$\Theta_k(-\Omega^{-1}) = \left(\frac{\det(\Omega/i)}{k^g} \right)^{1/2} \cdot \Theta_{1/k}(\Omega)$$

The modular S -transformation thus sends $k \rightarrow 1/k$, while level *negation* $k \rightarrow -k$ arises instead from Koszul duality: the dual algebra $\mathcal{H}_k^!$ has curvature $-m_0 = -k \cdot c$.

3. *Geometric interpretation.* The bar cohomology classifies:

$$H^*(\bar{B}_g^{\text{ch}}(\mathcal{H}_k)) \cong H^*(\text{Jac}(\Sigma_g), \mathcal{L}_k)$$

where $\mathcal{L}_k$ is the line bundle of level k theta functions.

Proof. We prove the theorem for arbitrary genus $g \geq 1$ in five steps, then illustrate Step 3 explicitly for genus 1.

Step 1: Abelian factorization of the bar differential. The Heisenberg OPE $\alpha(z)\alpha(w) \sim k(z-w)^{-2}$ has no simple pole. By Proposition E.4.9, the bar differential on $\mathcal{H}_k^{\boxtimes n} \otimes \Omega_{\log}^p(\bar{C}_n(\Sigma_g))$ decomposes as a sum of commuting pairwise operators $d_{\text{bar}} = \sum_{i < j} d_{ij}$, each extracting the double-pole residue at the collision divisor D_{ij} . In particular, the bar complex is cocommutative: $\bar{B}^{\text{ch}}(\mathcal{H}_k) \simeq \text{coLie}^{\text{ch}}(V^*)$ (Theorem E.3.13).

Step 2: Identification with Chevalley–Eilenberg cohomology. On a closed Riemann surface Σ_g , the current $\alpha(z) = \partial\phi(z)$ has $2g$ zero modes: the integrals $\oint_{A_i} \alpha dz$ and $\oint_{B_j} \alpha dz$ ($i, j = 1, \dots, g$) over a symplectic basis of $H_1(\Sigma_g, \mathbb{Z})$. By Hodge theory these span $\mathfrak{h}_g := H^1(\Sigma_g, \mathbb{C}) \cong \mathbb{C}^{2g}$, an abelian Lie algebra. The level- k central extension equips $\mathfrak{h}_g$ with the symplectic form $\omega_k = k \cdot \omega$, where $\omega \in \Lambda^2(\mathfrak{h}_g^*)$ is the intersection pairing (normalized so that $\omega(A_i, B_j) = \delta_{ij}$).

Because the bar complex of $\mathcal{H}_k$ is cocommutative and the bar differential decomposes pairwise, the genus- g bar complex reduces to the Chevalley–Eilenberg complex of the one-dimensional central extension $\mathfrak{h}_k = \mathfrak{h}_g \oplus \mathbb{C} \cdot c$ with bracket $[v, w] = k \omega(v, w) \cdot c$:

$$\bar{B}_g^{\text{ch}}(\mathcal{H}_k) \simeq \text{CE}(\hat{\mathfrak{h}}_k) = (\Lambda^*(\mathfrak{h}_g^* \oplus \mathbb{C}), d_{\text{CE}}), \quad d_{\text{CE}}(\xi) = k \omega \quad \text{on the central generator } \xi.$$

This is the content of Theorem E.2.25: the pairwise factorization collapses the full configuration-space bar complex to a finite-dimensional cochain complex.

Step 3: Descent to the Jacobian. The Abel–Jacobi map (Definition 13.6.5)

$$\mu: \Sigma_g \rightarrow \text{Jac}(\Sigma_g) = \mathbb{C}^g / (\mathbb{Z}^g + \Omega \mathbb{Z}^g)$$

identifies the zero-mode lattice with $H_1(\Sigma_g, \mathbb{Z}) \cong \mathbb{Z}^{2g}$. The level- k central extension defines a local system $\mathcal{L}_k$ on $\text{Jac}(\Sigma_g)$ whose monodromy around the lattice vector $\gamma \in \mathbb{Z}^g \oplus \Omega \mathbb{Z}^g$ is $e^{2\pi i k \omega(\gamma, -)}$. Concretely, sections of $\mathcal{L}_k$ are functions $f: \mathbb{C}^g \rightarrow \mathbb{C}$ satisfying the quasi-periodicity conditions

$$\begin{aligned} f(z + e_\alpha) &= f(z), \\ f(z + \Omega e_\beta) &= e^{-i\pi k \Omega_{\beta\beta} - 2\pi i k z_\beta} f(z), \end{aligned}$$

which are precisely the transformation properties of the Riemann theta function at level k (Theorem 13.6.7).

The CE differential d_{CE} on $\Lambda^*(\mathfrak{h}_g^*)$ maps, under this descent, to the Dolbeault-type differential computing $H^*(\text{Jac}(\Sigma_g), \mathcal{L}_k)$. The key point is that the cochain complex $(\Lambda^*(\mathfrak{h}_g^*), d_{\text{CE}})$ with d_{CE} determined by $k\omega$ is isomorphic to the de Rham complex of the flat line bundle $\mathcal{L}_k$ on the torus $\text{Jac}(\Sigma_g)$: the translation-invariant differential forms on $\mathbb{C}^g/\Lambda$ with coefficients in $\mathcal{L}_k$ form a complex $\Lambda^p(\mathfrak{h}_g^*) \otimes \mathcal{L}_k$, and the flat connection $\nabla = d + k\omega$ on $\mathcal{L}_k$ induces precisely the CE differential. This gives the isomorphism:

$$H^*(\text{CE}(\hat{\mathfrak{h}}_k)) \cong H^*(\text{Jac}(\Sigma_g), \mathcal{L}_k).$$

Combining with Step 2:

$$\bar{B}_g^{\text{ch}}(\mathcal{H}_k) \cong \text{CE}(\hat{\mathfrak{h}}_k) \otimes H^*(\text{Jac}(\Sigma_g), \mathcal{L}_k).$$

Step 4: Modular transformation. The symplectic group $\text{Sp}(2g, \mathbb{Z})$ acts on $\text{Jac}(\Sigma_g)$ via $\Omega \mapsto (A\Omega + B)(C\Omega + D)^{-1}$. For the involution $\Omega \mapsto -\Omega^{-1}$ (corresponding to $A = D = 0, B = -C = I_g$), the A - and B -cycles are exchanged: $A_i \leftrightarrow B_i$. The level- k theta function

$$\Theta_k(\Omega) = \sum_{n \in \mathbb{Z}^g} e^{i\pi k n^T \Omega n}$$

transforms by Poisson summation on the lattice $\mathbb{Z}^g$:

$$\Theta_k(-\Omega^{-1}) = \left(\frac{\det(\Omega/i)}{k^g} \right)^{1/2} \Theta_{1/k}(\Omega).$$

This is the multivariable generalization of the Jacobi identity $\theta_3(-1/\tau) = (-i\tau)^{1/2} \theta_3(\tau)$. The S -transformation thus sends $k \rightarrow 1/k$ at the level of sections of $\mathcal{L}_k$.

Separately, Koszul duality reverses the curvature: the dual algebra $\mathcal{H}_k^!$ has $m_0 = -k \cdot c$ (Theorem E.2.20), contributing the level negation $k \rightarrow -k$. Together, these give the full modular intertwining: Koszul duality on $\mathcal{H}_k$ at genus g acts on the Jacobian via the symplectic involution of the period matrix.

Step 5: Geometric interpretation. Taking cohomology of the bar complex and applying the isomorphisms of Steps 2–3:

$$H^*(\bar{B}_g^{\text{ch}}(\mathcal{H}_k)) \cong H^*(\text{Jac}(\Sigma_g), \mathcal{L}_k).$$

This is the cohomology of the level- k line bundle of theta functions on the Jacobian, which is the statement of part (3) of the theorem.

Genus-1 illustration. For $g = 1$, the Jacobian is the elliptic curve $T^2 = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ with $\tau \in \mathbb{H}$. The zero-mode lattice is $\mathfrak{h}_1 = \mathbb{C}^2$ with symplectic basis $\{A, B\}$ and $\omega(A, B) = 1$. The CE complex is $\Lambda^*(\mathbb{C}^2)$ with $d_{\text{CE}}\xi = k dA \wedge dB$, and the local system $\mathcal{L}_k$ has quasi-periodicity $f(z+1) = f(z)$, $f(z+\tau) = e^{-i\pi k\tau - 2\pi i k z} f(z)$. An element of $\bar{B}_1^{\text{geom}}(\mathcal{H}_k)$ has the form $\alpha(z_1) \otimes \alpha(z_2) \otimes f(z_1, z_2) \eta_{12}$, and the Fourier expansion $f(z_1, z_2) = \sum_{n,m \in \mathbb{Z}} c_{n,m} e^{2\pi i(nz_1/\tau + mz_2)}$ gives the bar differential $d(\alpha \otimes \alpha \otimes f \eta_{12}) = k \sum_n c_{n,n}$. The constraint $\sum_n c_{n,n} = 0$ defines the kernel, and the quotient by the image identifies with sections of $\mathcal{L}_k$ on $T^2 = \text{Jac}(\Sigma_1)$. Under $\tau \rightarrow -1/\tau$ the A - and B -cycles exchange, and the Jacobi identity $\theta_3(-1/\tau) = (-i\tau)^{1/2} \theta_3(\tau)$ gives the modular transformation of part (1). $\square$

Example E.4.6 (Explicit genus-1 computation). For the torus T^2 with modulus τ , we compute the bar complex explicitly in low degrees:

Degree 0.

$$\bar{B}_0 = \mathbb{C} \quad (\text{vacuum})$$

Degree 1.

$$\bar{B}_1 = \bigoplus_{(n,m) \in \mathbb{Z}^2} \mathbb{C} \cdot a_{n,m}$$

where $a_{n,m}$ represents the mode $a(z)e^{2\pi i(n\operatorname{Re}(z)+m\operatorname{Im}(z))}$.

Degree 2.

$$\bar{B}_2 = \bigoplus_{(n_1,m_1,n_2,m_2)} \mathbb{C} \cdot (a_{n_1,m_1} \otimes a_{n_2,m_2}) \cdot \eta_{12}$$

The differential is:

$$d(a_{n_1,m_1} \otimes a_{n_2,m_2} \cdot \eta_{12}) = k\delta_{n_1+n_2,0}\delta_{m_1+m_2,0}$$

Cohomology.

$$H^1(\bar{B}_1^{\text{geom}}(\mathcal{H}_k)) = \frac{\ker(d : \bar{B}_1 \rightarrow \bar{B}_2)}{\operatorname{im}(d : \bar{B}_0 \rightarrow \bar{B}_1)}$$

This computes the homology of the Jacobian variety $\operatorname{Jac}(T^2) \cong T^2$ with the level- k structure.

Modular transformation. The S -transformation $\tau \rightarrow -1/\tau$ acts on modes:

$$a_{n,m} \rightarrow a_{m,-n}$$

This exchanges the roles of n and m , swapping A-cycles and B-cycles. In the bar complex, this induces:

$$\bar{B}_1^{\text{geom}}(\mathcal{H}_k, \tau) \xrightarrow{S} \bar{B}_1^{\text{geom}}(\mathcal{H}_{-k}, -1/\tau)$$

This is the manifestation of complementarity at genus 1: the modular S -transformation exchanges the bar complex of $\mathcal{H}_k$ with that of its complementary partner (not the Koszul dual $\mathcal{H}_k^! = \operatorname{Sym}^{\text{ch}}(V^*)$, which is structurally different).

Remark E.4.7 (Physical interpretation: quantum complementarity). At genus 1, complementarity is electromagnetic duality on T^2 : A-cycle winding (position) exchanges with B-cycle winding (momentum), and the S -transformation $\Omega \rightarrow -1/\Omega$ acts as Fourier transform on $\operatorname{Jac}(T^2)$. The level shift $k \rightarrow -k$ is the quantum manifestation of this classical symplectic duality.

Remark E.4.8 (Koszul duality as higher-dimensional Fourier transform). Chiral Koszul duality is a higher-dimensional Fourier transform: the bar construction

$$\bar{B}(\mathcal{A}) = \bigoplus_n \int_{C_n(X)} \mathcal{A}^{\boxtimes n} \otimes \Omega_{\log}^*(\bar{C}_n(X))$$

with kernel $\eta_{ij} = d \log(z_i - z_j)$ exchanges $\mathcal{A} \leftrightarrow \mathcal{A}^!$, with Verdier duality $\mathbb{D}_{\text{Ran}} \bar{B}(\mathcal{A}) \simeq \mathcal{A}_{\infty}^!$ (Theorem 11.1.84) as the inversion formula. For commutative algebras, the n -point contributions factor pairwise, recovering a linear integral transform.

For $\mathcal{H}_k$ on Σ_g , this reduction is literal: bar cohomology computes $H^*(\operatorname{Jac}(\Sigma_g), \mathcal{L}_k)$, the Koszul duality map acts via $\Omega \mapsto -\Omega^{-1}$, and Poisson summation on $\mathbb{Z}^g$ gives Fourier inversion. At genus 1: $\tau \mapsto -1/\tau$ and $\theta_3(-1/\tau) = (-i\tau)^{1/2} \theta_3(\tau)$. At genus g : $\Theta(-\Omega^{-1}, \Omega^{-1}z) = (\det(-i\Omega))^{1/2} e^{i\pi z^T \Omega^{-1} z} \Theta(\Omega, z)$.

E.4.6 FROM FOURIER DUALITY TO CHIRAL KOSZUL DUALITY

Remark E.4.8 identified the chiral bar construction as a nonlinear generalization of the classical Fourier transform. We now develop this identification in three stages of increasing nonlinearity: the classical abelian transform, its higher-dimensional extension to Jacobians of curves, and the genuinely non-abelian generalization to configuration space integrals with non-factorizing kernel. The passage between stages is governed by a single datum: the order of the OPE pole.

E.4.6.1 Stage I: pairwise factorization and the abelian kernel

PROPOSITION E.4.9 (*Abelian factorization of the bar differential*;). Let $\mathcal{A}$ be a chiral algebra on a smooth curve X whose OPE contains no simple pole:

$$\phi^a(z)\phi^b(w) = \frac{C^{ab}}{(z-w)^2} + \text{reg.}$$

Then the bar differential on $\mathcal{A}^{\boxtimes n} \otimes \Omega_{\log}^P(\overline{C}_n(X))$ decomposes as a sum of commuting pairwise operators:

$$d_{\text{bar}} = \sum_{1 \leq i < j \leq n} d_{ij}, \quad [d_{ij}, d_{kl}] = 0 \quad \text{for } \{i, j\} \cap \{k, l\} = \emptyset.$$

Each d_{ij} extracts the second-order residue at the collision divisor $D_{ij} \subset \overline{C}_n(X)$, acting only on the tensor factors $\mathcal{A}^{\boxtimes \{i, j\}}$ and the logarithmic form ω .

Proof. On an element $\alpha = \phi^{a_1}(z_1) \otimes \cdots \otimes \phi^{a_n}(z_n) \otimes \omega$, the bar differential extracts OPE residues at each collision divisor. When the OPE has no simple pole, the only contribution from D_{ij} is the double-pole coefficient:

$$d_{ij}(\alpha) = C^{a_i a_j} \cdot (\text{contraction at } z_i = z_j) \cdot \text{Res}_{D_{ij}}(\omega).$$

This operator depends only on the tensor factors at positions i and j and on the restriction of ω to D_{ij} . For disjoint index pairs $\{i, j\} \cap \{k, l\} = \emptyset$, the operators d_{ij} and d_{kl} act on independent tensor factors and extract residues at transverse divisors in $\overline{C}_n(X)$, so they commute. $\square$

Remark E.4.10 (*From pairwise decomposition to classical Fourier analysis*). The pairwise decomposition (Proposition E.4.9) is why abelian chiral algebras produce linear integral transforms: the multivariate Fourier kernel factors as $e^{i\langle x, \xi \rangle} = \prod_j e^{ix_j \xi_j}$, and the chiral bar differential on $\mathcal{H}_k$ reduces to iterated pairwise residue extraction, which on Σ_g becomes Fourier coefficient extraction on $\text{Jac}(\Sigma_g)$.

Remark E.4.11 (*Convolution–multiplication exchange*). The bar functor exchanges the chiral product $\mu: \mathcal{A} \boxtimes \mathcal{A} \rightarrow \Delta_* \mathcal{A}$ with the coproduct

$$\Delta: \bar{B}_n^{\text{ch}}(\mathcal{A}) \longrightarrow \bigoplus_{p+q=n} \bar{B}_p^{\text{ch}}(\mathcal{A}) \otimes \bar{B}_q^{\text{ch}}(\mathcal{A}),$$

defined by restriction to the boundary strata $D_{S,T}$ of $\overline{C}_n(X)$, the chiral analogue of $\widehat{f * g} = \hat{f} \cdot \hat{g}$. For $\mathcal{H}_k$ on Σ_g , this identifies the chiral product with convolution on the Jacobian (Theorem E.4.5).

The parallel between classical Fourier duality and chiral bar-cobar duality is summarized in the following dictionary.

Classical Fourier	Chiral bar-cobar	Abelian specialization
Dual group $\hat{G}$	Koszul dual $\mathcal{A}^!$	$\mathcal{H}_k^! = \text{Sym}^{\text{ch}}(V^*)$
Kernel $e^{i\langle x, \xi \rangle}$	$\eta_{ij} = d \log(z_i - z_j)$	genus 0: $dz/(z - w)$
2-point integral	n -point configuration integral	n -pt = $\binom{n}{2}$ pairwise
$\widehat{f * g} = \hat{f} \hat{g}$	$\bar{B}(\mu) = \Delta_{\bar{B}}$	convolution $\leftrightarrow$ product
Fourier inversion	$\mathbb{D}_{\text{Ran}} \bar{B}(\mathcal{A}) \simeq \mathcal{A}_{\infty}^!$	$\Omega \mapsto -\Omega^{-1}$
Plancherel measure	spectral discriminant $\Delta_{\mathcal{A}}(x)$	$\Delta_{\mathcal{H}} = 1$ (flat)
Poisson summation	theta function identity	Siegel modular involution
$L^1(G)$ (convolution)	$U^{\text{ch}}(\mathcal{A})$ (chiral envelope)	lattice algebra $\mathbb{C}[\mathbb{Z}^g]$

E.4.6.2 Stage II: the non-abelian departure

The pairwise factorization of Proposition E.4.9 fails when the OPE contains a simple pole. This failure is the structural origin of the genuinely nonlinear phenomena in the bar complex of non-abelian chiral algebras.

PROPOSITION E.4.12 (*Non-abelian kernel non-factorization*;). Let $\mathcal{A}$ be a chiral algebra with OPE

$$\phi^a(z)\phi^b(w) = \frac{C^{ab}}{(z-w)^2} + \frac{f_c^{ab} \phi^c(w)}{z-w} + \text{reg}, \quad f_c^{ab} \neq 0.$$

Then the bar differential decomposes as

$$d_{\text{bar}} = d_{\text{pair}} + d_{\text{bracket}},$$

where $d_{\text{pair}} = \sum_{i < j} d_{ij}^{(2)}$ extracts double-pole residues and $d_{\text{bracket}} = \sum_{i < j} d_{ij}^{(1)}$ extracts simple-pole residues. Then:

- (i) For $n \geq 3$, the operator d_{bracket} on n -point elements is irreducibly n -body: the output $d_{ij}^{(1)}(\alpha) \in \bar{B}_{n-1}^{\text{ch}}(\mathcal{A})$ depends on all fields, not just the pair (ϕ^{a_i}, ϕ^{a_j}) .
- (ii) $d_{\text{bracket}}^2 \neq 0$ in general. The full identity $d_{\text{bar}}^2 = 0$ requires the cross-terms $d_{\text{pair}} \circ d_{\text{bracket}} + d_{\text{bracket}} \circ d_{\text{pair}} = -d_{\text{bracket}}^2$ and relies on the Borchers identity mixing pairwise and bracket contributions.

In the language of homotopy chiral algebras (Theorem 8.10.5), the identity $d_{\text{bracket}}^2 \neq 0$ is the obstruction to strict chirality, and the cross-terms $d_{\text{pair}} \circ d_{\text{bracket}} + d_{\text{bracket}} \circ d_{\text{pair}}$ are the secondary Borchers operations $j'_{(p,q,r)}$ (Definition 16.9.7) that restore $d_{\text{bar}}^2 = 0$ at the Ch_{∞} level.

Proof. The simple-pole extraction at D_{ij} produces

$$d_{ij}^{(1)}(\phi^{a_1} \otimes \cdots \otimes \phi^{a_n} \otimes \omega) = f_c^{a_i a_j} \left(\phi^{a_1} \otimes \cdots \otimes \underset{\text{pos. } i}{\phi^c} \otimes \cdots \otimes \widehat{\phi^{a_j}} \otimes \cdots \otimes \phi^{a_n} \right) \otimes \text{Res}_{D_{ij}}(\omega).$$

The contracted field ϕ^c retains position z_i and depends on both a_i and a_j through $f_c^{a_i a_j}$, while the remaining fields persist at their original positions. The output is an $(n-1)$ -point element whose dependence

on all remaining fields is irreducible: $d_{ij}^{(1)}$ cannot be expressed as an operator on the pair (ϕ^{a_i}, ϕ^{a_j}) alone, since the contracted generator ϕ^c interacts with ϕ^{a_k} at subsequent bar degrees. This establishes (i).

For (ii), consider $n = 3$ and compute:

$$\begin{aligned} d_{23}^{(1)} \circ d_{12}^{(1)}(\phi^a \otimes \phi^b \otimes \phi^c \otimes \eta_{12} \wedge \eta_{23}) &= f_e^{ab} f_g^{ec} \phi^g, \\ d_{12}^{(1)} \circ d_{23}^{(1)}(\phi^a \otimes \phi^b \otimes \phi^c \otimes \eta_{12} \wedge \eta_{23}) &= f_e^{bc} f_g^{ae} \phi^g. \end{aligned}$$

The sum $d_{\text{bracket}}^2 = f_e^{ab} f_g^{ec} + f_e^{bc} f_g^{ae} + f_e^{ca} f_g^{be}$ vanishes by the Jacobi identity, but the cancellation requires the additional contribution from $d_{13}^{(1)}$ and the double-pole cross-terms. In isolation, $d_{\text{bracket}}^2 \neq 0$: the identity $d_{\text{bar}}^2 = 0$ is a *coupled* identity between the Lie bracket and the level, not a consequence of either alone. $\square$

The non-abelian departure is sharpest in the following side-by-side comparison.

Example E.4.13 (Heisenberg versus Kac–Moody at bar degree 2). Heisenberg. The OPE $\alpha(z)\alpha(w) = k/(z-w)^2 + \text{reg}$ has no simple pole. By Proposition E.4.9, the differential on 3-point elements is purely pairwise:

$$d(\alpha_1 \otimes \alpha_2 \otimes \alpha_3 \otimes \eta_{12} \wedge \eta_{23}) = k \alpha_3 \otimes \eta_{23} - k \alpha_1 \otimes \eta_{13}.$$

Each term involves a single residue extraction and a single surviving field. The two terms cancel under d^2 by telescoping (Theorem E.4.20).

Kac–Moody $\widehat{\mathfrak{g}}_k$. The OPE has both poles, so the differential acquires a non-abelian correction:

$$\begin{aligned} d(J^a \otimes J^b \otimes J^c \otimes \eta_{12} \wedge \eta_{23}) &= \underbrace{k\delta^{ab} J^c \otimes \eta_{23} - k\delta^{bc} J^a \otimes \eta_{12}}_{d_{\text{pair}} \text{ (level, pairwise, “Fourier”)}} \\ &+ \underbrace{f_e^{ab} J^e \otimes J^c \otimes \eta_{23} + f_e^{bc} J^a \otimes J^e \otimes \eta_{12}}_{d_{\text{bracket}} \text{ (structure constants, 3-body, non-abelian)}}. \end{aligned}$$

The pairwise terms yield 1-point elements (scalar times a single current), as in the Heisenberg case. The bracket terms yield 2-point elements carrying the Lie structure constants f^{abc} ; these have no abelian counterpart and encode the failure of the bar kernel to factorize.
